The Blood in Bright's Disease.—Dr. Freund has studied this subject for the past three years, and now publishes his observations. They refer to cases of Bright's disease (chronic parenchymatous nephritis, with dropsy), in which the clinical features were well marked, and which were verified by pathological examination. The results were compared with other cases of albuminuria and dropsy, without Bright's disease. 1. Analysis of the blood of nine cases showed no changes in the absolute quantities of either organic or inorganic constituents. The only alteration was in the relative amounts of the globulins compared with the albumins in the serum. While in normal and other pathological conditions the relation was 1 to 1 and 1.5, in the 9 cases of Bright's disease it was 1 to 2.3. In 2 cases, in spite of the clinical diagnosis of Bright's disease, the relation of globulins to albumins was 1 to 1.1 and 1 to 11.3; in one of these cases the necropsy showed cystic kidney, in the other contracted granular kidney. This alteration of the relation of globulins to albumins cannot be held as specific, because in a case of pernicious anæmia it was found to be 1 to 2. 2. As regards the alkalinity of the blood, no specific abnormal condition was found. 3. The conditions of coagulation were found to be altered. While normal serum coagulates uniformly at a temperature of 70° to 74° C. to a firm jelly, in Bright's disease coagulation does not occur till 78° to 82° C., and the clot, instead of remaining firm, is easily broken up by shaking. It has been shown that much dilution alters the point of coagulation as well as the condition of the clot, and a dilution of 1.018 generally raises the coagulation point. Normal serum diluted to the same specific gravity as serum from Bright's disease was found to behave in the same way, and similar results were obtained in serum from dropsy without Bright's and in pernicious anæmia. 4. Semmola in 1881 showed that serum from Bright's disease had a greater power of diffusion than normal serum, or serum from cases of albuminuria without Bright's; Freund's experiments confirm this view, for in 15 cases of Bright's disease the diffusibility with egg albumin was 0.006 to 0.025 g. per cent.; in 3 out of 16 control experiments from other diseases the diffusibility was 0.003 to 0.004 per cent., 13 giving negative results.—*Wiener klinische Rundschau.*

Suprapubic Cystotomy for Tubercular Ulceration.—The following case of this kind is recorded by Dr. Moullin in *The Lancet:* A woman twenty-two years of age was admitted into the London Hospital in January, 1894, suffering from cystitis. Her illness began three years before, with an attack of hæmaturia, which lasted upward of six weeks. Apparently it was caused by lifting a heavy weight. At the same time micturition became more frequent. There was no pain, but she grew weak and ill, and was unable to continue at work as a domestic servant. A few months later, after resting at home, she began to suffer from pain shooting

down the right leg from the loin. Micturition became more and more frequent, until at last it took place nearly every hour. Each act was attended by intense smarting, felt chiefly at the neck of the bladder, and continuing for some time after the bladder was emptied. Blood made its appearance again. The urine became foul and loaded with mucus; and for the six months previous to admission the suffering was so great that she was almost confined to bed, any attempt at walking causing intense dragging pain over the pubes. The patient was slightly built, but fairly well nourished. There was no history of previous illness of any importance. The lymphatic glands were not enlarged, the heart and lungs were normal, and there was no history of phthisis in the family. The hypogastric region was very sensitive to pressure, but there was no tenderness over the kidneys on either side. Micturition was exceedingly frequent, night and day, and was accompanied by the greatest suffering. The average amount of urine passed in twenty-four hours was only twenty-five ounces of 1.015 specific gravity. It was alkaline in reaction, always contained a large amount of blood intimately mixed with it, and threw down a heavy precipitate of blood, mucus, pus, and phosphates. Microscopic examination showed the presence of tubercle bacilli upon one occasion. Benzoate of ammonia was given internally, and the bladder was washed out at regular intervals with boracic acid and lactic acid, but without result. No improvement followed, and as the patient, who had been under treatment for many months, was beginning to lose weight, it was determined to explore the bladder under an anæsthetic. A number of ulcers coated over with an adherent, blood-stained, caseous deposit were found just inside the orifice. A week later supra-pubic cystotomy was performed. The sides of the bladder were held apart with sutures passed through the edges of the muscular coat; a Ferguson's speculum was introduced through the wound, and all the ulcers that were accessible were scraped and cauterized with Paquelin's cautery. Those that were situated on the anterior surface of the bladder, and which could not be reached in this way, were scraped with a Volkmann's spoon, and then iodoform was thoroughly rubbed in. All the ulcers were situated near the orifice of the bladder; there were none to be seen or felt on the fundus. The lower angle of the wound was left open and a drainage-tube introduced into the bladder; the rest was sutured and dressings of sal alembroth gauze and wool applied. The tube was shortened on the third day and removed a few days later. Urine acid in reaction was passed naturally on the fifteenth day, and at the end of three weeks the wound was soundly healed and the patient was allowed to get up. At first there was considerable pain on micturition, but this soon wore off. Five weeks after the operation the patient passed urine four times during the day and twice at night. Six months later, when she was seen again, the frequency during the day remained the same, but she had to rise only occasionally at night. The urine was acid and contained only a little mucus, and the patient had gained flesh and strength.

The number of cases in which supra-pubic cystotomy and cauterization have been performed for tuberculous disease of the bladder is not very large. Guyon has recorded two; Reverdin one; Battle one, in which, owing to the size of the ulcer, chloride of zinc was used instead of the actual cautery; Pilcher four; and Bell three. In three cases Bardenheuer has dissected away the entire mucous membrane, practically abolishing the bladder, for very little of the lining was reproduced. In nearly every case of cauterization the results as reported were good, and there can be little doubt that in many instances this operation might be resorted to with advantage. Ulceration of the bladder attended by strangury and hæmaturia is of not uncommon occurrence in young adults of both sexes, and in a large proportion of cases yields readily to local and palliative treatment. In these the ulceration is not tuberculous, or, if it is, the ulceration is very recent and involves only the most superficial layers of the mucous membrane. When the disease has lasted some time, as in the present instance, and has affected the whole thickness of the mucous membrane, and perhaps the submucous tissue as well, leaving deep ulcers coated over with a dense adherent layer of caseous débris, pus, and phosphates, the momentary application of dilute solutions of lactic acid or other drugs can be of no avail. They can never penetrate unaided through the protecting layer. In such cases the prognosis is so unfavorable, the suffering as the disease advances so intense, and the risk of supra-pubic cystotomy as it is performed at the present day so slight, that it is difficult to understand why it is not more frequently resorted to. Tuberculosis of the bladder may not be common as a primary affection. It is usually regarded as secondary to disease of the kidneys or (in males) of the genital organs. But the fact that many of the cases in which it has occurred have been women, who do not suffer in the same way from genital tuberculosis, and whose kidneys were healthy, makes it rather doubtful whether in the case of men there is not a tendency to exaggerate the secondary character of the disease. The neck of the bladder is involved more frequently than the fundus, not because of the proximity of the orifices of the ureters or of the vasa deferentia, but because its blood-supply is so much larger, and it is so liable to attacks of congestion, and because its functional activity is so much greater.

Vaginal Resection of the Rectum.—Dr. Rehn states that in cancer of the rectum in females the affected gut can be readily removed through a vertical incision made in the middle line of the posterior wall of the vagina, and carried backward in the perineum as far as the external sphincter ani. By such an incision he was able, with very little difficulty and without much hemorrhage, to remove an extensive cancer from the rectum of an aged woman. The incision of the posterior wall of the vagina, he states, permits of free removal of a large malignant growth and facilitates the separation of the diseased mass from the surrounding soft parts. The rectum having been plugged with antiseptic gauze and the vagina thoroughly disinfected, the posterior vaginal wall is carefully incised and separated from the diseased gut. The perineum is next incised in the middle line and the rectum below the seat of disease isolated, ligatured, and divided. The upper and cancerous portion of the gut is now drawn through the vaginal wound and excised. This stage of the operation, it is asserted, can be effected with but little hemorrhage and with free exposure of the diseased structures. An opening in the peritoneum can be readily dealt with in this operation, and any enlarged glands in the meso-rectum can be removed without difficulty.—*Centralblatt für Chirurgie.*

Congenital Constipation.—Marfan, in a clinical lecture on constipation in infants, discusses at some length the so-called congenital or anatomical constipation associated with undue length of the colon and folding of the sigmoid. (*The British Medical Journal.*) Instead of making the simple S or Σ curve, the sigmoid is thrown into several folds, which may be variously disposed. He quotes from the *Thèse* of Bourcart (Paris, 1863) a classification into three types — ascending, transverse, and descending. Of these the commonest is the ascending type, in which the colon, after entering the pelvis and passing across it near the middle, turns sharp upon itself and ascends out of the pelvis again before descending once more to open into the rectum. This anatomical peculiarity favors delay of fæces in this part of the intestine, with consequent absorption of fluid, and the formation of large hard masses difficult of expulsion. The stools are firm or pasty, or dry solid balls, sometimes streaked with blood, an indication of excoriation of the anus. When there

has been no stool for several days there may be a good deal of flatulent distention, which causes discomfort, but pain is not a prominent symptom. By palpation the mass of fæces may be felt, generally in the left iliac fossa. Occasionally the efforts which the child makes appear to determine the production of hernia, most commonly of the umbilicus, and also prolapsus ani. A convulsion may occur at the time of expulsion of a large mass of fæces. Anal fissures are liable to be produced by the passage of these large masses; and when not seen exteriorly their presence may be suspected if the child cries much and ceases to make effort, or if the solid fæces are streaked with blood. The coprostasis may lead to colitis—simple, mucous, or ulcerative. Marfan believes that the cases of so-called congenital dilatation of the colon, of which a few instances have been described, are really secondary to prolonged coprostasis due to this congenital peculiarity of the sigmoid. As to treatment, he thinks that something might be done by attending to the diet, and especially by using sugar water to dilute the milk. If in children at the breast there is reason to believe that the milk is deficient in sugar, it is well to give the child a small quantity of sweetened water before suckling. Laxatives and purgatives are not to be recommended. The best treatment is injections of tepid water, of water with a little sea salt (gr. j. to ℥ j.), or with glycerine (℥ ss. in ℥ vj.), or of oil. He prefers the last-named, ℥ j. of oil in emulsion with the yellow of an egg in about ℥ viij. of water. He uses a long soft tube, which he says usually passes easily after a small quantity of the injection has been introduced. He sees no objection to giving the injections daily or even oftener; though there may be some prejudice to overcome before the nurse can be induced to do this. Injections may sometimes be replaced by suppositories; for this purpose he uses a hollow suppository of cocoa butter containing about eight grains of glycerine and a little soap. In older children a small quantity of aloes (gr. ¾) or calomel (gr. ⅓) may be added, but in infants these drugs should be avoided. Massage of the abdomen along the course of the colon may also be of use. When a case is seen presenting signs of obstruction the best treatment is to wash out the stomach, and then to endeavor to remove the hard masses from the rectum with the finger or a spoon. Electricity may also succeed in cases of obstruction, and the author relates one case in point. Occasionally faradization may succeed—one electrode in the rectum and the other moved about over the course of the colon. If the continuous current be used the strength ought not to exceed 15 to 20 milliampères. The positive pole should be in the rectum at first for five minutes, and the current then reversed and interrupted subsequently every twenty seconds for another five minutes.

Vesical Hernia.—The subject of vesical hernia has lately received considerable attention. Dr. Ernst Michels recently communicated to the Medico-Chirurgical Society a case in which, during the operation for radical cure of hernia, the bladder was found and a portion removed in mistake for the sac. The stump was put back into the abdomen and the inguinal canal closed. The mistake was not discovered until twenty-four hours after the operation, when the patient began to complain of pain in the hypogastrium and to pass blood with the urine. The bladder was fully exposed by abdominal section, and the wound, which was discovered in its extra-peritoneal part, closed with sutures, the bladder being drained by a Jacques' catheter. The author of the communication pointed out that there were two distinct kinds of vesical hernia; in one the bladder was contained within a peritoneal sac, but in the other the extra-peritoneal portion of the bladder descended, and this was a much rarer condition. The bladder had been wounded in almost all the cases the records of which the author had examined, as it was exceedingly difficult to recognize it. With this Mr. Macready agreed, and stated that the accidental opening of the bladder in these cases had been done by many accomplished surgeons, and that he had himself done so. In his case the wound of the bladder was not discovered until the ninth day, when urine was found trickling from the wound. Mr. Arbuthnot Lane records a case in which a hernial protrusion of the bladder was found outside the true sac in the operation for the cure of a large inguinal hernia. On pressure fluid could be forced out of it into the abdomen. It was thought to be a portion of the bladder, but to make sure was opened and then sutured. It was freed from its adhesions to the outside of the hernial sac, and returned into the abdomen. A case in which a portion of the bladder formed part of a hernia is reported by Mr. Rose, which differs from the other recorded cases in that symptoms of bladder trouble were present. Micturition was very painful at times, and there was retention occasionally, associated with some increase in the size of the hernia. The radical cure operation was performed, and the painful micturition ceased. The hernia was an inguinal one, although the patient was a young woman. The cases of Mr. Lane and Mr. Rose are, however, quite different from Dr. Michels' case, in which the bladder alone protruded, and resembled the hernial sac itself, a condition in which the bladder has almost always been taken for the sac, and opened as such, happily without any serious consequences, the opening thus accidentally made having been carefully sutured in each case.—*The Hospital.*

The Pathogenesis of Diabetes Mellitus.—Dr. Kaufmann upholds the view that the excess of sugar in the blood in diabetes is always due to an increase in the sugar formation, and not to a diminished sugar destruction in the capillaries. He believes that in the normal condition the destruction of sugar in the blood is always compensated by an equivalent sugar formation by the liver, and that any modification of the destruction of sugar in the tissues reacts at once on the liver by the nervous paths or by the blood, and impresses on the sugar formation an activity in direct relation to the sugar destruction. In hibernating animals the sugar in the blood diminishes during the period of torpor, although the sugar destruction in the tissues is greatly decreased. After the revival the sugar in the blood increases greatly, though the consumption of sugar in the tissues is increased. Under normal conditions the amount of sugar in the blood of the horse is increased during muscular activity; also during digestion there is an increase of the sugar in the blood. In these physiological conditions the increase of sugar in the blood is to be explained by increased sugar formation. This is also the cause of the glycosuria after poisoning by curare and morphine, in asphyxia, after the administration of anæsthetics, after lesions of the nervous system, and after extirpation of the pancreas in animals. In the case of pancreas extirpation the evidence against the increased sugar production is stronger. But the chief argument against the increased sugar formation is the supposed diminution of oxidation in diabetes. Recent researches have shown, however, that in many cases of diabetes the activity of oxidation and nutrition is the same as in the normal state. Lépine and Barral, from the chemical examination of the blood, conclude that in experimental pancreatic diabetes, and in diabetes in man, the glycolytic power of the blood is diminished—that is, the power of sugar destruction is diminished. Kaufmann and Chauveau have made a series of analyses of the arterial and venous blood in healthy persons and in cases of diabetes, but they have never found any difference between the normal sugar destruction and that in diabetes. Kaufmann has isolated the liver by tying all its vessels in a healthy dog, and also in another dog which had been rendered dia-

betic by extirpation of the pancreas. The action of the sugar-producing focus being suppressed, the sugar in the blood gradually became diminished during its circulation in other parts of the body. But an hour after the insolation of the liver the blood had lost the same proportion of sugar both in the healthy and in the diabetic animals. After having determined the diminution of sugar, Kaufmann re-established the circulation in the liver by removing the ligatures placed on the vessels. He found that the sugar in the blood soon regained its previous percentage. Hence he concludes that sugar destruction proceeds with the same activity in dogs rendered diabetic by pancreas extirpation as in the normal condition, and that the excess of sugar in the blood is due to increased sugar formation by the liver. He believes that increased sugar formation and not diminished destruction in the capillaries is the cause of the excess of sugar in the blood in the diabetes produced by pancreas extirpation, by lesions of the medulla, and in all other ways.—*La Semain Médicale.*

Congenital Obliteration of the Bile Duct.—At a recent meeting of the Pathological Society of London (*The Lancet*) Dr. Francis Hawkins exhibited a specimen showing congenital obliteration of the ductus communis choledochus. This duct was obliterated and appeared as a mere thread about one inch before joining the duodenum. The hepatic and cystic ducts were pervious, as was also the ductus communis choledochus for nearly an inch before becoming obliterated. The gall-bladder was not enlarged and was empty. The liver was enlarged, very firm, and of a dark olive-green color, with fibrous bands running over the surface, which was slightly irregular. The blood-vessels were normal. The pancreatic duct was pervious and the opening into the duodenum was seen. Microscopical examination on section of the liver showed it to be cirrhotic. There was a right inguinal hernia containing the cæcum and appendix. There was also a small localized empyema at the left pulmonary base. The specimen was removed from a male child, aged at death four months and two weeks, who was admitted into the Royal Berkshire Hospital suffering from jaundice, which had first been noticed eight days after birth. The jaundice was of a deep olive color and the stools were white. Hemorrhage from the mouth occurred on two occasions and epistaxis once. The family history was not important. Only two similar cases had been shown before the society, and from a diagrammatic representation of the local condition of obliteration of the bile ducts made by Dr. John Thomson, of Edinburgh, it would appear that, including the two cases above mentioned, only six were recorded in medical literature where the ductus communis choledochus was alone obstructed. The cause of the jaundice was thought to be due to the change in the liver itself owing to the bile ducts becoming constricted and obliterated. The cystic and hepatic ducts were pervious and yet contained no bile.

Digestive Troubles in Diabetics and their Treatment.—Dr. Grube, of Neuenahr, has several times observed in diabetic patients gastric crises very similar to those of tabes (*The British Medical Journal*). The patient all at once experiences a violent pain in the abdomen, especially at the pit of the stomach, accompanied ordinarily with swelling of the belly and eructations. Violent contractions of the stomach are appreciable on simple inspection. Very soon there supervene nausea, acid vomitings, and sometimes diarrhœa and cramps in the calves of the legs. The tongue is foul, the pulse quickened, the buccal mucous membrane dry; a little fever is noted. The urine may contain, besides sugar, acetone, but it does not give the reactions of diacetic nor oxybutyric acids. Lastly, the breath acquires an odor recalling that of chloroform. These symptoms, which Grube attributes to an irritation of the vagus by toxic substances circulating in the blood, last from some hours to one or two days, and leave behind them a more or less prolonged state of enfeeblement. The best treatment of these gastric crises consists in immediately provoking an alvine evacuation by means of aqueous or oily enemata, and in applying hot fomentations over the belly. Internal medicaments and feeding are impossible, owing to the vomiting. The drinks best supported immediately after the cessation of the crisis are milk, chicken broth, tea, or weak brandy and water. These crises, although not dangerous *per se*, are of bad augury, for they indicate that the disease is reaching its final stage. To avoid their recurrence, the diet must be altered, so that fleshy foods do not predominate too much, and the regularity of the action of the bowels must be attended to. Besides these acute digestive troubles, at certain periods of the disease a state of chronic dyspepsia is frequently observed, characterized by diminution of appetite, especially by dislike for meat, by painful digestion and constipation. The best treatment Grube believes to be an alcoholic extract of pancreas taken after the three principal meals, a remedy which, though not improving the glycosuria, may undoubtedly be beneficial in relieving the digestive disturbances.

Varices of the Œsophagus.—According to Dr. Friedreich, the veins of the œsophagus are divided into two groups, one of which enters the superior cava, and the other the portal vein. In the anastomosis about the œsophagus these veins far outnumber the arteries. There is an inner plexus in the submucosa, and an outer plexus on the periphery. Both these plexuses anastomose freely. There is a free anastomosis between the portal vein group and the superior cava group which gives a direct communication between the portal and general venous system. In most of the cases of varices of the œsophagus the liver has been the organ affected as the primary cause of the dilatation of the vessels. The author reports the following case: A girl, six years of age, began to be sick when two and a half years old. She began to get weak and pale, and complained of pain in the head and in the region of the liver. There were signs of indigestion. One year before, 1892, the child had a sudden vomiting of blood, with continued vomiting and diarrhœa. In the following summer the child had another attack of vomiting and diarrhœa. October 13, 1893, the child was admitted to hospital with vomiting of blood. There was no abnormality of heart or lungs. The abdomen was distended, but not tender. It was thought that the child was suffering from an ulcer of the stomach. In five days another severe attack of hematemesis occurred, this time followed by bloody stools. This was followed in ten days by a typical attack of chorea, which gradually improved as the child gained strength. There were no stomach symptoms after this until the child died of a third attack of hemoptysis. At the autopsy the ventricles were dilated and the muscle soft. The endocardium was flecked with spots and stripes of intense yellow color. The pericardium and lungs were normal. The peritoneal cavity contained about a pint of milky fluid. The peritoneum and glands were normal. The liver and the much-enlarged spleen were the seat of fatty degeneration. Section of the portal vein, thoracic duct, and vena azygos were negative. The only positive lesion was an extensive varicose condition of the œsophageal veins. They were knotted and thickened, and some almost as large as a lead-pencil. The point of bleeding could not be discovered.—*Deutsches Archiv für klinische Medicin.*

The University of California.—The Medical Department held its annual commencement on July 13th. The number of medical students during the past year was one hundred and twenty-two.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 3, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Abstract of a Report of the Gynecological Service at Mount Sinai Hospital for the Twelve Years Ending January 1, 1895.—DR. PAUL F. MUNDÉ read the paper. The number of patients admitted to his service at the hospital during these twelve years was 4,211. Of these 2,211 were discharged cured, 1,456 improved, 191 unimproved, 102 died, 313 were discharged after examination as not gynecological.

Laceration of the Perineum.—There were 184 cases of laceration of the perineum; 121 incomplete, 63 complete. One hundred and forty-one were cured by operation, the others were improved. Up to 1886 he performed the operation employed by Emmet and Thomas, making a butterfly-shaped denudation and using silver-wire suture. While he could not deny that his results were good, still he had a few failures, and the operation had the fault of being long and somewhat difficult. In the summer of 1886 he saw Mr. Tait do the so-called flap operation, without removal of any tissue, and operating so rapidly that only those nearest him could see what was being done. Dr. Mundé had since preferred this method, and had employed it in 30 or 40 cases without a single failure. He had discarded silver wire because it produced pain.

After referring to catarrh, ulcer, and stricture of the rectum as not infrequent causes of symptoms seemingly of a gynecological origin, and their treatment by stretching the sphincter and applying a solution of nitrate of silver, he next referred to urethral tenesmus, for which he had found dilatation usually an efficient remedy. In chronic cystitis, with decided disease of the mucosa, mouth medication was of little value. The bladder should be washed out once or twice a day with a solution of borax or Thiersch's solution. In decided disease of the mucosa a cure could not be effected without making a vaginal fistula.

Fistulæ.—Of 13 cases of fistula between the bladder and sexual organs, 2 were between the bladder and uterus, 11 between the bladder and vagina. In one of the former he turned the uterine canal into the bladder, menstruation taking place through the bladder. The other patient died from an ovarian abscess which had not been suspected, and which ruptured during the operation. Of the cases of vesico-vaginal fistula, 9 were cured, 1 improved, 1 refused an operation. The Sims method of operating was employed, namely, shallow paring of the edges of the fistula, not including the bladder-walls in the sutures. Silver wire was used.

Rectocele, alone or along with prolapse of the anterior vaginal wall and bladder, was present in 110 cases. If an operation were required, the two conditions were treated at the same sitting. The symptoms of rectocele, without decided laceration of the perineum, could be relieved by holding up the backwardly displaced uterus with a pessary. If the perineum were torn and the posterior vaginal wall were very much relaxed a pessary could not be retained, and only narrowing that portion of the vagina would give relief. A pessary, however, might still have to be worn for the uterine displacement. He was decidedly in favor of curing a pronounced rectocele by operation, and employed Hegar's method of triangular denudation of the posterior vaginal wall and mattress stitch, which he preferred to the method of Thomas and the later one of Emmet.

Dr. Mundé did not operate as often on cystocele as on rectocele, for the reason that, unless there were complete vaginal prolapsus calling for narrowing of both posterior and anterior walls, the simple cystocele operation was not so successful in its permanent results as that on rectocele. This was because of greater pressure on the bladder and anterior vaginal wall in the erect position. Where there was not too much vaginal prolapsus along with the cystocele, and no displacement of the uterus, Gehrung's pessary sufficed without a plastic operation. In the combined operation, he preferred to use the tobacco-pouch suture, recommended by Stoltz, anteriorly.

In fifteen cases of stenosis and atresia of the vagina, he restored the canal or made a new one. In one case there was double uterus and vagina, the vaginal canal on one side being closed and causing pain by retention of menstrual blood. He excised the septum and made one canal from vulva to fundus. In two cases there was epithelioma originating in the posterior wall of the vagina, a rare seat of the disease. The cervix was healthy. He could only use the curette and caustic, giving but temporary relief.

Cervical Laceration; Cancer.—The most common disease of the uterus was laceration of the cervix—518 cases. Emmet's operation was performed in 342 cases, with 316 recoveries. In 160 cases an operation was not considered necessary, the symptoms being relieved by the sharp curette, iodized phenol, and nitric acid. A lacerated cervix required operation, not so much for the laceration itself as for the symptoms which it produced. He had become convinced that absolute rest in the recumbent position was not at all necessary for union of the lacerated lips after Emmet's operation, but if it were not enforced and there should be failure, one would be blamed for not having taken the necessary precautions. His custom had been of recent years to direct patients to remain abed a week, then get up and go about, and come to his office after the first menstrual period, when he usually removed the stitches. He had seen, in properly selected cases, more benefit result from operation on the lacerated cervix than from any other treatment of any one of the minor lesions of the female sexual organs. Another reason for operating was the possibility of malignant disease developing in the raw, bleeding tear. How many of the 54 cases of epithelioma of the cervix which appeared in his list were due to laceration of the cervix he was unable to say. At any rate, probably more than two-thirds of all the patients with epithelioma of the cervix seen by him had borne children, and probably had suffered from more or less cervical laceration. In only 3 of the 54 cases was he able to achieve a cure. The galvano-cautery wire was used. Of the remaining 51 cases all he was able to do in 40 was to remove as much of the diseased tissue as possible with the sharp curette and chloride of zinc. One of the patients lived four years after one such treatment. In 11 cases the entire uterus was removed per vaginam, but in no instance with permanent recovery. In fact, out of 26 cases of vaginal hysterectomy, with 3 deaths, not one patient had remained free from disease longer than nine months, and in no case had life been prolonged more than two years. The uterus was extirpated in 6 cases for malignant disease of the body—4 epithelioma and 2 sarcoma. The patient recovered, but the disease returned. He was perfectly aware that vaginal hysterectomy was attended by a smaller mortality, but he could not help feeling that the supra-pubic method of complete hysterectomy was more surgical and technically superior. "I do not feel that my own experience justifies me in attempting again to remove a cancerous uterus, unless a thorough careful examination, if necessary under anæsthesia, has convinced me that the uterus alone is involved and that the parametrium is absolutely free from disease. I do not see the use of subjecting the patient to the danger, discomfort, not to mention expense, of a hysterectomy, whether vaginal or supra-pubic, for the removal of her cancerous uterus,

unless there are at least seventy-five chances out of a hundred in her favor for a permanent cure. Acting on this principle, I have refused many an operation which I have good reason to believe has afterward been performed by others, who could not possibly have had any reasonable expectation of curing the patient. Many cases of cancer of the cervix, indeed, in which the patient does not bleed and has only a comparatively trifling discharge, suffers no pain, in fact, hardly knows that she is afflicted with an incurable disease—many such cases, I repeat, should, I think, be left alone. The disease progresses more slowly, I am sure, if it is not interfered with, and when the case is at once recognized to be incurable, what is the use of inflicting unnecessary pain and discomfort upon the patient? Simple palliative remedies will in such cases, it is my honest conviction, do much better for the patient than doubtful or hopeless operative procedures.

I may as well say here that, so far, I have not happened to meet with a case where I could conscientiously perform the now so popular operation of extirpation of the uterus per vaginam for diseased appendages and pelvic suppuration. I do not question the justifiability of vaginal extirpation of the uterus for suppuration of the appendages and pelvic tissues, in properly selected cases, but my experience certainly leads me to regard such cases as not very common, as rather the exception than the rule in diseases of the adnexa and pelvic inflammation, and I cannot help questioning the judgment of surgeons who report with pride several hundred such operations performed by them during the last three or four years, with but trifling mortality. It seems to me that these gentlemen are riding a hobby as fascinating as it is likely to be ephemeral.

Endometritis.—Only such cases of endometritis were admitted as could not be safely treated at the office or clinic, yet the number admitted was two hundred and ninety-seven. The chief significance of chronic non-puerperal endometritis was the production of sterility, and it was for this reason chiefly, and also for the irritating discharge, that the cases were admitted. The treatment consisted of dilatation and curettage of the uterine cavity, followed by thorough application to the endometrium of fifty per cent. solution of chloride of zinc in the worst cases, and of a solution of iodized phenol in milder cases. A sterilized drain was then inserted through the internal os, the patient put to bed, and all precautions taken against inflammatory reaction. A repetition of the cauterization with milder solution, if thought best, usually resulted in a permanent cure in the course of two or three weeks. There were 197 cures, 94 cases of improvement out of 297 operations, only 6 being mentioned as discharged unimproved. The best hope for a permanent cure of chronic endometritis would result from impregnation and normal delivery.

Fibroids.—There were 130 cases of fibroids of the uterus; in only 3 was the growth limited to the cervix, and was removed by enucleation and traction through the vagina. In one instance the patient was pregnant in the fifth month, and rupture of the membranes and prolapse of the umbilical cord necessitated immediate action. He first removed the tumor, weighing three pounds, and then easily extracted the child and placenta. The other two cases occurred in virgins, and cervix and perineum had to be split, after which the tumor was extracted with the obstetric forceps, the cervix and perineum being repaired subsequently. In 21 cases the fibroid had developed into a polypus and was removed with comparative ease. In 29 cases abdominal hysterectomy was performed, with 25 recoveries. The extra-peritoneal treatment of the stump was adopted in all cases up to within two years, since which time he had employed the intra-peritoneal method, leaving a small portion of the cervix which he covered with peritoneum. All these cases had recovered.

In 46 cases the symptoms were improved in the course of time by ergot, curetting, and intra-uterine galvanization. In 3 cases galvano-puncture of the fibroid was practised through the vagina, and a current up to 150 milliampères was passed through the tumor and uterus for fifteen minutes under anæsthesia, only one sitting being given in each case. The treatment was followed by quite extensive inflammation and sloughing, but the tumor gradually disappeared and all three of the patients were discharged cured.

In nearly one-half of all the cases of fibroids the symptoms were not regarded as sufficiently severe to warrant any dangerous operative procedure. His custom was to advise the expectant treatment in all cases of fibroids which do not call for immediate surgical interference, but he had been careful to recommend to such patients to present themselves two or three times a year for examination, or whenever sudden increase in the tumor or alarming symptoms manifested themselves. In numerous cases the tumor was found, after a year or more, in its original condition or diminished in size, causing no symptoms. He had seen great benefit result from the persistent use of galvanism, without puncture, in the arrest of growth or diminution in the tumor.

Dilatation for Sterility.—Discission and dilatation of the uterine canal for congenital constriction was performed ninety times, the object being chiefly to cure sterility. The canal was kept open in former years by hard rubber stem, lately by packing with iodoform gauze. What the results were on the sterility he was unable to say, since such patients seldom returned to report.

Retroversion or Retroflexion was present in 161 cases: 85 recoveries, 66 improved, 10 unimproved. The recoveries were mostly due to Alexander's operation, a few to ventral fixation; the improvements were due to retention of the uterus by pessary. He still preferred Alexander's operation to all others for radical cure of displacement, had performed it seventy-five times in this list, with very few failures. If there were uterine prolapsus, Alexander's operation alone would not suffice to retain the organ, but it was necessary to also narrow the vaginal canal anteriorly and posteriorly, and do perineorrhaphy. Twice he operated by Freund's new method for prolapsus of uterus and vagina, by inserting a series of circular thick wire sutures round the prolapsed mass, beginning at the external and replacing it step by step as each suture was twisted. The result, so far as he could judge, was perfect. Of course the vagina was almost entirely closed, the stitches being left in as permanent splints.

In one case of inversion of the uterus of a year's duration, repeated efforts to replace the organ failed. He was finally obliged to remove the ovaries, close the abdominal wound, and apply an elastic ligature to the pretty well mutilated uterus, the result being a sloughing of the organ and a complete recovery. He would hardly recommend this procedure, but under the circumstances saw no other way out of the difficulty.

Hysterorrhaphy, or ventral fixation of the fundus uteri, was performed ten times for retroflexion and twice for prolapsus, with one death in prolapsus. He could not conscientiously favor this operation for a condition which in no way endangered life.

Disease of the Ovaries and Tubes.—Salpingitis, acute or chronic, more or less associated with chronic oöphoritis, occurred 651 times, with 75 recoveries after removal, 41 cured after local treatment without operation, 512 improved after palliative local treatment, 22 unimproved, 1 death after operation. He said it would have been very easy for him to have operated on probably 500 of the 651 cases, without putting his conscience to a very dangerous tension, but he had always felt that, while it was easy to remove the appendages, it was never possible to restore them, and he did not believe any patient had seriously suffered through delay in removal of

the appendages for which he might have been to blame. When it came to distention of the tube with pus the case was quite different, for out of 40 cases recorded he removed the diseased organs by cœliotomy in 26, with 21 recoveries, and cured 11 others by vaginal incision and drainage. As a rule he preferred to remove every pus tube by abdominal section, unless it was firmly adherent to Douglas's pouch, was unilateral, and could be easily and safely opened and drained by the vagina.

Tubal Pregnancy.—In 15 cases the Fallopian tube was removed for pregnancy, before or after rupture, with 13 recoveries. He was no longer a convert to galvanism for the arrest of tubal pregnancy, although he had had a successful case of the kind twelve years ago. It was exceedingly difficult to lay down positive rules for the guidance of the surgeon where hemorrhage had ceased and the patient's condition was good, yet, unquestionably, the proper course was, if the diagnosis were reasonably certain and the blood was not encapsulated, to open the abdomen at once and remove the ruptured tube. In one of his cases the rupture had occurred a month previously, there was general peritonitis, the abdominal cavity was full of foul, decomposing blood; yet the patient recovered.

Cœliotomy for ovarian tumors and cysts of the broad ligaments was performed 149 times Of these, 128 were ovarian tumors, with 11 deaths. The rest comprised hæmatoma, carcinoma, papilloma, acute œdema of the ovary, and 7 cases of cyst of the broad ligament. Two cases of fibroid of the ovary, both recovered after operation. In 25 cases the ovarian tumor was dermoid, 10 of the right, 10 of the left ovary, 5 of both ovaries. In one case the dermoid on one side contained a large switch of black hair about six feet long. In 23 cases torsion of the pedicle of the tumor was found, all recovering but one. The torsion was usually to the right in cysts of the left ovary, to the left in cysts of the right ovary, so that it was usually found on the opposite side from its origin.

A number of cœliotomies were performed for other conditions of the abdominal organs, such as tubercular peritonitis, general purulent peritonitis, sarcoma of rectus muscle, displaced kidney, perityphlitic abscess, and for exploratory purposes.

Pelvic Peritonitis and Pelvic Cellulitis.—Pelvic peritonitis was the most common affection in his service: 602 cases, with 304 recoveries, 281 improved, 10 discharged unimproved, 7 deaths. The attack might last a long time, even for months, yet the exudate completely disappear, and the pelvic organs be restored apparently to their normal condition. In a large majority of cases the disease had its origin in an acute salpingitis, and the worst prognosis regarding ultimate restoration to entire health was certainly found after gonorrhœal infection. Pelvic cellulitis was noted in 79 cases, with 67 recoveries, 8 cases improved, 4 not benefited, no deaths. With rare exceptions the cases of pelvic cellulitis followed parturition. The differential diagnosis between the two classes of cases was not easy. His treatment had usually been absolute rest, thorough cleaning out of the bowels to begin with, then regular but easy evacuations every two or three days. Cold or hot applications to the abdomen. When the temperature had gone down and only the exudate remained, he applied blisters with hot poultices over the abdomen. Opium only to relieve pain. In 103 cases the pelvic exudate underwent suppuration, with 87 recoveries, 6 improved, 1 not improved, 9 deaths. In 95 cases the abscesses were opened by lateral abdominal section, in quite a number through the vagina also—opening where the mass pointed most prominently, but preferring the vagina.

Pelvic Hæmatocele and Hæmatoma.—When the effusion of blood was free in the peritoneal cavity, and appeared not to have reached its limit, abdominal section should be made; but when it had become encapsulated, or was extra-peritoneal and bulged deep into the vagina, he had found its evacuation through the vaginal roof, no matter where it may originally have started from, to be a perfectly safe and efficient method. Out of eleven cases of hæmatocele treated in this manner he had three deaths, and out of sixteen cases of hæmatoma two deaths. He did not believe the results after abdominal section would have been nearly as good.

To show the increase in the service of the hospital, there were admitted, in 1883, 181 patients, and 47 operations were performed; in 1894, 505 patients, with 295 operations. He had always sought to cure his patients without resorting to the knife whenever it was possible. If he had erred on the side of conservatism, there were plenty other operators ready to correct his error.

Dr. R. A. Murray asked Dr. Mundé what had been the difference between the results of the former method of doing trachelorrhaphy alone, and of the later method of doing curettement and trachelorrhaphy.

Dr. Brettauer, who had assisted Dr. Mundé in many of his operations and had acted in his place part of the time during his vacations, expressed his pleasure at the author's conservatism in view of the many radical operations being done by others.

Dr. P. A. Harris wished to know whether the author had found the ureters ever in danger while narrowing the vagina for prolapsus of the bladder. He had never injured them himself, but had feared that he might.

Dr. C. E. Quimby thought it strange that, as a general practitioner, he saw so few cases of suppurative disease of the appendages when gynecologists reported so many. A writer in the Medical Record had stated that in the vast majority of cases of pus-tubes gonorrhœa was the cause. He wished to know if this was in accord with Dr. Mundé's observations, and whether the pus had been examined for gonococci.

Dr. H. L. Collyer said he had seen a good deal of Dr. Mundé's work, and knew that he could have made a better showing in his operative statistics had he been less conservative; but it would have been at the expense of more mutilated women. In his opinion the effect of electricity on fibroids was to cause an absorption of exudate rather than absorption of the fibroid itself.

Medical Treatment of Chronic Endometritis.—Dr. A. Jacobi said there was no chapter in the paper which had not given him instruction. He hoped the author, who had used the material chiefly for drawing surgical lessons, would write another paper showing the influence of disease of the pelvic organs on other organs of the body and on the general health, and also on the etiology of the diseases treated. Regarding chronic endometritis, of which he had himself seen a good deal, he had given up its treatment by chloride of zinc because of the tendency of this agent to produce cicatrization of the surface. In parametritis Dr. Jacobi had been able to do a good deal by bichloride of mercury internally, amounting to a quarter of a grain a day, kept up with intervals for perhaps six weeks. If he wished a speedier effect, he changed off from bichloride of mercury to iodide of potassium weekly. This treatment certainly did good.

Dr. Mundé closed the discussion. Replying to Dr. Murray's question, he said both classes of cases had gotten well when treated by trachelorrhaphy, but those in which curettement was done at the same sitting got well sooner. He had never wounded the ureters in operating for cystocele, the vaginal denudation not extending deep enough. There was danger of chloride of zinc producing contraction of the uterine canal, still he used it with precautions in endometritis, because of its beneficial effects. He did not think old plastic or fibrous adhesions could be influenced by internal medication, as mercury or iodide of potassium.

The Loomis Entertainment Fund.—The President stated that the trustees had provided a modest refreshment from the Loomis Entertainment Fund. In donating ten thousand dollars, the interest of which was to be devoted to this purpose, Dr. Loomis had wished to

awaken interest in the Academy, and it was hoped the members would wait and partake of the refreshments. It is understood that a collation will be announced on the card regularly hereafter.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 22, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT.

Lacer's Liver.—DR. DONALD M. BARSTOW exhibited a liver that had been taken from a woman, sixty years of age, who, while crossing one of the ferries, had been suddenly seized with vomiting and faintness, and who had become unconscious before the arrival of the ambulance from the Hudson Street Hospital. She died a few hours later. At the autopsy, which was made by Dr. George P. Biggs, it was found that the cause of death had been an extensive cerebral hemorrhage, the result of an endarteritis. The liver was a typical example of what is known as "lacer's liver." A groove or sulcus ran across the anterior surface of the organ, and indicated that the constricting force had pressed the lower half of the liver down below the tightly laced corset. The liver also presented the general appearance of cirrhosis of syphilitic origin.

Displaced Cæcum with Volvulus.—DR. GEORGE P. BIGGS presented a specimen, removed from a male Italian, thirty years of age, who had been admitted to the Hudson Street Hospital, complaining of constipation which had existed for eleven days. He had abdominal pain, most marked on the left, and the abdomen was moderately distended. His temperature was 99 4° F., in the rectum. Examination showed an indistinct mass in the left inguinal region. A number of enemata were given with negative result. As his condition grew steadily worse laparotomy was performed on the following day. The incision was first made in the median line, and a mass was felt in the left side of the abdomen which was thought to be a distended and strangulated sigmoid flexure. A second incision was then made over this mass, and a considerable quantity of thin fecal matter escaped through this incision. Supposing that the gangrenous sigmoid flexure had been opened into, it was sutured to the abdominal end and packed with gauze. The patient died within a few hours.

The specimen presented showed that the gangrenous gut found in the left iliac fossa was not the sigmoid flexure, but the cæcum. The latter had a long, free mesentery, and the cæcum had become completely twisted upon itself, and folded over to the opposite side of the abdominal cavity. The speaker said that it was not uncommon to find a cæcum with such a long mesentery, but he had never before seen one twisted upon itself in this manner.

Gunshot Wound of the Skull.—Dr. Biggs presented two portions of skull, showing the points of entrance and exit of a bullet. The bullet had entered the temporal region, six inches above, and a little anterior to, the external auditory meatus. The skin about the wound for a distance of nearly half an inch had been blackened by the powder. There was a comminuted fracture in the centre of the left parietal bone, about two centimeters in diameter. The bullet, as shown in the specimen, was found lying in the substance of the bone itself. It had produced a comminuted fracture, particularly of the external plate, and had become flattened against the bone. The course of the bullet was from the lower end of the right fissure of Rolando through the upper portion of the right lateral ventricle to the upper end of the left fissure of Rolando. Fragments of bone were found along the course of the bullet. A small fragment driven off from the bone at the point of entrance of the bullet was forced downward, and to the left, through the right corpus striatum, and across to the left hemisphere, and through the left frontal lobe, and was finally arrested at the orbital plate of the frontal bone. This fragment was large enough to produce considerable laceration of the cerebral substance.

Puerperal Septicæmia in a Dog.—Dr. Biggs then presented the organs from a dog, dying of puerperal septicæmia. The dog had been originally one of the attractions at a neighboring museum. About four weeks ago it had been confined. Almost immediately thereafter the animal was observed to be ill, and to have diarrhœa. After about a week fluid began to accumulate in the peritoneal cavity, and the animal became markedly emaciated. About one week ago the dog was sent to a veterinary hospital, and here some of the fluid was withdrawn from the abdominal cavity and found to be almost clear. The animal died shortly afterward. Examination of the uterus showed an acute inflammation, involving the entire thickness of the wall-organ at one cornu. There was evidence also of a subacute peritonitis. The spleen was soft, congested, and enormously enlarged. There was a thrombosis of the left ventricle of the heart, located behind the posterior cusp of the mitral valve. The kidneys showed very marked parenchymatous nephritis. Both the small and large intestine showed a diffuse inflammation, and in places deep ulcerations.

The Society then adjourned.

Clinical Department.

TOTAL REMOVAL OF TONGUE—KOCHER'S METHOD—RECOVERY.

BY WILLIAM WATKYNS SEYMOUR, M.D. HARVARD.

TROY, N. Y.

PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF VERMONT, FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, ETC.

JULY 2, 1895, Mr. L——, fifty-four years of age, blacksmith, was referred to me by my friend Dr. H. C. Gordinier for opinion as to the propriety of operation. The patient had never used tobacco and had never had any venereal disease; but seven or eight years ago he had had some obstinate fissures on the dorsum of the tongue. The teeth were poor, ragged, and ill kept. Five months ago he first noticed an ulcer on the left border of the tongue, and had two teeth removed by Dr. Lyman, of Troy, who advised the patient to consult a competent surgeon. He consulted a physician, who made light of his trouble, and, while daily cauterizing the tongue, told him he was getting better. So far was this from the fact that in the five weeks previous to his consulting Dr. Gordinier and his reference to me, the tongue, from being readily protruded beyond the teeth, had become as hard as a bone and so painful as to prevent restful sleep.

The tongue was warty, but at no part was there any ulceration, and only from the history could I determine the point of origin. The left sublingual gland was greatly enlarged, and in addition there was also a mass of enlarged lymphatics in the submental triangle. Except for symptoms due to the malignant disease the patient seemed in good physical trim and of unlimited grit. The dangers of the disease, the improbability of a radical cure, and the risks of operation were thoroughly explained to him, and he consented to an operation.

On July 7th, with the assistance of Drs. J. W. Morris, Donald and Archibald Buchanan, I operated by Kocher's method. The patient was on his back, and Vienna mixture was used for the anæsthetic. The right lingual artery was first tied; then tracheotomy was done, and the pharynx was packed with a sponge. I

then made a submental flap on the left side so that at the same time I could remove the implicated glands. The ligature of the right lingual was a tiresome piece of work, as pulsation in it was so feeble that I was at a loss to know whether it was an artery ; even a slight change in the position of the head would stop all pulsation. When the trachea was opened respiration stopped, necessitating artificial respiration. Again, when all bleeding from the tracheotomy wound appeared to be controlled and the tube and sutures had been inserted, I was obliged to reopen the wound and ligate a small vessel. The submental dissection gave admirable access to the diseased structures and ready control of the bleeding vessels. Through this opening the entire tongue and floor of the mouth were readily removed. The ligature wound was sutured and sealed with iodoform collodion, and the same was done with the flap wound, save at the upper part of the posterior limb, where a feeding-tube was passed into the stomach and allowed to remain. The sponge-packing of the pharynx having been removed, the mouth was irrigated with a weak carbolic solution, and iodoform gauze packing was introduced into the floor of the mouth. A thick dressing of sterilized gauze was applied over all.

Despite the duration of the operation (nearly two hours) there was absolutely no shock.

As is my custom in all operations on the throat or mouth, the patient was put in a bed with the foot very considerably raised so as to favor drainage into the mouth and away from the respiratory tract.

For the first twenty-four hours the patient was fed by enemata, and afterward by the feeding-tube in the neck. After the first twenty-four hours the gauze-packing was removed, and the mouth was washed with a mild carbolized solution. The after-progress was uneventful. The patient was up and out on the fifth day—not, however, with my consent. The tracheotomy-tube was removed on the tenth day, and the feeding-tube on the eleventh day, after which the patient fed himself with a "duck," to which was attached a piece of rubber tubing. This was rendered easier by the practice which he had taken, at my suggestion, before operation. Although the patient before the operation had been racked with pain, he has not required a single dose of medicine since, and is now working daily at his trade, feeling as strong as ever ; he can swallow meat by washing it down with fluid after it has been well chewed, and one can understand most of what he says.

The total excisions of the tongue which I had heretofore seen had either been done by bisecting the lower jaw or by Billroth's or Regnoli's substantial excision, and none of them seemed to afford the thorough view given by Kocher's operation. The ligation of the lingual was the hardest part of the operation. Of preliminary tracheotomies I have always been a little shy, having seen the respiration cease instantly in two cases on seizing the trachea with a tenaculum, and twice when the trachea was opened. Three of these cases were tracheotomies for diphtheria, and one a tracheotomy preliminary to excision of the upper jaw by my former visiting surgeon, Dr. George W. Gay, of Boston. This latter case finally breathed noticeably a very long time after Dr. Gay had finished his operation. Following my Boston training, I used ether almost entirely in my early work, but after myself taking it for a cœliotomy, and ending most diabolical laryngeal irritation from it, I have come to use more and more the so-called Vienna mixture, especially in abdominal work. I have found it expeditious, not at all irritating to the respiratory organs, and to occasion less nausea than has come from ether alone, whether administered profusely as in Boston, or with Clover's or Ormsby's inhalers. In the after-treatment of such operations on the mouth, in tracheotomy, and in intubation, permanent inversion for drainage I believe to be a great advance.

Dr. Casselbury, of Chicago, suggested inversion as a means of feeding intubation cases, but nowhere have I found any evidence of its employment over a period of several days for drainage. It is wonderfully efficient, and I am sure will minimize inspiration in pneumonias if employed in such operations as excision of tongue, tracheotomy, intubation, thyrotomy, and laryngectomy. Trever's suggestion, to have the patient, for some time before operation, practise feeding himself with a vessel, to the spout of which a rubber tube is attached, is an excellent one ; although I should in any subsequent case again employ a feeding-tube such as I used, and which is very highly recommended by Mr. Arthur Baker. In these cases the important factors are early recognition, radical operation, drainage, and feeding. Jonathan Hutchinson has very recently declared that no one should die from cancer of the tongue ; but to attain this Utopian state of surgical practice time, and with time life, must not be frittered away by needless delay or harmful cauterizations.

The cautery, chemical or actual, does not go to the root of the evil, and the same may be said of the partial operations—the wedge and hemi-excisions. The total excision does go as far as possible, and should be done early for cure. If the tongue is movable and the floor of the mouth and glands free, I would, as a rule, prefer Whitehead's operation through the mouth, but in more extensive disease I cannot imagine an operation which, better than Kocher's, satisfies all the conditions of operation. Hemorrhage is well controlled, implicated glands are accessible as well as the whole floor of the mouth, and the field of operation is better exposed than by any other method. By it also both drainage and feeding are easier than by other methods.

To prevent infarction and inspiration in pneumonia invert the patient until granulation is well advanced.

Specimens from the mass we hardened in formalin and then cut by embedding in celluloidin, and subsequently stained with hæmotoxylin, and with alum carmine. The disease was shown to be clearly epitheliomatous. Sections showing toward the surface great masses of squamous epithelium with innumerable nests everywhere. The small-celled infiltration extended everywhere, between the muscles and into the areolar tissue. The patient, two weeks after operation, weighed 116 pounds, and now weighs 148 pounds.

TREATMENT OF GONORRHŒA.

By ISAAC E. WILLIAMS, M.D.,

ST. MARY, O.

I WRITE this article not because I am a specialist in this line of work, but with the hope of offering a few good suggestions which have aided me much in the treatment of gonorrhœa.

In the beginning, I wish to state that my experience teaches me : 1. That the abortive treatment by nitrate of silver injections is a success. 2. That many injections in common use are not strong enough to do any good, and that they may be made stronger with better effect and without danger of stricture or other harm. 3. That nearly all cases of gonorrhœa should be cured in a time not exceeding three weeks, and that seventy-five per cent. of them should be cured in from ten to fifteen days. These facts I can demonstrate in practice. I have been the entire rounds of injections and internal medication. The former I regard of more importance than the latter. I think it is a mistaken idea to obstruct the posterior urethra with the finger to prevent the fluid from reaching far back, as it can do no harm if the urine be passed immediately before injecting. The sphincters will guard the bladder. The injection should be held in for a few minutes by closing the meatus.

In the beginning of an acute attack, before the dis-

charge becomes purulent, I advise the following injection :

℞. Argenti nit ..... gr. 5.
Aqua dest ..... oz. 1.
M. Sig.: Inject after urinating, every ten hours, until the discharge becomes purulent. Use a blunt-pointed syringe, holding two drachms. A calomel purge (five grains) may be given with benefit, followed by alkaline diluents and cannabis sativa in small doses for four days. Then the following :

℞. Plumbi acet ..... gr. 20.
Zinc. acet ..... gr. 12.
Aqua dest ..... oz. 1.
M. Sig.: Inject four times a day after urinating.

This injection should cause slight burning sensation. If too severe, add half an oz. distilled water. If after using one or two days it cause no smarting at all, increase the plumbi acet. to 24 gr. to the 4 oz. It will be seen that our aim in the first stage is to destroy the more superficial parts of the infected mucous membrane, and in the second, to lessen hyperæmia by astringents. If the penis is red and swollen, with lips of meatus everted, the second formula will afford prompt relief. Nothing will so quickly disperse a chronic gleet. If the prostate is involved, I give fld. ext. saw palmetto one-half teaspoonful every four hours. When the bladder becomes irritable or inflamed, fld. ext. couch grass idr., with 4 drops fld. ext. gelsemium every four hours. Nothing but distilled water should ever be used as the vehicle for the injection.

For gonorrhœa in the woman, the infected parts should be well swabbed with the following :

℞. Argenti nit ..... gr. 5.
Aqua dest ..... oz. 1.

The vagina should be well opened with a speculum before swabbing. Alum, 60 gr. to the oz. of vaseline, may be introduced on a tampon before going to bed. This should be taken out in the morning and the vagina well washed out with warm water.

A PRELIMINARY NOTE ON THE USE OF PHENOL AS A PRESERVATIVE OF DIPHTHERIA ANTITOXIN.

By CHARLES B. FITZPATRICK, M.D.,

NEW YORK.

On the 2d inst., Dr. J. L. Kortright and I had a conversation about the young girl, named Valentine, which he had treated for diphtheria. As is generally known, he administered antitoxin, and the patient died in about three minutes.[1] Immediately after the injection, a "lump" was felt by the patient at the seat of the injection ; this was followed by a general tingling sensation, convulsions, opisthotonos, and cessation of respiration. The autopsy showed a congestion of the brain, meninges, liver, and kidneys. No microscopical examination was made.

In the discussion mentioned we went over a number of the possible causes of the death, and could come to no satisfactory conclusions. Finally, it occurred to me that the above-described symptoms could very well have been caused by carbolic acid. I then described to Dr. Kortright some of my experiences with guinea-pigs which had been poisoned by phenol, and he agreed that it could account for the symptoms. The serum he had used in the Valentine case contained phenol as a preservative.

The second point to decide is : Could a poisonous amount of phenol, by some oversight or accident, have been present in a flask of antitoxin which had been preserved by it ? By going over the steps of the technique it will be seen that such an occurrence might be readily brought about.

After the blood is drawn, it is put in an ice-box. The serum is then drawn off. The usual way is to collect a large quantity, so as to make one test do for as much as possible. The phenol is then added to this serum.

It is a well-known fact that phenol is not readily dissolved in cold aqueous solutions. If it be added to such solutions, even when thoroughly shaken up, it forms a much stronger solution near the bottom, after it has been allowed to settle.

My experience with guinea-pigs, although incomplete, is interesting, and, taken together with the literture, strengthens the probability that phenol caused the death of the Valentine case.

A guinea-pig, weighing 542 grains, received 2 ctm. of a 1 to 40 solution of phenol, subcutaneously. On the third day it developed fairly well-marked opisthotonos and clonic convulsions, which resulted in death in four hours. Autopsy showed congestion of the brain, liver, and kidneys.

At another time, while testing some serum, I was very much put out to find, in a series of tests, that the guinea-pig which had received the largest amount of antitoxin died within twenty-four hours, with convulsions resembling those in the preceding case. I have no doubt now but that this was due to phenol.

I have also produced convulsions in rabbits. Salkowski[1] records the same, and death in the midst of a convulsion. In the dog similar symptoms are produced.

In man, Dr. Taylor[2] records a case in which the man fell unconscious within ten seconds after taking a fatal dose of phenol ; two minutes later he was completely unconscious, pulseless, with irregular respiration, and in less than a minute more was dead.

Convulsions may also be present in man. These observations show that if phenol be administered it can cause death, with practically the same symptoms as those were which occurred in the Valentine case.

It is not my intention to give an elaborate treatment of this subject, but just to indicate what would justify a belief in the probability that phenol might have been the cause of death in Dr. Kortwright's case.

In my article "Notes on the Preparation of Diphtheria Antitoxin,"[3] I have spoken of the use of phenol as a preservative, when the antitoxin is sufficiently strong to be used in doses of 10 c.c., or approximating that. My present judgment is that, although phenol is the best preservative, it is too dangerous to be used. Camphor answers all the necessary indications.

October 14, 1895.

[1] Dr. Kortright's article describing this case will appear in an early number of a Brooklyn medical journal.

GOLD SPECTACLES AS A CAUSE OF ASTHENOPIA.

By W. H. BATES, M.D.,

NEW YORK.

Case I.—The first case was reported in the Medical Record, February 23, 1893. It is so typical that with its further progress it deserves a brief notice here. The patient was a lady, who had worn steel frames for some years. She desired to wear gold spectacles, but could not do so because of the headache and pain in her eyes, produced by the glasses. It was discovered that she could wear the glasses when the gold nose-piece did not touch the skin. A piece of rubber was vulcanized on the under surface of the nose-piece and the patient wore the glasses with comfort. Since then the rubber has worn through from time to time, and the pa-

tient has been compelled to have it replaced. The patient was seen recently, more than three years after the glasses were ordered, and she still wears her gold spectacles with comfort.

Case II.—The wife of a physician. She complained of headaches and asthenopia. Her general health is good, and she says that she has never been sick. She does not impress one as being hysterical. The vision of both eyes is $\frac{20}{20}$.

September 25, 1894.—Under homatropine hydrobromate, three per cent. solution: Right eye with + 1.5 D.S. = $\frac{20}{20}$; left eye with × 1.25 D.S. = $\frac{20}{20}$. These glasses were ordered in steel frames, to be worn all the time.

November 2d.—The patient is relieved of her headaches from wearing the glasses constantly. She now obtained gold frames. Her headaches returned at once. If a piece of paper was placed under the nose-piece, preventing the gold from touching her nose, she had no discomfort from the glasses. The optician fastened a piece of cork on the nose-piece to prevent the gold from touching the skin. Headaches occurred as usual. A careful examination of the frames, while worn by the patient, showed that the cork did not prevent contact of the gold with the nose. A piece of rubber was vulcanized on the under surface of the nose-piece of the gold frames, which prevented the gold from coming in contact with the skin. The patient was able to wear the gold spectacles with relief to her headaches and asthenopia.

Case III.—Mrs. G——, aged thirty-three, has suffered from headaches and asthenopia for several years. Her general health is poor. Under three per cent. solution homatropine, May 16, 1894, her refraction was as follows: O.D. + 1.5 D.S. ⌒ + 0.5 D.C. 60°. O.S. + 1.5 D.S. ⌒ + 1.25 D.C. 90°. These glasses were ordered in steel spectacle-frames for constant wear. Her headaches and asthenopia were relieved. In the following September she obtained gold spectacles. She was unable to wear them because the pains in her eyes and head produced by the glasses were too severe. After having a piece of rubber vulcanized on the under surface of the nose-piece, thus preventing contact of the gold with the skin, the patient was able to wear the gold spectacles.

Case IV.—Miss W——, aged twenty-eight, has suffered from asthenopia for several years. She had also Blepharitis and chronic conjunctivitis. Under homatropine her refraction, October 8, 1894, was: O.D. + 1.0 D.S. ⌒ + 0.75 D.C. 45°. O.S. + 0.5 D.S. ⌒ + 0.5 D.C 120°. These glasses were ordered and worn in steel frames with relief to all her symptoms. About Christmas-time she was presented with a pair of gold frames. She was unable to wear the gold frames because of the severe pain which began in both eyes as soon as the glasses were worn. Wearing the gold frames also increased the redness of the edges of the eyelids and made the eyes stream tears. The patient returned to find out if her glasses were all right. She was anxious to wear the gold frames. In order to determine if the gold frames caused the trouble, a piece of paper was placed under the nose-piece, preventing contact of the gold with the skin of the nose. She now felt all right, wearing the gold frames. With a note to the optician she hurried down town to have her gold frames fixed. The optician placed tortoise-shell on the under surface of the nose-piece to prevent contact of the gold with the skin. The patient felt better than with the gold frames, but they were still troublesome. An examination showed that the tortoise-shell was held fast by metallic pins, which may have caused the trouble. Vulcanized rubber was substituted and the patient was able to wear the gold spectacles with comfort.

Summary.—1, Steel spectacles relieved; 2, gold spectacles could not be worn; 3, gold spectacles with the gold not in contact with the skin, relieved.

64 East Fifty-eighth Street.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL NURSES—THE LATE SUMMER PUBLIC HEALTH—CHARGE OF MANSLAUGHTER—DIFFICULTIES FROM INFECTIOUS HOSPITAL OVERCROWDING—MR. ERNEST HART'S STATEMENTS—REPUDIATION FROM MADRAS.

London, September 28, 1895.

The correspondence on "White Slaves in Hospitals" still goes on, and excites as much interest as can be expected. Many grievances have been named which must fall heavily on the nurses, and after the exposure which has taken place managers must move or the charities will suffer. Surprise is here and there expressed that the nurses do not themselves complain, but the truth is they dare not. The rule of the matron or secretary is absolute, and often these officials are not fit for their post. The matron may be an experienced nurse but unrefined, a housekeeper without the tact or knowledge required to provide an appetizing but economical diet. Even when a lady occupies the position her rule is despotic, and she is apt to forget that some at least of those under her are of equal social position, and often better educated. An appeal to the Board is, I know, almost always hopeless, and results in dismissal with a view of maintaining discipline. The Boards of Management have now had warning. The public requires them to maintain justice as well as discipline. It is admitted on every hand that the women who take to nursing are very easy to manage, as they expect to sacrifice many comforts. They are certainly prepared to endure every hardship incidental to their vocation, but that is no reason why Boards should increase those hardships by neglecting their own duties of supervision, and committing undue authority to any one they cannot or will not control.

No doubt the question of finance will come before these Boards. Let them remember that economy does not consist in buying inferior food for nurses, or in arranging a dietary which is not nutritious. The question of long hours is more serious, as a great increase of the staff would be costly. But it will never pay to knock up the nurses by overwhelming them with work, and the numerous women one meets who have broken down under the strain proves the real urgency of the grievance.

We are enjoying or enduring—according to the temperament—a period of prolonged fine weather and almost unparalleled heat for this time of year.

In town it is oppressive, but in the country delightful, though in the full sunshine it is too hot for many. In the early mornings and evenings I have experienced nothing like it for many years.

The health of both London and country continues good. There was a slight rise of mortality in London last week, but only to sixteen per one thousand, and in other towns the returns were as favorable, while Croydon only registered nine. There is an increase of scarlet fever in some districts, and diphtheria maintains its hold.

A sad case of death in parturition has occurred, and resulted in the arrest of the doctor in attendance on a charge of manslaughter from neglect or recklessness. At the inquest it was alleged that he was intoxicated, but other statements were that he was ill and had taken chloral. He had been in practice some thirty years, and had attended over five thousand labors. He will have to stand a trial, when perhaps it will be shown that the preliminary investigation is incomplete.

An incident at the East End last week seems to point to the need of some further supervision of cases of in-

fectious disease for which the hospitals have not room. A child with scarlet fever was taken to the London Hospital. An ambulance was sent for and the patient removed to the hospital of the Asylums Board, but as this was full the child was conveyed home again in the ambulance. No further steps were taken by the parents, and no bed seems to have been vacant. The child died in ten days, and at the inquest the father said that it was no use sending for a doctor, as he would only have ordered removal to hospital. Either ignorance or carelessness seems to have been partly to blame. The hospital accommodation is sometimes overstrained, and there has been great difficulty in providing more. It is suggested that when a patient is sent back to his home some account should be kept to prevent his remaining unattended ; but surely most people would send for a doctor.

The Madras branch of the British Medical Association has, at a special meeting, adopted a vigorous protest against the resolution of the Public Health section on Indian sanitation, which it declares to be based on erroneous statements of Mr. Ernest Hart.

Many members of the Association have been led away by Mr. Hart's statements, some of which are certainly erroneous. The Indian medical officers, too, have been disgusted by the superciliousness and contempt for their experience he has displayed. Some of his remarks respecting the senior officers in the service were most insulting, and coming from one whose knowledge of the matters he spoke of was altogether second-hand, naturally gave offence. Some previous protests have accordingly appeared, in reply to one of which a leading article was issued in the journal of the offensive kind Mr. Hart is so capable of. This article holds up to ridicule a distinguished medical officer as the holder of military rank, lieutenant-colonel, and this after all that has been claimed for officers in the service ! also as having been engaged largely in civil practice ! Then it extols Mr. Hart and his knowledge, which is purely theoretical, while that of veteran officers is practical. Mr. Hart has never been nice about giving offence, and has delighted to dip his pen in gall, but it is time he gave up his bitter personalities. Already many are remarking that the Association pays him to edit the journal, not to insult members, and a few are anxious to know what he has been paid for his trip to India, and whether the Association has been paying for his other tours? But the financial reformers of the Association are not likely to extract information.

OUR PARIS LETTER.

(From our Special Correspondent.)

MEDICAL PARIS HERSELF AGAIN—BEQUEST TO THE FACULTY—THE PUBLIC AND THE PASTEUR INSTITUTE—HIGH INFANTILE MORTALITY—QUACKS AND CHARLATANS—GOOD RULES FOR BICYCLISTS—MUSIC AS MEDICINE.

PARIS, September 25, 1895.

PARIS, that is medical, professional Paris, is beginning to be herself again ; almost all the leading practitioners are back from their long outing, and nearly every day sees the arrival of some distinguished professor of the Faculty. All the buildings making that formidable pile known as the "École de Médecine," are being cleaned, the schedule of lectures and courses are posted, and all will very shortly be ready for the formal opening of the winter semestre, which nominally takes place October 15th ; but it will be fully a month later before everything is in full working order.

Professor Brouardel, the Dean, has been authorized by the Faculty to accept the bequest of Mr. Ch. I. Mautter according to the conditions of his will, for the foundation of an annual prize in favor of a woman doctor, authoress of a work on the diseases of children.

The General Council of the Seine, considering that the prefectoral administration has sent to the different mayors of Paris instructions regarding admission to the Institut Pasteur of persons bitten by mad dogs, and that these instructions are not within reach of the public, who mostly ignore them altogether, have voted that precise instructions regarding the formalities to be complied with for the admission of wounded to the Institut Pasteur be posted in every commune ; and that they be printed, with all other instructions relative to hygiene, upon the inside covers of copy-books used in the public schools, just as tables of botany or historical synopsis would be. This is an example that your New York Board of Health would do well to follow, at least in so far as hygiene is concerned, and, of course, vaccination. The health of Paris is not quite as good as in the corresponding month in previous years. For instance, the *Bulletin de Statistique Municipale* records 982 deaths during the last week ; whereas there were 880 the week before, the average for September being 832. Torrid weather has prevailed in Paris for some days past, the sun has shone mercilessly in a cloudless sky, running the thermometer up into the nineties, and this accounts largely for the increase in the mortality-rate. The number of deaths from infantile diarrhœa, athrepsis, etc., during the first year of life has been 152, almost the double of the ordinary (78) at this season ; moreover, those caused by diarrhœa, between the ages of one and four years, have amounted to 36, or nearly triple the average (13). As is always the case, the heat has fallen heaviest upon the poorer population in the sequestered quarters of the city, who do not give sufficient care to cleanliness nor to the alimentation of their young children, and where pure milk and scrupulously clean vessels are the exceptions. Epidemic diseases are rare. Typhoid fever has caused but 8 deaths instead of 13—the average.

Notwithstanding the severe requirements to attain the grade of "Doctor" and the stringent new laws regulating the practice of medicine in France, many quacks and charlatans still remain to be dealt with. All the medical societies have now a legal standing as syndicates ; the secretary has only to notify the authorities of any case of illegal practice that may have come to his knowledge, and such person is proceeded against at once. Nevertheless, we counted, only yesterday, ten medical posters giving the name of a "doctor" on each, his address, and hours of consultation, in public urinals on the Boulevards. One of these has just been condemned by the tribunals to a fine of 1,000 francs. Next, the Court of Appeals of Paris has likewise condemned a druggist to 25 francs fine, and 100 francs damages for counter-prescribing, an evil from which physicians and the public suffer in other large cities as well. It seems that the druggist in question prescribed a prolonged application of a two per cent. solution of carbolic acid on an excoriated thumb.

M. Rochebave has just formulated the following precepts, which every bicycle amateur would do well to follow : 1. Only ride on a bicycle after consulting your doctor. An examination should be made, not only before but after riding, as certain cardiac derangements only manifest themselves under the influence of fatigue or over-exertion. 2. Only go at moderate speed, twelve kilometres an hour. Only increase that rate of speed after methodical and daily training. Even after a few days of interruption, recommence at a low speed. 3. Overcome as much as possible the desire to go fast. Bicycles almost roll of themselves. It is very difficult not to yield to the "delirium of rapidity." With a light machine on a good road, the slightest breeze aiding, an amateur can easily do twenty kilometres an hour. This is too much ; since at twelve or fourteen kilometres the pulse-beats rise to 150 per minute.

An interesting work has just been given us by Dr. Ferrand, a psychological essay on music.

From a medical stand-point music may truly be con-

sidered a profound moderator of the activity of the nervous system, and deserves a place in therapeutics in the same category as the antispasmodics, that is to say, agents that modify the activity of the nerve-centres in communicating to them impressions other than those which they are accustomed to obey. In varying its different measures, the mechanism of its rhythm, the vivacity of its melody, the complexus of its harmony, music would seem to act as an antispasmodic, either simple, stimulant, or moderating. Finally, music is capable of acting upon the seat of motor and auditive sensations, and upon the seat of images corresponding to those sensations—capable, consequently, of exciting sensory ideas and the sentiments belonging to them. Dr. Ferrand's conclusions are certainly very interesting to those making diseases of the nervous system a specialty. The subject, however, is by no means new and the remedy not difficult of application; only the physician himself should have a thorough knowledge of it in order to know exactly what conditions to fulfil, or what choice to make, how much musical exercise to prescribe, and what works would be best for his patient to hear or perform.

MEDICAL LANGUAGE.

To the Editor of the Medical Record.

Sir: A paragraph in your issue of September 17th, p. 342, under the head of "Hippopyrrhine," suggests to me the following remarks: Of course it is stupid and out of place to use the word "vaccinate" or "vaccination" for anything that has no connection with the cow or with "vaccinia." Dr. Badour takes great pains to forge a new word, which, if not intelligible, is at least barbarous, though being Greek. The term is certainly clumsy, as you well style it. I, a humble member of the profession, not "learned nor fond of word-making, venture to remind you that there are two good old words," which seem to me to hit "off the case neatly and euphonically;" I mean "to inoculate with" or "to imp with." See New High German, *impfen;* Middle High German, *impfen, impfeten, impeten;* Old High German, *impfôn, impffitôn, impitôn, anglosam, impian.*

By the way, I am much afraid that my friend Dr. Achilles Rose's scheme, to have New Greek adopted as the international medical language, has little chance ever to become realized. Greek, old or modern, is just as little known as Hebrew or Chinese in a great part of the world, namely, at least, where people speak Spanish or Portuguese. Honestly though, being a German, I would rather propose to adopt English, which, besides its other advantages, has that the English-speaking people form so great a majority of the civilized world. That is a fact, and there is no fighting against facts. If we are not able to have a soul above national pride and vanities, we are not yet fit for anything really "international."

Dr. Semeleder.

Cordoba, State of Vera Cruz, Mexico,
September 26, 1895.

The Health Department and the Examination of Tubercle Bacilli.—The St. Louis Health Department makes free microscopic examinations of sputum for tubercle bacilli. The Health Commissioner asserts that certain doctors send specimens to the Health Department for examination, and then charge their patients $5 each for this. Such a proceeding does not seem right to the Health Commissioner, and is not in accord with medical or other ethics. When a government, however, undertakes the job of providing free examinations, free medicines, free inspections, free vaccinations, free disinfections, etc., it must expect some friction before the state of perfected paternalism is reached.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 12, 1895.

	Cases.	Deaths.
Tuberculosis	99	112
Typhoid fever	17	11
Scarlet fever	34	2
Cerebro-spinal meningitis	1	3
Measles	40	1
Diphtheria	151	25
Small-pox	1	1

Dual Personality and the Double Brain.—A favorite theory with some speculative psychologists, and one which appears to be gaining ground, is that the two cerebral hemispheres are capable, to some extent, of independent activity. The theory has been evoked to account for those strange but well-established cases in which an individual appears to possess two states of consciousness, two personalities as it were—such cases as afford the basis of fact for Stevenson's weird romance of "Dr. Jekyll and Mr. Hyde." Dr. Lewis C. Bruce, in the last number of *Brain*, records a case which is more strongly in favor of the double-brain theory than any, so far as we know, previously reported. The man was an inmate of the Derby Borough Asylum. He was a Welshman by birth, and had been a sailor by occupation. He was a lunatic, but his mental characteristics were very different at different times. In one state he was English, in the other, Welsh. In the English stage he was the subject of chronic mania. He spoke English, but understood and could converse in Welsh. He was restless, destructive, thievish, and fond of playing practical jokes. He exhibited a fair amount of intelligence, wrote, drew pictures of ships, related incidents in his past life, recognised the doctors and attendants, and was bold and fearless in his manner. His memory, however, was a blank as to what occurred in the Welsh stage. Thus, on one occasion he burnt his arm during the Welsh stage, but, passing a few days later into the English stage, he could give no account of how he suffered the injury. Yet he could remember events which had happened earlier in an English stage; for instance, a year later he could recall accurately particulars about Christmas decorations. He knew coins and their purpose, he recognized varieties of tobacco, and sought to obtain the weed by fair means or foul. He named the primary colors, and was pleased with the sound of a tuning-fork. Taste, smell, and touch seemed to be unimpaired. His circulation was good (pulse of high tension), he had a good appetite, his bowels acted well, and he was very fond of his bath. Into the Welsh stage he passed either suddenly or by way of an intermediate stage; in the Welsh stage he was in a condition of dementia. He understood Welsh, but talked a gibberish in which, however, some Welsh words were recognizable; he did not understand English. He sat doubled up in a chair for hours, did not attempt to move at meal-times, was sly and suspicious, did not recognize doctors or attendants, his circulation was weak, his extremities livid, his legs often œdematous (pulse of lower tension). He suffered from constipation, disliked bathing, did not recognize coins or tobacco, was alarmed at the sound of a tuning-fork, and appeared to have no power of discriminating by smell or taste. As far as the symptoms so far mentioned go, it might be possible to explain the man's dual states, taking our clew from the fact that he retained some knowledge of Welsh in his demented stage, by suppos-

ing that some variation in the blood-supply might have thrown in and out of action the more recently organized centres, which, as the man was born Welsh, would be the organization for speaking English, while the Welsh part of the speech-centre would still remain capable of some, though a very imperfect, form of activity. This hypothesis, however, appears to be negatived by the fact that he was right handed while in the English stage, left-handed while in the Welsh stage. While in the intermediate stage, when this was observed, he was ambidextrous, and spoke a mixture of English and Welsh, understanding both languages. This fact seems to leave us no alternative but to conclude that in the English stage the left, in the Welsh stage the right hemisphere was the more active. In the Welsh stage, when he attempted to write, the result was practically illegible, but he used the left hand and traversed the paper from left to right. In the English he wrote with the right hand from left to right, and rather more legibly. He could also write with his left hand, but then traversed the paper from right to left, and his writing had the characters of mirror-writing—that is, it could be read when held up to a mirror.—*The British Medical Journal.*

Provident Associations and the East-Side Doctors.—A writer in the *New York Herald* calls attention to a new kind of co-operative scheme of medication, which has been started in this city, on the plan of an insurance association. Although the scheme is spoken of as "new," it is practically a form of the provident insurance associations, such as have been attempted in England. The writer says: "Nearly every head of a family, in this eastern section of the city, belongs to a secret benefit society of some sort. Until lately these societies confined their activity to life insurance, funeral benefits, and sick benefits, but lately the feature of medical insurance has been added to several of them. The plan is to engage some young physician who, for a fee of seventy-five cents per quarter from each member of the society, undertakes to attend the member or his family in case of sickness. At first sight it seems as if this might be a profitable arrangement in the case of a society with one thousand or more members, but in practice it is not so. Every member of the society has several children, one or more of whom are almost constantly ailing, and the slightest ailment furnishes an excuse to call the doctor when his visit costs nothing extra. One young physician who rashly entered into contracts with three of these societies, having an aggregate membership of fifteen hundred, told me that he estimated that he got three-quarters of a cent for each call he made. 'I can find no time for private practice,' he said. 'To-day I have had forty-two calls from my society patients, and I have an average of thirty a day. I am all worn out with the work, and when my quarter runs out nothing will induce me to renew the contract. Why, if a child scratches its finger I have to go and dress it, and I have even found cases where the society members called on me to visit their neighbors, passing them off as members of their own family and charging them a small fee for the accommodation.'"

The Adventures of a Scientific Paper.—In consequence of his communication on the serum treatment of tuberculosis presented to the recent annual meeting of the British Medical Association, Professor Maragliano, of Genoa, says *The British Medical Journal*, has had an amount of greatness, or at any rate celebrity, thrust upon him which he is probably beginning to find somewhat inconvenient. Though the paper was professedly intended for the British Medical Association, it seems, by a mysterious process of thought transference, to have been brought immediately to the knowledge of the editor of our esteemed contemporary the *Berliner klinische Wochenschrift*, who published it *in extenso* in his issue of August 12th, before we ourselves had had the opportunity of seeing the document. Almost simultaneously it appeared in the *Gazzetta degli Ospitali*, the *Riforma Medica*, and other Italian journals, and copious extracts from it were given in the leading political papers of Europe. Immediately after the London meeting the Professor's philanthropic zeal appears to have led him to Bordeaux, where he presented the same communication to the Congress of Internal Medicine which met in that city. Several of the French medical journals are angry with Professor Maragliano for having offered a second-hand article to the Bordeaux Congress, and have therefore declined to let the paper appear in their report of the proceedings.

Malingering and Miracles.—Pierre Delanay, supposed to have been cured in a miraculous way at Lourdes, has confessed that he only shammed illness. He describes his case as follows: Having served for some time as a hospital assistant, and thus become familiar with the clinical jargon, Pierre one day declared himself the victim of an attack of locomotor ataxia. For five years he fooled the doctors and had a good time in bed, with nothing to do but to dispose of the nourishing diet which his sad case called for. The doctors seem to have had their suspicions, however, and a severe course of "the fire and hanging method" decided Pierre that the game was not worth the candle; so he decided, in the words of the song, to "go where he was respected." At Lourdes he was received with open arms, and when in the sacred grotto he threw away his crutches and proclaimed himself cured, he was received with cries of acclamation. Archbishops and bishops hastened to testify to the miracle, the Marquis de Villeneuve gave him an easy and lucrative post, and the world was made easy for the "brand plucked from the burning."

To Avoid Poisoning by Tinned Food.—Some light is thrown by *The Lancet* upon the mysterious cases of poisoning by tinned food which from time to time are reported. They are believed to be due to neglect of the caution against eating tinned foods that have been exposed to the air for some time after being opened. The exact manner in which poisonous substances, technically known as "ptomaïnes" are generated so rapidly is not known with certainty, but the fact that they are produced in sufficient quantity to cause very grave symptoms of poisoning have been brought out in a multitude of instances. In one well-known case the first half of the contents of a tin of lobster was consumed with no ill effect, but the rest, a few days afterward, proved extremely poisonous. It is suggested that as a safeguard manufacturers might label the tins with some such notice as, "The contents of this tin are perfectly wholesome when eaten fresh from the tin, and afford good food, but the public is advised not to expose the contents for any length of time to the injurious influences of the atmosphere." The writer goes so far as to suggest that some such warning might be insisted on by the Legislature.

Petrifaction of the Human Subject.—There exists in a Florentine museum in Italy a number of examples of the skill of petrifying the dead and preserving their features, which was possessed by the late Dr. Girolamo Segato. *The Lancet* notes the recent finding of a petrified head of a young woman, who had died of tuberculosis, which is the most striking specimen of his art. In the past sixty years there seems to have been no particular change in this head, which preserves the features and even the complexion, with the most weird realism.

Denver's Home for Consumptives, which has been erected by Mrs. W. D. Sloane and Mrs. Auchmuty and others at a cost of $150,000, was opened a few days ago. The home is not a hospital. Only incipient cases are taken. There are to be no nurses and no resident physician, and each will pay for medical at-

tendance. There will be a "mother," or matron, who will preside over the home, and there will be no rules except those that enforce hygienic cleanliness. The cost of living at the home is $6 a week. We take it that the purpose of the home is to help poor people who are in the incipient stage of consumption only.

The Walker Memorial Hall.—Dr. Henry F. Walker, of New York, who was for many years associated in practice with Dr. T. Gaillard Thomas, has presented his native town, Pittsford, Vt., with a handsome building, to be known as Walker Memorial Hall, in memory of his parents, the Rev. Dr. Charles Walker and wife; and the dedication services were held on September 11th. Addresses were made by Dr. Walker, his brother, Rev. George Leon Walker, of Hartford, the Rev. Dr. George A. Boardman, and others. The building is to be mainly occupied by the MacClure Circulating Library, which was founded nearly a century ago. Dr. Walker, besides being the donor of Walker Memorial Hall, has furnished Pittsford with an excellent system of water-works and sewerage.

The Three Kinds of Doctors.—The *St. Louis Medical Journal* divides physicians into three classes: Those who read, those who do not read, and those who pretend to read. Our contemporary does not make any attempt to give the census of these different classes, but intimates that the third class is unduly prominent in this country.

Absorption of Drugs by the Bladder and Urethra.—Dr. J. P. Walsh says that absorption takes place from the bladder, vagina, and urethra (*University Magazine*). Absorption is a matter of lymphatics, not of epithelial cells. The various forms of cells lining different parts of the respiratory, digestive, and genito-urinary tracts play mainly a protective part for the lymphatic structures beneath. That in some places they have a heightened activity, and seemingly a selective action in absorption is true; but at no part do they absolutely prevent absorption. Even the cutaneous epithelium, with its horny epiderm will allow the passage of a number of substances. Rapidity of absorption, then, depends on the richness of the lymphatic structures in a part, and not on the character of the mucous membrane covering it. The lymphatics in the bladder are not numerous, but they are easily demonstrable. Absorption should take place then, though not rapidly. His specific conclusions are that: 1. The bladder absorbs somewhat slowly the drugs that are injected into it, but it has a true absorptive power. 2. The urinary constituents, water and solids, are, to a certain extent, reabsorbed from the bladder, when allowed to remain in it for some time. 3. The anterior urethra absorbs more readily and rapidly than the bladder. The posterior urethra, about as the bladder does. 4. The vagina absorbs very readily ordinary drugs that are injected into it.

Nine Days Asleep.—An experiment which the *Western Reserve Medical Journal* calls interesting, but which we should say was dangerous and uninstructive, was recently conducted in Cleveland by a professional hypnotist. A boy was put to sleep on July 15th and told not to wake up for seven days. About 2 A.M. on the morning of July 18th the boy awaked, however, but was at once put to sleep again by the hypnotist and remained so until the evening of July 25th. He had then slept seven days and gone without food nine days. Two physicians were in charge of the experiment, and watches of eight hours each were assigned to students of the second-year class of the Western Reserve Medical College, so that at no time was the boy alone, and at no time were less than two students present. The experiment, says the *Journal*, was unquestionably scientifically conducted, and is of no little interest to medical men in showing that the hypnotic state may be prolonged at least a week, during which time tissue-change goes on as in natural sleep (Sohn lost some twenty pounds in the week), but the natural sensation of hunger does not seem to awaken the subject.

Aristocratic Doctors.—According to the *Gaulois*, Count de Goyan, a prominent Royalist, and formerly a member of the Chamber of Deputies, has taken the degree of Doctor of Medicine at the Paris Faculty, with the object of giving himself up to the treatment of the sick poor. In this, Count de Goyan has followed the example of the Duc de Rivoli (also a former Deputy), Count de Sinéty (a member of the Jockey Club), and M. Rembielinski (well known in Paris society). All these gentlemen began the study of medicine after the age of thirty, and went through the prescribed course, passing their examinations and taking their degree in the ordinary way. Baron Henri de Rothschild, who is also preparing for the medical profession, entered himself as a student when very young. He has a pronounced taste for surgery, and his present intention is said to be to found a surgical hospital at his own expense.

The New McLane Hospital.—This hospital, which is winning a good deal of reputation for its hospitality, as well as its architectural appointments, held a reception to the officers of kindred institutions, and the physicians of Boston and neighborhood, on October 1st.

Dr. Frank Parsons Norbury, who recently removed to St. Louis to assume the editorial management of the *Medical Fortnightly*, has been elected to the chair of Practice of Medicine and Clinical Medicine in the St. Louis College of Physicians and Surgeons.

Snake-bite Antitoxin.—In British India alone there are each year from eighteen to twenty thousand deaths from snake-bite. Hence the unusual interest of Professor Fraser's recent lecture before the Royal Society of Edinburgh, giving data obtained by him during several years experimental work on an antidote for snake-poison, obtained by following principles similar to those utilized in the antitoxin treatment of diphtheria. The *Popular Science Monthly* states that he first immunized an animal by repeated small doses of the snake-poison, slowly increasing the quantity, until the animal was taking at a single dose many times the minimum lethal amount for a non-immunized individual. Into another animal was then injected some of the blood-serum from the immunized case, and it was found that this prevented any ill effects from a subsequent injection of venom. Still a third animal was given an injection of pure venom; and, when distinct symptoms of poisoning appeared, was treated with the immunizing serum with the result that the symptoms of poisoning disappeared and no ill effects followed.

Therapeutic Use of Extract of Bone-marrow.—In a paper by Dr. John S. Billings, Jr., read before the Johns Hopkins Medical Society, the efficacy of bone-marrow was considered, and its use illustrated by the history of selected cases. The first case of anæmia treated by this agent was reported by Fraser. Results were excellent. Bigger gave an account of a boy suffering from leucocythæmia, who also was treated with bone-marrow. There was rapid diminution in the size of the spleen and marked improvement within a week. In the author's cases, those of chlorosis, were benefited, while the persons suffering from pernicious anæmia were not improved. The conclusion is that the extract of bone-marrow may be of value in cases of ordinary anæmia and chlorosis that would be benefited by iron in other forms. The marrow was given in a glycerine extract. Twelve ribs of sheep were carefully scraped and chopped into small fragments, then rubbed up in a mortar with one pound of glycerine. This was allowed to macerate for three or four days, being kept in a refrigerator during that time. It was then strained through gauze, and the resultant liquid given in teaspoonful doses three times a day.

THE PRACTICE OF MEDICINE IN THE LIGHT OF BACTERIOLOGICAL RESEARCHES.[1]

BY A. ALEXANDER SMITH, M.D.,

NEW YORK.

THE scientific and accurate demonstration of the relationship of micro-organisms to disease is of comparatively recent date. Although prior to 1882 a large number of observations had been published in the attempt to establish the relationship of cause and effect between microbes and disease, the medical profession was slow to accept the conclusions. Koch's researches, published in 1882, marked a long step in advance. His method was the first exact one, and by its aid he was able to discover many new points in the morphology and biology of micro-organisms. His method, an account of which was published at that time (1882), has been very little modified to the present day, and "Koch's law," to the postulates of which a micro-organism must conform before it can be considered the cause of a certain disease, is still the authority. Scientific men had been prepared by the labors of earlier investigators to accept Koch's conclusions. Indeed it is doubtful if, without such earlier investigations, Koch's conclusions would have been so readily accepted. Koch's investigations demonstrated the relationship of a specific micro-organism to disease, first by showing the constant presence of such micro-organism in the tissues or fluids of the individual suffering from such disease; then its absence in all other diseases; then its isolation, growth, and repeated cultivation, and finally its power of reproducing that disease after inoculation in certain animals.

The pioneer worker in modern bacteriology was Colm, professor of botany in Breslau. He had students but no systematic course. Koch was probably the first to give a systematic course; this was given in Berlin in 1880 and 1881, but was not open to all applicants, being under governmental control. The first open courses were given in Munich, by Frobenius, and in Göttingen, by Flügge, in 1883 and 1884. Dr. Welch, now of the Johns Hopkins Hospital, took these courses, and in 1886 and 1887 gave, in the Pathological Institute of the Johns Hopkins Hospital, the first open course in instruction in bacteriology in the United States. This was modelled after Koch's course. In the spring of 1885 Dr. Herman Biggs gave instruction in bacteriology in the Carnegie Laboratory in this city, he having taken instruction in the winter of 1884 and 1885 from Müller, a director in the Dental Institute of the University of Berlin. In the last ten years courses of instruction have been established in many places in Europe and this country, and medical students are given the opportunity for instruction in this important branch of medical study. In this country, recently, laboratories have been established in connection with boards of health, local and State, for the prosecution of bacteriological work.

[1] Being the Address on Medicine delivered before the New York State Medical Association, October 15, 1895.

It may prove not uninteresting to glance at the work of the past.

Leuwenhoeck first observed micro organisms in 1675.

Pleuciz, a contemporary of Leuwenhoeck, was the first to advance the idea that micro organisms are the cause of disease, and that each disease has its specific organism, transmitted through the air. He was unsparingly ridiculed, however.

Müller, in 1773, was the first to make any close study of micro-organisms; he first classified them (yeasts, fungi, etc.).

Davaine, in 1863, first demonstrated the probable relation of a specific organism to a specific disease.

Rindfleisch, in 1866, first demonstrated the presence of micro-organisms in pathological lesions.

Pasteur may be said to have been the first to thoroughly study micro-organisms. He was originally a chemist, but noticing one day that certain solutions of the tartrates, after standing, underwent changes in their polarizing properties, he investigated the subject and thus started on his life's work, the results of which have been so wonderful and valuable. In 1857 he published his investigations of the lactic-acid fermentation, following this up with his work on the diseases of vines, beer, etc. He proved each fermentation to be due to a certain organism, and that if its entrance be prevented fermentation could not take place. While his early work does not come directly into the field of medicine, it influenced it greatly. The process which destroyed grape-vines was a true disease; he considered it as such, and after determining its etiology, pointed out a mode of cure. His later work on anthrax, gangrenous septicæmia, and suppuration, brought him directly into human medicine. The value of his work is inestimable. Our ideas of sterilization are based on his work, and he first succeeded in isolating an organism by means of his method of "successive cultures." Koch's solid media method is simply an advance on the same line. Pasteur first stated that micro-organisms are absolutely essential to life on the globe, that they occupy a middle position between the animal and higher vegetable kingdom, and by decomposing animal matter into its component elements, renders it available as food for the plant world, which in turn supplies the animal world with food and oxygen. In a word, he demonstrated the fallacy of "spontaneous generation."

Lemaire discovered the value of carbolic acid as an antiseptic, and believing suppurations of wounds to be due to germs from the air, he treated such wounds with carbolic acid. This was the first step toward the antiseptic treatment of wounds which Lister worked out to such brilliant results afterward.

Villemin, in 1865, first demonstrated the infectious nature of tuberculosis, by showing that it could be transmitted to animals by inoculation.

In the early half of this century it was enough to say that a disease was due to inflammation of a particular organ or organs, and that such inflammation could be caused by cold, sudden changes, and so on. The contagious and epidemic nature of the various acute diseases was well recognized. Thirty years ago the spread of such diseases was thought to be through the air. Cholera and typhoid fever alone were thought by many to be transmitted by means of drinking-water or food. We now know that transmission through the air plays a very minor rôle, at least in those diseases in which the

micro-organism has been demonstrated. It has been proven that solid particles of matter, such as micro-organisms, do not rise from moist surfaces. Bacteria are mainly diffused by adhesion to the hands, to clothing, etc., or by drying up, when they take the form of dust and are blown about. How easy to demonstrate from this the great value of prophylactic measures. It is comparatively easy to destroy the vitality of micro-organisms in the moist state, as in typhoid-fever stools, for example, and correspondingly difficult where they are all around us in the atmosphere in the form of infected dust.

The changes brought about by our present knowledge of bacteria are more marked in surgery than in internal medicine. The discovery of the organisms of suppuration, of the effects produced upon them by bichloride of mercury, carbolic acid, and other substances, and the demonstration that an operator can go almost anywhere in the body so long as he keeps everything clean and aseptic—these facts have revolutionized surgery and obstetrics. We no longer hear that a wound is "suppurating nicely," but if it does suppurate the surgeon wants to know the reason, whether it is his fault or that of his assistants. There is blame somewhere.

In obstetrics, if proper precautions are taken, the many dangers from sepsis which formerly surrounded the patient have been reduced to the minimum. In internal medicine, on the other hand, there has been no such marked progress. While the discovery of the bacterial nature of certain diseases has been of great value in prophylaxis, and has demonstrated the futility of certain lines of treatment, no material advance has been made in the actual treatment of disease by internal medication. Exception may be made in the case of diphtheria, which will be discussed later. This is chiefly due to the fact that in diseases we do not find the specific organisms localized in limited and accessible areas. Where surfaces are accessible, such as the skin and mucous membranes, and cavities like the pleural and peritoneal cavity, specific local treatment based on the knowledge of the microbe origin of many diseases affecting them, has been of great practical utility. We have not yet found an agent which, if given internally, will surely and rapidly kill the micro-organisms, and not at the same time kill or injure the living tissues of the body. Antiseptic and aseptic methods are, for this reason, only beginning to be employed in internal medicine. The tendency now is to prevention of the spread of the disease by individual prophylaxis. The application of the various methods can only be thoroughly and effectively carried out when the physician understands the reasons for his actions, keeping clearly in mind the objects to be attained. It is the practising physician to whom is intrusted the application of the discoveries and advances made by the laboratory workers; hence the importance of a familiarity with the theories and principles of bacteriology on the part of every physician. The present ideas as to the contagion and diffusion of disease have been extended to other diseases, the precise micro-organism of which we are as yet ignorant of; for example, scarlet fever, measles, small-pox, etc.

The study of the products of micro-organisms, the toxins, antitoxins, bacterio-proteins, toxalbumins, etc., has become most important. In the early bacteriological work it was thought the bacteria themselves were the direct cause of the manifestations of disease. It has now been proven, however, that these manifestations are due to the toxins produced by the bacteria. It is through the study of the action of these substances that our modern ideas of immunity have been evolved. Many observers hold that it is by the artificial production of immunity that we shall be able to combat the infectious diseases in the future. There are three chief ways of producing it in man.

First, by producing a modified form of the disease (vaccination). Over a hundred years have elapsed since Jenner first applied in medicine the principles of immunity against disease, by employing vaccination as a protective means against small-pox. Neither he nor his immediate followers understood the principles of immunity as brought about by vaccination. His first observations, however, have stood the test of time, and clinical facts have only served to strengthen his position. It was reserved for the genius of Pasteur to make a satisfactory scientific demonstration of their truth by his eminently brilliant discoveries concerning the protective power of inoculation in animals and fowls. Pasteur's method of securing immunity depended essentially on submitting the individual or animal to the attack of the disease-producing organism itself in an attenuated form—at least in a form modified in such a way as to lessen its virulence. Soon, however, other methods were devised. These later methods of securing immunity do away with the necessity of any contact whatever between the individual and the bacteria themselves. One of these methods is by the introduction into the system of the bacterial poisons produced by the specific organisms, but without the bacteria.

The third chief method, the latest, is by the introduction into the system of the serum of an animal, which is either naturally or artificially immune to the disease in question. Koch, Chauveau, Buchner, and in later times Behring, Roux, and Kitasato, have done the most important work on this subject.

So far, the treatment of disease by injections of the toxic products or toxins of the specific micro-organisms has not been of marked value. It has been tried in tuberculosis (Koch's tuberculin), typhoid fever, and latterly in cancer, by injection of the toxins of the micro-organism of erysipelas. Serum therapy offers the most promising results, and in view of the wonderful effects of the antitoxin treatment of diphtheria we may look for a similar treatment in typhoid fever, lobar pneumonia, and cerebro spinal meningitis; in fact in all the diseases produced by micro-organisms in which the micro-organisms themselves are the source or the cause of the production of the curative substances.

The very fact that recovery from infectious diseases is spontaneous, suggests that there is in such diseases a power on the part of the blood to produce an agent which is antagonistic to the toxins which have caused the manifestations of the disease; and after the toxins have been neutralized by such antitoxin, the remaining antitoxin affords such immunity as is generally observed. It has long been known that in many of the infectious diseases one who has suffered one attack is usually immune against a subsequent attack.

Let us glance at some of the infectious diseases in detail, and trace the influence bacteriology has produced upon our views concerning them.

In lobar pneumonia early treatment was based upon the idea of its being an inflammation pure and simple. Bleeding and purging were resorted to, counter-irritation in its various forms was thought highly of. The necessity of stimulation was well recognized. Relief, as far as possible, of the main symptoms occupied an important place. The occurrence of pneumonia in so-called epidemic form was recognized by Laënnec.

The discovery of the bacillus of Friedländer in 1883, and that of the "diplococcus pneumoniæ" by Fraenkel in 1886, while modifying and confirming some of the existing views, has had practically very little influence upon the treatment of the disease. Sternberg, in our own country, discovered this micro-organism in the saliva in 1880. Other bacilli than those named have been demonstrated as present in different forms of pneumonia, such as streptococci, staphylococci, tubercle bacilli, and influenza bacilli. The pneumonia due to the diplococcus of Fraenkel is believed to be the one which runs the typical course of a lobar pneumonia, and constitutes about seventy-five per cent. of all cases. Those pneumonias running an irregular course are ex-

plained by the bacteriologist on the ground of the presence and influence of one or more of the other bacteria named. It has been proven, too, that in a pneumonia due to the pneumococcus alone, the prognosis is more favorable than in the irregular forms alluded to. For some years prior to the discovery of these organisms the recognized treatment was an expectant and supporting one, and in the main is so still.

The only attempts that have been made to evolve a line of treatment from our knowledge of the pneumococcus were those of the brothers Klemperer. They believed that the pneumococcus produced an "antipneumotoxin" which, when present in sufficient quantity, put an end to the disease by crisis. They claimed to have isolated this substance, and the first results by its use were promising. Further investigation has not substantiated their claims. While pneumonia is occasionally contagious, it is of such rare occurrence that prophylaxis, even if we knew how to bring it about, would be superfluous. The pneumococcus being a very frequent inhabitant of the mouths of healthy individuals, it seems impossible to make use of any prophylactic measures other than avoidance of constitutional depression of any kind. The frequent association of otitis media, cerebral meningitis, pericarditis, and the occasional occurrence of endocarditis and peritonitis in the course of an attack of pneumonia, was formerly thought to be accidental accompaniments. Their occurrence is now explained by the presence in the exudate of the pneumococcus of one or more of the other organisms named.

The cholera spirillum, discovered by Koch in 1884, is generally admitted to be the specific organism present in the production of cholera. Our knowledge of this fact has had little effect on the actual treatment of the disease, unless the large tannin and water injections be considered an outcome of this knowledge. It was found by experiment that tannin was to a certain extent antagonistic to the virulence of the cholera spirillum. Because of this fact and its known astringent effects it was suggested in the treatment of cholera.

The discovery of the specific organism has been of the greatest value in preventing the spread of the disease.

It is also possible to determine, by means of the proper bacteriological methods, at the beginning of an epidemic of some diarrhœal disease, whether it is true cholera or not. In quarantine work this method of diagnosis is especially valuable, and leads at once to the use of proper precautions to prevent the spread of the disease. Work is now being done in Germany upon a cholera antitoxin, but the reports so far published are insufficient to warrant our forming any conclusion as to its value.

Tuberculosis has been one of the most thoroughly studied of diseases, and was generally ascribed to a micro-organism before Koch, in 1882, reported his discovery of the tubercle bacillus. The climatic and dietetic treatment of tuberculosis cannot be said to have been advanced by this discovery. On the other hand, in diagnosis, prognosis, and prevention of the spread of the disease, it has been of the utmost service. The demonstration of the presence of the bacillus in the sputum, the stools, the urine, the secretions from sinuses —indeed its presence in many situations—have often made definite a suspected diagnosis. It has shown that at least many of the so-called scrofulous conditions are tuberculous. While the communicability of tuberculosis was recognized long before 1882 by clinical observation, the discovery of the bacillus and subsequent researches served to emphasize the fact that tuberculosis must be placed among the infectious communicable diseases, and that communicability must be recognized under certain conditions. Since the discovery of the bacillus the modes of infection by it have been more definitely demonstrated. Our views of heredity in regard to tuberculosis have been greatly modified. The disease was formerly thought to be directly transmitted from parent to child. Now it is believed to be transmitted very rarely, and that only by the mother. Heredity does play an important rôle in many cases, in that it transmits a soil ready for the reception, growth, and development of the specific germ when this is implanted.

The importance of infection by inhalation was recognized early after the discovery of the bacillus. It led quickly to the thorough sterilization of the moist sputum. The sputum is found to contain the virus in large quantity, and when dried takes the form of dust and disseminates everywhere. It has been demonstrated that the dust of rooms and wards of hospitals which have been occupied by tuberculous patients is in many instances infective. Any condition under which the dust infected with tuberculous virus can be inhaled may be the means of infection. The importance of this fact cannot be too highly emphasized in the direction of the prevention of the spread of the disease. Direct intimate contact may communicate the disease. It may be communicated by inoculation, but it then usually remains localized. Milk may be the means of infection. We are all constantly exposed to the infection from the presence of millions of the micro-organisms in the air we breathe at times. Some of us escape because of the fortunate lack of vulnerability of our tissues. All possible means should be resorted to for the prevention of infection. Koch's tuberculin has been a disappointment. It still, however, retains the confidence of a few observers in a modified form, but is now mainly used in the diagnosis of tuberculosis in cattle.

It is generally believed that the bacillus discovered by Eberth in 1880 is the cause of typhoid fever. Based upon this discovery efforts have been made to introduce methods of treatment directed toward the destruction of the bacilli or their toxic productions, but without definite success. It is only in prophylaxis and in the prevention of the spread of the disease that this discovery has had any great effect upon internal medicine. It has confirmed the belief, held by many before its discovery, that milk and water and food are the chief modes of infection. In many instances the bacteriologist has been able to definitely trace the source of an epidemic of typhoid fever by discovering the bacillus in the water-supply. The typhoid bacillus has wonderful vitality. The bacteriologist has demonstrated that it is capable of withstanding for a brief period a dry temperature of 194° F., but if exposed to a moist heat at a temperature of 140° F. for twenty minutes its vitality is destroyed. Enclosed in a block of ice at a temperature considerably below freezing-point, it maintains its vitality for months, but if the water in which it is contained be alternately frozen and thawed five times a day its vitality is destroyed in three days. I only name these among the many points illustrating its vitality.

The Germans have lately tried treating typhoid with sterilized cultures of the typhoid bacillus grown in thymus bouillon. The results at first were promising, but subsequent trials have been far from satisfactory.

Tetanus was first shown to be infectious and the bacillus isolated in 1884. Soon after Nicolaier demonstrated the presence of the same bacillus in various kinds of soil, and inoculation of animals with the soil containing these bacilli produced tetanus.

It is interesting to note the extraordinary virulence of tetanus toxin, it being from two hundred to four hundred times as virulent as strychnine. Immunity to tetanus has been procured by inoculating an animal with the blood-serum of another which has had the disease. An antitoxin prepared from the blood-serum of immunized animals has been used and reported as successful. The testimony in regard to the results is conflicting and the treatment by this method is still on trial. Perhaps with improved methods of preparation

of the antitoxin, and a better knowledge of the quantity required in any given case, better results may be obtained.

The greatest influence exerted over internal medicine by bacteriology has been in connection with diphtheria. The profession has been slow in accepting the view that the bacillus discovered by Löffler in 1884 is the cause of diphtheria, and there are still many who disbelieve it. The prevailing opinion now is, however, that this bacillus is the cause of true diphtheria. The first effect of the discovery was the abolition of certain useless lines of treatment, and the recommendation of others. Constitutional and local treatment were not displaced by this discovery, nor are they now. The greatest change in treatment brought about by the discovery at first was the more persistent and intelligent use of local treatment. The next step was the recognition of bacteriological methods and results in diagnosis, many believing the presence of the Löffler bacillus the only positive criterion of diagnosis. Diphtheria had long been recognized as highly contagious. The discovery of the specific organism but served to emphasize that fact. It is now possible to find out how long the micro-organisms remain in the throat and nasal passages after the patient is apparently cured, and how long it is necessary to resort to quarantine.

One very important feature has been the demonstration that many of the milder forms of inflammation of the mucous membrane of the throat and nasal passages are diphtheria and are capable of communicating the disease. It has recently been shown that this bacillus is not infrequently found on the mucous membranes of the throat and nasal passages of persons otherwise apparently well. This is true, too, of other bacilli in this and other situations. The mere presence of a bacillus of any kind is not sufficient to account for the manifestations of the disease of which such bacillus is the specific cause. Some additional factor seems necessary. Some agency causing such bacillus to show its pathogenic activity.

As to the final and greatest steps in advance, the results of the researches of Löffler, Behring, Aronson, Roux, and others, "the antitoxin treatment of diphtheria," it has been the foremost subject in the medical world the past year. It has had, and still has, its opponents, some claiming the serum acts harmfully on the kidneys, others, that it causes destruction of the blood-corpuscles, enfeebles the heart's action, and favors the occurrence of paralysis. All these objections have been met and contradicted. Even admitting there are possibilities of occasional deleterious effects, the wonderful beneficial results many times outweigh the possible harm.

The first publication demonstrating the principles of serum therapy were made in 1890. In the autumn of 1891, the first trial of serum-therapy in human diphtheria was made. The first attempts were with a weak serum and insufficient doses. From time to time articles on the subject appeared up to August, 1894, when the serum prepared at Höcht was placed on sale.

Roux's address at Budapest, in September, 1894, aroused the attention of the whole medical world to the possibilities of the serum-therapy of diphtheria. During the past year it is estimated that 100,000 injections will fall far below the number. It needs no argument now to establish its value. The testimony is overwhelmingly in its favor as a curative agent. From all sources in Europe and this country comes the clinical evidence of its power. It has reduced the mortality enormously. Not only have its wonderful effects been shown on the disease when established, but its power of securing immunity to those who have been exposed to the contagion is marked.

The results of serum therapy in diphtheria being so favorable, the field for work of like character in connection with other infectious diseases is almost without limit. The outlook for the future is most promising. Bacteriological researches of a most important kind have been made in connection with veterinary medicine. Of interest to us as physicians is particularly the work in connection with such diseases as can be communicated to man. I need only mention them here. Hydrophobia, anthrax, actinomycosis, glanders, and we may include tuberculosis in this group. To name hydrophobia without associating with it Pasteur's name would be a neglect of recognition of eminent scientific work. It was his investigations in connection with this disease which may be said to have led up, in part at least, to the study of immunity by means of serum-therapy.

Bacteriological researches have made clear many points in the etiology of diseases which before were obscure. It offers a satisfactory scientific explanation of the communicability of certain diseases. It has made diagnosis more definite, and in some instances aided in diagnosis which was impossible by any other method. It has led to more accurate prognosis. It has explained complications which before were considered accidental occurrences. It has revolutionized surgical and obstetrical practice. It has made it possible by intelligent sanitary surveillance to restrict and prevent the spread of dangerous epidemics. It has led up to the specific treatment of diphtheria (and possibly tetanus), and to conferring immunity for a longer or shorter period to those exposed to it.

A recognition of these conclusions brings the bacteriologist and clinician into most intimate relationship, each one as a necessary aid to the work of the other. The results of the work of the laboratory must be confirmed by the careful, conservative tests of the clinician. By their combined work only can the results of laboratory investigations be made of wide-spread practical benefit.

An Epidemic of Toothache.—One of the most curious features of the Chitral campaign is the extraordinary prevalence of toothache—"the hell o' a' diseases" Burns calls it—among the officers. The matter is receiving the serious attention of the medical authorities, and it is hoped that some very interesting statistical results will be gained from the careful investigation which is now taking place. The epidemic first made its appearance after the active operations were over, and the various regiments had received orders to stand fast for the summer, and reached its most violent form just before the long-expected order to partially evacuate the country had arrived. An epidemic of toothache is something unusual.

Knives should never be placed in carbolic lotion, for even a diluted solution of the acid quickly impairs their edges.

Reform Needed in German Insane Asylums.—That a thorough reform of the German system of dealing with the insane and with those wrongfully charged with being insane is needed admits now of no doubt. Since the sensational Forbes case, which proved the convent asylum at Mariaberg, in the Rhine district, a veritable torture-chamber worthy of the dark ages, a number of similar discoveries have been made in other institutions, such as the one in Bremen, and one in Dortmund. With that quite a string of individual cases have been brought into daylight, of persons wholly sane, yet detained for years, at the instigation of powerful enemies or greedy relatives, in private or public institutions for the insane. Just at present the National Association of Physicians for the Insane is holding a conclave in Hamburg, the principal theme of their discussions being "Reform of Insane Practice." Under existing laws and methods nobody is safe from the danger of being, at a moment's notice and without any formality, torn from his home and confined in some mad-house.

TENDON GRAFTING.

A New Operation for Deformities Following Infantile Paralysis, with Report of a Successful Case.[1]

By SAMUEL MILLIKEN, M.D.,

NEW YORK.

SURGEON-IN-CHIEF OF THE NEW YORK INFIRMARY FOR CRIPPLED CHILDREN; SURGEON TO THE INFANTS' AND CHILDREN'S HOSPITALS, RANDALL'S ISLAND.

Believing this to be the first case reported where a healthy muscle has been made to do the work of one which was completely paralyzed without in any way interfering with its own function, the following details are presented, as the success of the operation speaks for itself. It is a well-known fact that cases of anterior poliomyelitis, where the muscles of the lower extremities are paralyzed during early childhood, offer little encouragement from electrical treatment beyond the development of certain muscular fibres which escaped apparently recovered so far as the disposition to take nourishment was concerned, it was noticed that the right leg was almost powerless, so much so that the child could not walk. The case was subsequently treated by massage and electricity, and at the age of two years a brace was applied which enabled him to walk.

Examination.—When I first saw the case, on removing the brace with the patient sitting on a chair, it was easily seen that the trouble was with the anterior tibial group of muscles, as the right foot dropped into the position of equinus. On attempting to voluntarily flex the foot on the leg, all the toes were seen to respond, but the whole foot was forced into extreme valgus. This led me to conclude that it was the innermost muscle of the group, viz., the tibialis anticus, which was mostly, if not solely, involved; this muscle, from its prominent position in a healthy condition antagonizes not only the peroneal group, but the tibialis posticus as well. Owing to the paralysis of the tibialis anticus the power of flexing the foot on the ankle was limited to the three remaining muscles of the group, viz.: the extensor proprius pollicis, the extensor longus digitorum, and the peroneus tertius, which, from their distal attachment, were of little use in this direction; while, on

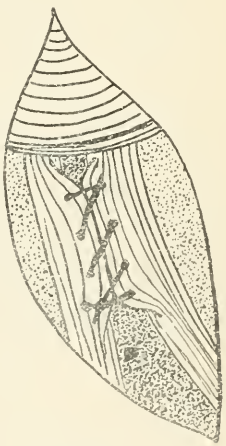

Fig. 3.—Showing Sheath of the Tendons United with Continuous Suture.

the inflammatory process; while the mechanical appliances are only employed with the hope of aiding the victim in locomotion and preventing deformities, such as tendinous and muscular contractions and bony displacements. The neurologist and orthopedic surgeon have learned long ago that, combined with the above conservative measures, so far as offering a cure, it was folly to even anticipate it; thus thousands of cases of infantile paralysis are doomed to the wearing of braces all their lives.

The delay of most two years in reporting this case was for the purpose of allowing sufficient time to elapse without the use of the brace that I might be sure the deformity was permanently relieved.

Joseph H——, nine years of age, came under my observation in December, 1893, and at that time was wearing the ordinary club-foot brace on the right side. The previous history given was that of the ordinary cases of infantile paralysis. When about eighteen months of age, and quite healthy, the child was attacked with fever, which was sufficiently severe as to cause him to be put to bed and the family physician called in. The attack was of only a few days' duration, and although the other hand, in the absence of such an important antagonist it is easy to account for the extreme valgus into which the foot was forced. In addition to the above deformity there was a marked "hammer toe," due to the over-exertion of the extensor proprius pollicis. An electrical examination only verified the above, and as the anterior tibial nerve supplied all four muscles, it was decided to take part of the extensor proprius pollicis tendon and graft it into the tendon of the tibialis anticus, which was paralyzed.

Operation.—On February 14, 1894, under ether anæsthesia, an incision one and a half inch long was made, extending from just below the annular ligament obliquely over the tendons of the extensor proprius pollicis and tibialis anticus. (See Fig. 1.) The sheath of each tendon was carefully opened for a distance of about one inch. The tendons were then split with a small Adams fascia knife, and an inch flap taken off of each. The flap from the tibialis anticus, of course, being left attached to the distal, while that from the extensor of the great toe was attached at its proximal or muscular end.

Before incising the tendon of the extensor of the great toe, it was pulled down by means of a blunt hook, so that a flap could be gotten as high up as possible.

[1] Read at the meeting of the New York State Medical Association, October 15, 1895.

This was done for two reasons: 1st, so as to relax the tendon, thus relieving the "hammer toe," and 2d, so as to insure the action of the extensor proprius pollicis on its new insertion if union was obtained. The cut surfaces of the flaps were adjusted and sutured with three fine kangaroo tendons interruptedly (Fig. 2). The outer flap of the sheath of the extensor proprius pollicis was then sewn to the inner flap of the sheath of the tibialis anticus (Fig. 3), with a continuous suture, so as to prevent the newly united tendons becoming adherent to the overlying structures, thus making a new sheath which would not interfere with the action of the muscle, which was to do its own work and that of the one which was paralyzed. The skin was closed with fine interrupted catgut-sutures, and dressed aseptically.

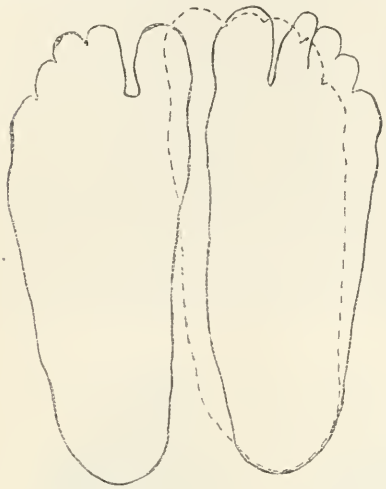

Fig. 4.—Showing Adduction of Right Foot following Operation.

Fig. 5.—Showing Voluntary Flexion of Right Foot following Operation.

The foot was immobilized with a plaster-of-Paris splint, the deformity having been previously corrected by manual force. The case progressed uninterruptedly, and it was dressed for the first time on the tenth day, a window being made over the wound in the plaster for that purpose. The catgut sutures had been absorbed, but the skin had not united primarily, as I had hoped it would; however there was no pus, nor had there been as much as one degree elevation of temperature since the operation. The non-union was caused by the pressure of the plaster-of-Paris splint which had been put on rather snugly. Under balsam-of-Peru dressing the skin wound healed in ten days. Every day for three weeks after the operation gentle passive motion of the great toe was made, so as to prevent the tendon becoming adherent to its sheath. The foot was kept in a plaster-of-Paris splint for six weeks, when a very light brace with a limited joint at the ankle was applied. The immediate improvement in the case was even noticed by the parents, as the foot no longer became abducted when an attempt was made to raise it, such having always resulted before the operation was performed. It is now five months since the brace was left off altogether, and although there has never been any electricity or massage employed, the boy has been encouraged to take all the exercise possible. He is now quite an expert on roller-skates, walks without a limp, and can adduct the foot to almost normal (Fig. 4). There is still a slight "hammer toe" on extreme flexion of the foot, but nothing as compared to the condition before operation (Fig. 5), while flexion of this foot on the leg is almost as good as the unaffected side (Fig. 6).

Fig. 6.—Showing Voluntary Flexion of Left or Normal Foot.

My other work in this line is so recent as to prevent further report of cases at present, but I think with this excellent result the field has been opened for tendon grafting in these otherwise hopeless cases of infantile paralysis.

640 Madison Avenue.

Vacancies in the Medical Corps of the Army.—Despite the fact that the last Congress reduced the number of officers in the medical department of the army, it is reported that the corps is already nearly down to the new limit. With two retirements recommended some time ago, and that of another officer which occurs in less than ten days, and a fourth in December, the corps will then be three below the maximum. Accordingly an examination for the vacancies will be held during the next few months.

Prince Edward of York, who may some day be the king of England, was reported to be deaf and dumb. This story is, however, denied "authoritatively" by *The Lancet*, which says that "he is in every respect a fine child, that he displays remarkable intelligence for his age, and that he can already repeat a number of words." Our esteemed contemporary thinks the Americans, to whom it credits the origin of the report, are very unreasonable to expect a child, even the great grandson of a queen, to be able to converse fluently in several languages during the first year of its existence.

OBSERVATIONS ON PELVIC CONTRACTIONS.[1]

By AUSTIN FLINT, Jr., M.D.,

NEW YORK.

CONTRACTIONS of the pelvis in which the deformity is marked occur but rarely and are always easy to recognize. Contractions of a minor degree, however, occur very frequently, and the diagnosis is often very difficult. To prove that this is true, I have analyzed six thousand cases of confinement with reference particularly to the diagnosis, the frequency with which contractions occur, and, if possible, to draw some general conclusions in regard to prognosis and treatment.

The influence which even a moderate degree of contraction has upon labor is not entirely mechanical. So many other conditions must be taken into account, such as the size and compressibility of the fœtal head, a faulty presentation or position, or a prolapse of the cord, due often to the existence of contraction, that rules for treatment cannot be based on measurements alone. A pelvis with certain diameters may in one case permit the spontaneous delivery of a well-developed child, and a pelvis with the same diameters may in another case demand operative interference, often of a serious nature. Such examples are frequently met with and are difficult to explain. I have, therefore, not attempted to fix upon any exact measurements under which all pelves are strongly contracted, and over which all pelves are moderately contracted, but shall take all cases together, remembering, however, that the vast majority belong to the latter class. In the first place, I may define what I have called "contraction," explaining at the same time the methods of diagnosis.

As it is rare, if not impossible, to find two pelves with the same diameters throughout, some standard must be fixed separating the normal from the abnormal. In describing the size of a pelvis, we speak of the distance between the spines and crests of the ilia, the external conjugate diameter, which is measured from the fossa beneath the spine of the last lumbar vertebra to the middle of the upper border of the symphysis in front. The diagonal conjugate diameter extends from the lower border of the symphysis to the promontory of the sacrum. The true, or obstetrical conjugate, is the distance between the promontory and a point on the inner surface of the pubis just below its upper border. All of these diameters can be measured accurately, with the exception of the last, which must be calculated from the diagonal conjugate. I have not considered as contracted, pelves in which the distances between the spines and crests of the ilia alone were diminished. In all cases in which these measurements were very much below the normal standard, the other diameters were also diminished. When the normal proportion was disturbed, that is, when the distance between the spines was as great as, or greater than, the distance between the crests, a diagnosis of rachitis was made, and in these cases the other measurements were usually found to be abnormal. This leaves but two diameters which must be measured—the external and the diagonal conjugates. The true conjugate is the more important, and is the one which is designated in defining the degree of contraction. The method of determining the true conjugate is to subtract from the diagonal two-thirds to three-fourths of an inch, or, in my experience, even more, this depending on an estimate of the height and inclination of the symphysis and the position of the promontory. The personal equation—the individual skill and experience of the examiner—enters so largely into the determination of this diameter, where a difference of even one-fourth of an inch is of the utmost importance, that it seemed to me safer, in collecting cases, to rely on the diagonal and external measurements, which can be determined exactly.

We owe much of our knowledge of pelvic deformities to the investigations of Litzmann; and I have followed as nearly as possible the limits as defined by him. The same limits have been adopted by all the German observers whose reports I have been able to examine or have seen quoted. Litzmann places in the class of contracted pelvis all cases in which the external conjugate measures 18 c.m. or less, or 7.2 inches. I have taken only pelves with an external conjugate of 7 inches or less. For the true conjugate, he places the limit at 9½ c.m., or 3.8 inches. I have adopted a diagonal conjugate of 4½ inches or less, which, reduced to the true conjugate, would make 3⅝ inches for the largest by the subtraction of only ⅞ of an inch.

The statistics which I have to present will be better understood if I first explain briefly certain details of the manner in which they were obtained. The records are from the written histories of six thousand consecutive cases of confinement, cared for by the Society of the Lying-in Hospital of the City of New York.

A woman applying for care during confinement is first subjected to a thorough physical examination, including careful pelvic mensuration. At this time the history of previous confinements, an examination of the urine, and other minor details are inquired into and recorded on a blank which is called a Pregnancy Sheet. This is numbered and filed away until the onset of labor, when it is taken out, brought to the case, and is finally bound with the record of the labor and puerperium, making a complete history of that individual case. If, at the time this "ante-partum examination" is made, there exists any abnormality, it is first verified by one of the resident staff, or the attending physician on duty, and a special "abnormality blank" is filled out and filed, thus guarding as far as possible against error.

A consideration of the class of patients from which these observations have been obtained is of interest. Comparing ordinary hospital statistics with statistics obtained from private practice, it is natural, and usually correct, to assume that complicated and difficult cases come to the hospitals; and therefore, abnormalities, including contractions, occur more frequently in institutions. In my statistics, however, the patients are all "out-door cases" of the poorer class, attended in their own homes, and thus fulfil more exactly the conditions met with in ordinary private practice. In other words, they represent, as nearly as is possible, the actual average condition. It is only recently, since the figures here presented have been analyzed, that an in-door service has been added to the hospital.

I have looked over the pregnancy sheets of these 6,000 cases and noted the confinement number of each one in which the external conjugate measured 7 inches or less, and the diagonal conjugate 4½ inches or less. Contractions were noted in 654 of the 6,000 cases, or in 10.9 per cent.

In round numbers, the frequency of contractions in Germany is said to be fourteen per cent. The report from Leopold's clinic for 1895 gives 610 cases out of a total of 2,512, or 24.3 per cent., nearly one-quarter of all cases. This is the largest proportion in any report that I have seen. Schwarz, in Göttengen, reports twenty per cent.; Spiegelberg, fourteen per cent., and sixteen per cent. is reported by Müller from the clinic at Berne. As, however, the Lying-in Hospital in New York is often called upon to treat premature cases and abortions, which are entered in the history numbers among these 6,000 cases, it would be more exact, in computing the frequency, to disregard them. Subtracting 347—the number of abortions and premature cases—from the total, the percentage of contractions would be raised to 11.56, which is nearer the conservative estimate of Litzmann and Schroeder. In 563 of these 654 cases of contraction, or in 86.08 per cent., the

[1] Read before the New York State Medical Association, October 16, 1895.

presentation was a vertex, and the delivery was without operative interference. A study of these spontaneous deliveries shows that in all cases the contraction was slight, a true conjugate of 3½ inches or more, but 3 cases of 3¼, and 1 of 3⅛ being noted. A certain proportion had a protracted first stage, in some cases as long as twenty-four hours. Frequently I would find it recorded that the head was delivered in the right occipital position; but in one or two cases only was the occiput posterior. I have not attempted to obtain exact figures on the frequency of right positions, for the reason that I have doubts about the accuracy of diagnosis. Many of these were undoubtedly occipito-posterior positions at the beginning of labor, and rotated anteriorly before delivery. Some of the cases of protracted first stage were undoubtedly due to a slow forward rotation of a posterior occiput. The percentage of spontaneous deliveries reported from Leopold's clinic was 69.5.

It is well known that the size of the pelvis is not the only factor that must be considered, but that the diameters of the child's head are of equal importance. I had hoped to be able to report some definite conclusions in regard to this point also, but regret that, although the measurements of the head are in every case taken, as well as the weight and length of the child, a comparison of the figures gave no definite results. In some instances, when the labor was protracted and difficult, the head measurements were found to be large and the weight of the child above the average; but in other cases the reverse was true.

In the remaining cases in which interference became necessary, 101 operations were done as follows: Forceps, 43; version, 29; breech extraction, 18; symphyseotomy, 5; craniotomy, 2; Cæsarean section, 1; decapitation, 1; induced labor, 1; conversion of brow to vertex, 1.

In some instances more than one operation was done on a single case, as, for example, symphysiotomy followed by version, so that the number of operations is greater than the number of cases—101 operations on 91 cases. A study of the results of these operations is interesting as regards the effect on the child. In the 43 forceps operations, 6 children were stillborn, and of the 37 born alive, 1 died in a few hours, 2 on the second day, and 2 on the fourth day. The remaining 32 were alive and apparently healthy when discharged from observation, usually about the tenth day. This is an infant mortality in forceps cases of 25⅝ per cent. It must be remembered, however, that forceps were applied to only the more difficult cases. A patient is reported as not progressing satisfactorily, and a call for assistance is sent back to the hospital. The case is then visited by one of the staff, and finally the attending physician is summoned. The result of this routine is that practically only those cases were delivered by forceps which could not have been delivered without aid, and some of them were exceedingly difficult.

Of the 29 versions which were done, the operation was undertaken in only 9 cases by reason of the pelvic deformity alone. The remaining 20 cases were complicated: 7 times by a prolapse of the cord; 5 times by a previous symphyseotomy; 4 times by a placenta prævia, or "hemorrhage;" twice by traverse presentations; and once each by a prolapsed arm and a face presentation. Of the entire 29 cases only 3 children were stillborn. One child died on the second day. What is remarkable, none of the stillbirths occurred in complicated cases. In the version cases the total infant mortality was 13⅜ per cent. As regards the other operations mentioned, all were done in strongly contracted pelves, with the exception of the 18 cases of breech extraction. An analysis of these operations would necessitate a detailed history of each case, which would be beyond the scope of this paper.

The general results in the 654 cases of contraction observed, are as follows: One maternal death; a case of placenta prævia, almost exsanguinated when seen, dying from shock four hours after delivery. Twins occurred nine times, making a total of 663 children. Of these 31 were stillborn. In only 4 cases was I unable to find a cause for death; 4 were premature; 4 macerated; 2 craniotomy cases, and, of course, dead before operating; 3 died from hemorrhage from a placenta prævia; 2 deaths were due to a prolapse of the cord; 1 child was hydrocephalic; 1 was decapitated; 1 during a breech extraction; and, finally, the 6 forceps and 3 version cases mentioned before, leaving 4 deaths unexplained. Including the 5 deaths subsequent to a forceps delivery and the 1 following a version, the total infant mortality is 37 out of 663, or 5.58 per cent., an exceedingly small proportion when we consider that all were in cases of contracted pelvis, and some of them operative cases, as difficult and under as unfavorable surroundings as could well be imagined.

The most important conclusion that can be drawn from these observations is in regard to the frequency of contraction. Using the standard of measurements adopted in the German hospital reports, contractions occur here with nearly the same frequency—ten or eleven per cent. here, as against fourteen per cent. abroad. To determine the average frequency, it is necessary to collect a large number of cases. In making up the figures which I have reported, the cases were taken in groups of one hundred each. In three different series of a hundred, but one case of contraction was noted; while in one series of a hundred, twenty cases were noted. Observations on only 100 cases, therefore, might in one instance show a frequency of one per cent.; and in another 100, a frequency of twenty per cent. Grouping the cases in series of 500, the smallest number in a series was 9 and the largest number 83, a very wide variation. In groups of 1,000 cases, the variation was from 53 to 137. In three groups of 2,000 cases each, the frequency was respectively 154, 249, and 251.

Diagnosis of contraction is possible only by careful actual measurements. A pelvimeter should form part of the obstetrical outfit of every practitioner. Pelvic mensuration should be employed as a routine practice in every case of confinement. Referring once more to the frequency, it will be observed that the number of cases progressively increases, showing that with practice and increased skill slight degrees of contraction may be recognized which are ordinarily overlooked. In the last two groups of 2,000 cases each, the variation is only 2, viz.: 249 for the first group, and 251 for the second. The diagnostic value of a shortened external conjugate is questionable. I have included such cases in my statistics, for the reason that they are included in other statistics with which I desired to make comparisons. An external conjugate of seven inches or less may be said to render the existence of a true contraction extremely probable. If the pelvic bones are slight, the external conjugate may be seven inches or even slightly less and still there be no actual flattening.

It has been shown that the majority of cases of contraction are spontaneously delivered, and the results are good for both mother and child. When there is only a slight degree, a true conjugate of three and a half inches or more, the treatment which gives the best results is expectant and non-operative; aid the natural forces; keep the bladder and rectum empty; stimulate pains; support the strength of the patient, and, when considering operative interference, be guided by other conditions. The obstetrician knowing the pelvic diameters, the presentation and position being normal and the pains good, who treats his patient expectantly, will have better results than one who operates simply because labor is delayed.

In pelves with a true conjugate of less than three and a half inches, operative interference usually is imperative. Only four such cases were spontaneously

delivered. The nature of the operation depends both on the degree of contraction and the size of the child's head. Just under three and a half inches, either forceps may be used or version done. The infant mortality in the use of forceps was a little more than twenty-five per cent., and in version a little more than thirteen per cent. This seems to show that version is the better operation; but a larger number of observations may demonstrate the reverse. Pelves in which the true conjugate is much less than three and a half inches call for more severe operations, and each case must be treated according to its individual requirements. At present the indeterminate factor is the size of the child's head. It is to be hoped that the instrument recently invented by Farabeuf for measuring the size of the head will prove of value. Should this be so, one of the main difficulties in treatment, namely, the necessity and choice of operations, will be at least partially removed, and a plan of procedure based on ascertained mechanical conditions alone, will become practicable.

SOME FRACTURES AND EPIPHYSEAL SEPARATIONS OF THE UPPER EXTREMITIES IN CHILDREN.[1]

By JOHN F. ERDMANN, M.D.,

NEW YORK.

Mr. President and Gentlemen: In considering the subject of fractures of the upper extremities of children it is not the intention of the writer to enter into the classification of fractures, so well understood already, but to present instead some cases with their means of diagnosis and treatment.

Considerable has been written upon simple fractures in children, but comparatively little upon the subject of epiphyseal separations. It is this latter subject that will be largely dealt with, particularly those occurring at the shoulder, elbow, and wrist joints. Although fractures in children are usually considered green-stick, or incomplete, the individual work of the writer in this class of cases, both on the living subject and the cadaver, leads him to believe that the majority of these cases are complete fractures with no displacement. This is due to the dense periosteum found in the young acting to a great extent as a fibrous splint.

During the past summer the long bones were fractured in all situations with varying force, and upon dissection in the majority of cases it was found that the fractures were complete, but held firmly by the periosteum that remained intact, while in a few cases only there were a few bony bands of connection between the two fragments.

Owing to the greater elasticity of bones in children due to the vascularity and less compactness, the bones are able to withstand a greater relative amount of violence, without sustaining fractures, than those of adults, in whom the bone is more compact, less vascular, and supported by a thinner layer of periosteum.

Causes.—In the greater number of cases reported in this paper the injury was the result of a fall from a low chair or out of bed. The well and ill nourished, suffered about equally. In several instances it was found that one of the patients had suffered from one or more fractures. The season of the year has no relative influence in these cases. Age is a predisposing factor only when considering the diagnosis of epiphyseal separations. As a predisposing factor we are well aware that the epiphyses can be separated from the diaphyses by trauma and disease up to eighteen or twenty years.

[1] Read before the New York State Medical Association, October 17, 1895.

Anatomy.—The upper epiphysis of the humerus unites with the shaft at about the eighteenth or twentieth year, and consists of the tuberosities and the head. The line of epiphyseal union corresponds internally with the lower margin of the articular surface of the humeral head. The lower epiphysis unites with the shaft about the sixteenth or eighteenth year, and the line of union is such that most separations take place backward. In the lower end of the radius and ulna the epiphyseal union takes place about the twentieth year.

Fractures of the Clavicle.—There are four cases of fracture of this bone to report, two of which were seen some ten days after the injury, with a history of a fall, slight pain over the clavicle upon manipulation, and inability on the part of the patients to use the arm as usual. Also that immediately after the injury was received nothing diagnostic of fracture of the clavicle was to be observed. After the eighth or tenth day either a mass or overriding of the fragments was found. Two of these cases were seen shortly after the injury, *i.e.*, within a few hours to a couple of days; in these latter cases nothing was found except the sensitiveness or pain at or near the seat of the injury, and upon asking the child to take some object held upward and outward from the shoulder, but feeble attempts would be made. With the history of the first two cases a diagnosis was made of fracture of the clavicle and so treated. Upon the patient's return in each of the latter cases, in the second week following the injury, a nodule of callus was found over the original site of pain, thus verifying the diagnosis.

In the cases of deformity reduction was followed by the application of a bandage to retain the fragments in proper position. In cases where no deformity was present, the bandage was placed upon the patient to prevent the laceration of the periosteal splint and making a complete fracture in case a few bony bands remained intact at the time of the injury. The dressings were removed in three weeks, in each case, at the latest, and upon examination, firm union and good results were found.

Case I.—A. G——, three years of age, girl, was knocked down four or six steps by the slamming of a door, on September 2, 1894; complained to her parents of pain, especially so when she made efforts that required abduction and extension of the arm. She was treated for a sprain for several days. Examination revealed a slight deformity over the junction of the outer and middle thirds of the right clavicle, with considerable pain upon pressure and no ecchymosis. Diagnosis: Fracture of the clavicle. Treatment: A flannel bandage to retain the reduced fragments.

Discharged with excellent results on September 28th. I am indebted to Dr. W. H. Guilfoy for this case.

Case II.—M. Van W——, aged three, girl; fell from an ordinary chair on August 28, 1894, striking directly upon her right shoulder. She was seen September 8th, twelve days after the injury, having been treated during these twelve days for a dislocation of the sternal end of the clavicle.

For the first ten days she gave evidence of pain, as in Case I., and on the night of the 11th a prominence was noted by her parents and the family physician. Examination revealed an overriding at the inner and middle thirds of the clavicle, pain and ecchymosis.

This case was treated exactly as Case I., and was discharged in twenty-one days, with a slight prominence that was supposed, from its shape, to be callus.

Case III.—A. K——, aged five and one-half, on May 17, 1895, was knocked down, falling on her right shoulder. For three days she complained of pain near her right shoulder, especially while being disrobed or lifted into bed. Her mother also noticed that she reached very gingerly for her food.

She was seen on May 20th, three days after the injury. Upon examination no deformity was present, but pain upon pressure over the clavicle, and also upon abducting and extending the arm, was found. Having the histories of Cases I. and II. in mind, diagnosis of fracture of the clavicle was made. Treatment, same as the previous cases. June 3d, or fourteen days after seeing her, there was an ovoid mass at the original site of pain, that was diagnosticated as provisional callus. This mass disappeared within three weeks.

Case IV.—M. W——, two years of age, fell out of bed June 29th; could not use her left arm in play, owing to pain near her left shoulder. Examination revealed only pain upon pressure over the outer and middle thirds of the clavicle, and also pain at this point when she made an effort to grasp anything held above her head. Diagnosis: Fracture of the left clavicle. Treatment: The same as in the preceding cases.

July 15th.—Small mass near the original site of pain, and on August 12th discharged, cured.

Throughout the remainder of this paper only epiphyseal separation of the upper and lower ends of the humerus, fractures of the lower end of the humerus, and epiphyseal separation of the radius and ulna in their lower extremities will be considered.

Epiphyseal separation of the upper extremity of the humerus does not occur later than the twentieth year, owing to the union of the epiphysis with the shaft about this period of life. The average age in these cases, according to Tubby, in "Guy's Hospital Reports of 1889," is eleven years. Causes of separation of the epiphysis are a fall from a height, or a glancing blow from above downward upon the shoulder, or disease of the epiphysis.

Anatomy.—As previously stated the epiphysis of the humerus consists of the articular surface of the bone with the two tuberosities; as a result of its separation, owing to the attachment of the capsular ligament to the anatomical neck of the bone, we have the joint involved at its inner aspect. The capsular ligament is attached to the shaft by fibrous expansions at the internal aspect of the head of the bone, and blends with the periosteum throughout the circumference of the shaft. By this blending there is formed a strong resisting fibrous tissue and an agent that limits, to a great degree, the displacements one may find in these cases. When a deformity is marked, it is due to laceration of this tissue, allowing the upper fragment or the epiphysis to be displaced forward and downward toward the subcoracoid region, resembling a subcoracoid displacement.

Signs: The arm hangs helplessly to the side; the elbow projects little or none at all; there is a striking and abrupt projection, slightly round, beneath the acromion. In the absence of swelling we can frequently outline the border of this projection as the upper part of the shaft with its bicipital groove, as shown in Case VII. Crepitus, if present, is of a soft, velvety character. The shoulder is broadened from before backward, but the natural roundness may be present; while in case of complete separation of the head and displacement of it, there is a characteristic flattening, and, as a rule, a mass downward and forward, in the region of the coracoid. Shortening is present only in cases of complete separation, and then usually about one inch. Little or no ecchymosis except that due to contusion.

Differential Diagnosis: These cases are liable to be mistaken for dislocations of the subcoracoid of subclavicular variety, but the usual manifestations of dislocation are absent.

Mobility is present, crepitus very frequently is found, and compression symptoms of the brachial plexus are absent.

Fracture of the upper extremity of the shaft of the humerus can be diagnosticated by the age of the patient, false motion, shortening little or none in fractures, shape of the upper portion of the shaft, ecchymosis usually marked, and grating crepitus.

Prognosis: Union usually occurs early, and is due, according to Mr. Tubby, of England, to the rich vascular supply of the rotator muscles attached to the tuberosities sending to the epiphysis the required nutrition. The upper epiphysis is chiefly instrumental in the growth of the shaft of the humerus, and as a result of its separation the growth of the length of the bone is liable to be materially interfered with. In a number of cases reported by Tubby, in "Guy's Hospital Reports of 1889," shortening of five inches has been noted. The prognosis referring to shortening is modified with the age of the patient; the younger the patient, the greater the danger of considerable shortening: the older the patient, the less the shortening.

Shortening and vicious union also is frequently caused by inability to properly replace the epiphysis.

Treatment: As in fracture of the surgical neck of the humerus. In cases in which it is impossible to reduce the displaced epiphysis, the author would recommend cutting down upon the head of the humerus, using the ordinary guide for an excision, reducing the deformity, then retaining proper apposition by means of sutures through the periosteum of the shaft and the capsule of the joint.

Case V.—J. D——, boy, thirteen years of age; was knocked down in 1891 by a mail wagon and thrown forward upon his right shoulder. He was seen within half an hour after the injury. Swelling was very slight, pain considerable, no deformity; high up false motion could be felt; by grasping the shoulder with the left hand, and moving the arm with the right at the same time, grating of a peculiar soft character was obtained. He was discharged at the end of the third week by his regular family physician. The family report "that you would not know the arm had been broken." Measurements in this case, four years after the injury, reveal a shortening of three-quarters of an inch.

Case VI.—P. B——, seventeen years of age, was seen on August 15, 1895, with the following history: While jumping down the stairs of an elevated railroad station, four days before, he fell forward and down about ten steps, striking on his left shoulder. Upon examination broadening of the shoulder from before backward, flattening, and a movable body high up in the joint region, soft crepitation, a slight amount of ecchymosis, considerable swelling, and an inch shortening were found. Diagnosis: Epiphyseal separation of the upper extremity of the humerus. He refused anæsthesia and further treatment.

Case VII.—M. McG——, aged sixteen, was seen on the same date as Case VI., with a history of a fall upon his left shoulder, as the result of a push while skylarking some five weeks before. He had been an inmate of one of our large hospitals and was being treated for a dislocation of the head of the humerus of the subcoracoid variety.

Upon examination no swelling, but marked flattening, broadening from before backward, and shortening one and one-quarter inch were found. A slightly convex deformity, continuous with the shaft, with the bicipital groove well marked upon it, was found beneath the acromion, and downward and in front, practically subcoracoid, a round fairly movable mass was felt.

Diagnosis of epiphyseal separation was made and further hospital treatment suggested, it being the intention to cut down upon the joint and reduce the head and retain it by silkworm sutures. Refused further treatment.

I am indebted to Dr. George Stewart for the following case:

Case VIII.—Girl, fifteen years of age, fell upon the right shoulder about September 1, 1895. On October 10th the condition is as follows: Arm helpless to the side of the body, no tilting of the elbow, one-half inch

shortening, flattening of the shoulder, apparent broadening from before backward, no swelling, a mass downward and inward from the joint and solid with the shaft immediately beneath the acromion, with internal rotation slightly marked. Diagnosis: Epiphyseal separation with vicious union.

Elbow.—Too great stress cannot be placed upon the proper diagnosis and treatment of fractures occurring at and about the elbow-joint; how frequently ankylosis is seen at varying angles, as a result of these injuries. In some cases there is a moderate degree of function of the extremity, while others are practically useless. The most frequent injuries occurring at this region are fractures of the condyles of the humerus, epiphyseal separation of the lower extremity, and dislocation of the bones of the forearm.

The cause of these injuries is usually a fall upon the elbow or upon the volar surface of the hand. The symptoms and signs vary with the conditions; if seen shortly after the injury diagnosis is readily made. Later the swelling is frequently so extensive as to obliterate all landmarks of the bony joint, and an accurate diagnosis can only be made after the swelling has subsided to a great degree, or by the assistance of an anæsthetic.

In cases of epiphyseal separation seen early there is a broadening from before backward, with a sharp, shelving border presenting below and posteriorly, as a rule, and extending across the entire width of the bone. Anteriorly the shaft projects with a sharp border over the backward displaced lower fragment. Motion of the joint is perfect, upon holding the lower fragment between the thumb and forefinger. The head of the radius bears its usual relationship to the external condyle. Crepitus, when elicited, is of a soft, velvety variety, in contradistinction to the grating found in fractures.

Prognosis: No extensive shortening is to be expected, as the length of the humerus depends mainly on the growth from the upper epiphysis.

Treatment: Reduction can be accomplished without much difficulty, then a posterior splint is placed upon the arm and forearm, with the latter almost completely extended.

In these cases, it has been the custom of the writer to remove the dressing in from ten to twelve days, and make slight passive motion, while the lower fragment is grasped and held firmly in contact with the shaft. The splint is removed at the end of the third week; then have the patient carry his arm in a sling for a week, allowing him to exercise the arm gradually.

Fractures of the condyles are due to the same causes as the former, but more frequently due to violence directly received, as in falls and occasionally a blow upon the condyle. The signs are broadening of the joint, movable body on either side, depending on the condyle broken. Displacement can be made of the forearm to the side of the fracture; the head of the radius is frequently pushed upward in case the external condyle is fractured, impairment of joint motions, and deformity of an oblique variety.

Treatment: Reduction; the use of adhesive strips to hold the condyle in place, and the limb treated in almost complete extension, slight passive motion in ten to fourteen days, then placing the forearm at an angle of 90° with the humerus, or continuing the third week with extension.

One factor in treating fractures of the elbow should be emphasized, and that is never to forget that the forearm should be placed in a position of slight abduction, so as to preserve its carrying properties, and that no upward pressure should be made upon the internal condyle. In fractures of both condyles the treatment has been the same as in cases of fracture of a single condyle, with the exception of the retaining strip of adhesive plaster.

Fracture of the Epicondyle.—Of this injury the writer presents the clinical history of but one case. The violence is direct and, upon examination, a small foreign body is found, usually forward, and downward below the elbow-joint. In the case cited, the internal epicondyle was pulled upward.

Treatment: Reduction, if necessary, by flexing the elbow; retain the fragment by an adhesive strip and bandage over all. Remove the dressing on the fourteenth to twentieth day.

Differential Diagnosis: Fractures of the lower extremity of the humerus are to be diagnosticated from dislocation backward of both bones.

The signs and symptoms of fracture in a recent case are so evident that this error should not be made, but in a case of epiphyseal separation, it is more likely to occur.

In dislocation, there is immobility of the joint, the head of the radius is pushed backward, or backward and upward, the olecranon protrudes posteriorly as a rounded or conical mass, while anteriorly there is a depression over the site of the elbow. These signs, when compared to the signs of epiphyseal separation as given, should enable one to arrive at a proper diagnosis.

Case IX.—D——, boy, aged ten, fell from a tree during the summer of 1892. Came to me through the kindness of Dr. E. T. T. Marsh during the fall of the same year. Upon examination, a ridge fully one-quarter inch wide and flat was found protruding backward and continuous with the lower end of the humerus, while anteriorly there was a ridge protruding forward and continuous with the shaft of the same bone. Extension was perfect. Efforts at flexion were checked with a dull sound, as if some object were being struck by the coronoid of the ulna, as the forearm came to about 90°. The elbow was not widened nor deformed, as is usual in cases of fracture.

Diagnosis: Old epiphyseal separation. Operative interference was advised, but not accepted. The boy's father stated recently that the condition was still the same.

Case X.—M. D——, two and one-half years of age, came under observation on May 12, 1894, with the history of a fall from a chair, striking on her left elbow. The ordinary signs of epiphyseal separation were present.

Treatment: The deformity was readily reduced and easily retained. The forearm was then placed in a condition of almost complete extension and bandaged to a posterior splint, extending from the upper third of the arm down to the wrist-joint. The splint was removed in twenty days and the limb bandaged for a week. Result excellent.

In connection with cases VIII. and IX. the writer refers you to the history of Case XV. for another epiphyseal separation at the elbow-joint.

Case XI.—M. O——, five years of age, fell down two steps August 2, 1894, striking upon her left elbow. She was seen on August 4th, with a straight splint upon the dorsal aspect of the arm and forearm. Upon examination, false motion, and deformity over the internal condyle and grating crepitus were found.

In this case there was also considerable swelling and ecchymosis. The deformity was reduced. A small strip of adhesive plaster was wound around the inner aspect of the forearm to retain the fractured condyle, the forearm was then abducted slightly and extended, and a posterior splint applied. She was discharged, with a good result, on September 2, 1894.

Case XII.—A. K——, five years of age, in June, 1893, fell four stories, striking the roof of an extension, then bounded off, falling to the ground. The case was seen immediately by Dr. DeGarmo, who very kindly referred it to the writer.

The boy was seen about an hour after the injury; upon examination, false motion at the site of the external condyle, deformity, some swelling, ecchymosis, and crepitus were found, with general contusion of the

trunk; otherwise he was in excellent condition. The limb was put in extension under chloroform anæsthesia and kept extended for three weeks, at the end of which time the splint was removed permanently. A week later the result was excellent, and owing to the boy's activity, he had regained complete function of his joint about the fifth week.

Case XIII.—C. O——, five years of age, fell down stairs about four steps on March 17, 1895, striking his right elbow. He was treated four weeks at two hospitals, previous to coming to St. Vincent's Hospital Dispensary. He was seen on April 19, 1895, one month after the injury, at which time the following conditions were found: forearm flexed at right angle, the external condyle displaced outward and downward, a cutaneous slough, the result of pressure, about the size of a ten-cent piece, over the tip of the condyle, joint ankylosed, and atrophy of the muscles of the arm and forearm. Under chloroform anæsthesia, the ankylosis was broken up, and the fractured and displaced condyle was reduced, and the limb treated in extension for three weeks. At the end of this time, there was no union of the fragments. For four weeks the boy remained under observation without union taking place, and was then sent into the hospital to keep him off the streets. He was discharged in two weeks, with union and a fair result.

Case XIV.—E. M——, aged seven, referred to the writer by Dr. Joseph Collins, three years ago, fell from an iron fence, striking upon his left elbow. He was seen four days after the injury with an enormously swollen arm and forearm.

Evaporating lotions were applied for almost a week, with the forearm extended. Then ether was given and a diagnosis of fracture of the external condyle was made; the usual treatment by extension was carried out for about a week, when the limb was encased in plaster, with the forearm flexed. The plaster was removed in two weeks. Within six weeks, the boy had almost complete flexion and extension. Recent reports in this case are entirely satisfactory.

Case XV.—Boy, seven years of age, was struck upon the inner side of his left elbow. Examination revealed a hard mass, about the size of a large pea, upward and backward from the internal condyle. No ecchymosis or swelling. Some pain at the elbow.

Diagnosis: Fracture of the epicondyle. Treated by adhesive straps and pad for fifteen days. Result good.

Radius and Ulna.—There is but one case of interest to report, that involves the bones of the forearm. This was an epiphyseal separation occurring in both bones at the wrist and a separation of the lower epiphysis of the humerus. The injury was received by falling down a flight of stairs, fourteen or fifteen in number.

As the main growth of the forearm depends upon the lower epiphysis, the importance with a view to prognosis, in cases of epiphyseal separation at this extremity, can readily be estimated. This injury is due to direct violence or by hyper-extension of the hand. The signs of this injury are a marked transverse deformity just above the wrist posteriorly, as compared to the oblique deformity in Colles's fracture; an anterior prominence due to the lower ends of the shafts of the radius and ulna, also of a transverse variety, and abnormal mobility above the wrist.

Treatment: A dorsal splint after reduction, extending to the fingers and retained for about three weeks.

Cases of epiphyseal separation of both bones are extremely rare, as compared to those of the radius or ulna alone. Dolbeau reports a multiple case, in which both, radius and ulna on the one side and the radius on the opposite side, suffered separations.

Owing to the fact that the main growth of the forearm depends upon the lower epiphysis, prognosis with a view to shortening is bad; in single separations, lateral deformity is usual. Numbers of cases of separation of the lower epiphysis in either bone have been reported, and a large proportion were followed as a result of the diminished growth of the injured bone by marked lateral curvature, the normal bone during its growth curving toward the injured side. In these cases it is advised to excise a length of the uninjured bone sufficient to overcome the deformity.

Case XVI.—M. D——, girl, four years of age. On May 17, 1894, fell down stairs and was brought to St. Vincent's Hospital Dispensary for treatment. She complained of pain in the wrist and elbow of her right side. Upon examining the wrist, a peculiar transverse deformity, sharply outlined, presenting upon the posterior aspect of the forearm about a half inch above the wrist-joint, was observed, while anteriorly there was a deformity continuous with the shafts of the bones of the forearm. At the site of the deformity during manipulation a soft crepitation was apparent. At the elbow there were the characteristic evidences of an epiphyseal separation of the lower end of the humerus.

Diagnosis: Epiphyseal separation of the lower end of the radius and ulna, and also at the lower end of the humerus. The separations were reduced and the limb was then placed upon a long posterior splint, extending down to the metacarpo-phalangeal articulations. She was discharged in four weeks with a good result.

In conclusion, the author desires to express his indebtedness to Drs. Joseph D. Bryant and Carl Beck for their kind permission to use such of their hospital material as might be of service to him.

149 West Forty-fourth Street.

A CASE OF INVERSION OF THE UTERUS OF FIVE DAYS' STANDING—SUCCESSFUL REDUCTION.

By A. A. DAVIS, M.D.,

AND

C. W. PACKARD, M.D.,

NEW YORK CITY.

The rarity of this accident is shown by the statement of Braun, who says that, in the clinic under the charge of Spaeth and himself, not one case of complete inversion of the uterus occurred in one hundred and fifty thousand labors. At the Rotunda Hospital in Dublin there was one case in one hundred and ninety thousand confinements.[1] Meadows had only one case in his practice. Probably most physicians—even those in extensive obstetrical practice—never meet with a case in a lifetime. We report the following case, believing that it will be found of unusual interest to the profession:

Mrs. B——, aged twenty-eight, primipara, was taken with labor pains early Sunday morning, September 29, 1895, and was delivered of a living child with forceps under chloroform at about seven o'clock the same evening, the perineum and vagina being much torn. The placenta was removed with some difficulty and a severe hemorrhage followed.

When the patient came out from under the influence of the chloroform, she complained of intense pelvic pain and a feeling of impending dissolution. Symptoms of collapse ensued. The attending physician had already gone to his home, two miles distant, so that it was necessary to call in a neighboring physician, who did what he could to help the patient through the night.

The next day, September 30th, patient had some fever. Temperature, 100° F.; pulse, 80; respiration, 20; and complained of pains which were thought to be the ordinary after-pains. Hemorrhage about double the amount of the usual lochial flow. Retention of urine. Catheter used once.

October 1st, 12 M.: Temperature, 101⅘° F.; pulse, 120; respiration, 20. 4 P.M.: Temperature, 100⅘° F. Pain and flow about as yesterday.

[1] Lusk's Midwifery, p. 563.

October 2d.—Temperature, 100½ F.; pulse, 112; respiration, 25. Flow diminishing. Uterine pains about every half hour.

October 3d, 11 A.M.—Temperature, 102½° F.; pulse, 128; respiration, 26. 1 P.M.—Temperature, 103° F.; pulse, 130; respiration, 30.

The preceding notes I make from chart records kept by a trained nurse, and from the mother of the patient who was with and took care of her during Sunday and Sunday night.

I first saw patient at 6 P.M. of this day, October 3d, the husband bringing me a note from the attending physician, asking me to see the case and write my suggestions in a note to him, as he was not able to meet me in formal consultation.

I found Mrs. B—— with the following symptoms: Temperature, 103⅜° F.; pulse, 128; respiration, 40. Face pale and anxious in expression. No great pain, but quite restless and wearied, having had but little sleep since Sunday. Lochia free and not particularly offensive. Bowels just freely opened by sulphate of magnesia; hypogastrium very prominent from tumor, reaching quite to the umbilicus. The nurse telling me that after the catheterization on Monday the patient had passed considerable water every two or three hours, I came to the conclusion that she had had an internal hemorrhage just after delivery, thus accounting for the symptoms of collapse upon coming out from under the influence of chloroform; that the uterus was now filled with clots, and that her fever was due to sepsis. I did not make a vaginal examination, not feeling at liberty, under the circumstances, to pursue my investigations any further. I accordingly stated my conclusion in a note to the doctor, who, however, did not visit the patient again, but withdrew from the case the next morning. At the request of the husband I now took charge of the patient.

Friday, October 4th.—Saw the patient at 11 A.M. Temperature, 103⅜° F.; pulse, 130; respiration, 30. General condition, in aspect, worse than when I saw her last evening. I proposed to clear the uterus of supposed clots and then wash it out with a hot carbolic solution. Upon placing her in position for this purpose and introducing my finger into the vagina, I found it filled nearly to the perineum by a large mass, quite hard, and with a surface not unlike a placenta to the feel. I did not succeed in finding the cervix. An inverted uterus occurred to my mind, but I was puzzled by the presence of the hypogastric tumor. I now directed the nurse to pass the catheter and draw off what water there was in the bladder, although she had reported that the patient had urinated just before my arrival. The result of the catheterization was forty-eight ounces of dark-colored urine and a great diminution in the size of the tumor. But still feeling what I thought to be the uterus above the pubes, I desisted from further attempts to complete my diagnosis, judging it to lay between an inversion of the uterus and a large hæmatocele. I accordingly sought the advice and aid of my friend, Dr. C. W. Packard, who saw the patient with me at 3.30 P.M. the same day. His report is herewith presented.

At the request of Dr. Davis I met him in consultation in the case of Mrs. B—— on Friday afternoon, October 4th, nearly five full days after her instrumental delivery at full term. I found the patient lying on her back with the legs extended, and apparently indifferent to all that was going on around her. Her face was pale, and its expression staring and apathetic. She roused sufficiently to answer "no" to my inquiry, as to whether she felt any pain. Her pulse was 126; respiration, 36; temperature, 103⅜° F., per rectum. The abdomen was slightly tumid, but soft, and a distended bladder was easily outlined through its walls. Fifty ounces of urine were at once drawn off by catheter, although forty-eight ounces had been drawn only four hours before. It then became easy to discover that no uterus could be felt in the abdominal cavity, but that there was a hard mass behind the pubis, and low down in the pelvis. Examination per vaginam revealed a hard tumor, the size of a child's head, just inside the vulva, and that completely filled the pelvic cavity. It was sensitive to touch, and felt like the inside of the uterus after delivery. Passing the finger high up, a thin flap of the cervix could be felt on the right side of the tumor. The patient was then turned gently upon her side, and by means of a large Sims speculum a part of the tumor was brought into good view. Its surface was moist with lochial discharge of normal odor, and covered here and there with films of loosely adherent coagula. The tumor as a mass was pale and anæmic from the diminished blood supply through the vessels of the constricted cervix.

Having determined that we were dealing with an inverted uterus, it was decided to etherize the patient and at once attempt its reduction. At the request of Dr. Davis I prepared to begin the operation that most certainly promised to be more tedious than successful. The finger-nails were trimmed short, and the usual antiseptic precautions observed. The patient was brought to the point of full surgical anæsthesia. The patient, lying upon her back, with my two fingers within the vulva, and with the other hand passed deep behind the pubis, it was found that the tumor was to some extent movable, and that it moved as a solid mass. The deep-seated pelvic portion as felt through the abdominal wall presented to the touch a hard and round surface, but no cupping of the cervix, such as writers describe, was distinctly appreciable. The whole mass, above and below, was very firm and hard, as if from tonic contraction of the entire organ.

The operation was begun by pressing the index and middle fingers firmly and steadily against the presenting fundus, at the same time making gentle counter pressure through the abdominal wall. Gradually the uterine wall yielded, so that at the end of fifteen minutes the two fingers were buried in the tumor as far as the distal joint. The whole hand was now passed into the vagina, and four fingers pressed firmly against the mass, thus pushing it toward the cervix by continuous pressure, the elbow meanwhile resting on the bed as a point of support. With the help of the thumb, some degree of massage to the uterine walls was accomplished, with a view to rendering them more pliable and thus more tractable to further manipulations. Very soon the uterine walls began to soften, whether from the relaxing effect of the anæsthetic, or from the manipulations, or from both combined, and the cervix as felt behind the pubis grew appreciably softer. At the end of half an hour it was possible to carry the fundus before the four fingers fairly into the mouth of the constricting cervix, where they were steadily held as a wedge. The cervix now dilated rapidly before the advancing hand. At this stage of procedure something was gained by seizing the cervix through the abdominal wall, and pressing it down behind the pubis in opposition to the fingers inside the cervix, which were pressing the fundus up—very much as in the manœuvre for reducing a strangulated hernia by pushing down the neck of the sac, and at the same time pushing up the contents of the sac. After this process had gone on for some time, it became evident that the mass in the vagina was rapidly diminishing in bulk, and that in the abdomen growing larger. The fundus was still held in the cervix, and seemed almost, but not quite, ready to pass through. Meanwhile, under the steady pressure from below, and with increasing dilatation of the cervix, the uterus was slowly returning itself, not by movement at the fundus, but at the cervix. The body of the uterus was unfolding itself back through the cervix, the tissues nearest the cervix returning first. At the end of forty-five minutes the uterine walls had become soft and completely relaxed, and the uterine mass in the abdomen had steadily accumulated

in volume, until it was estimated that three-fourths of the bulk of the uterus had been returned through the cervix. In the now completely relaxed condition of the uterine walls no help toward further reposition could be expected from muscular action, such as is reported to have suddenly completed the reposition in other cases, and it became evident that the paralyzed fundus must be carried to its place. In the early stages of the operation occasional contractions of the uterus were observed, but they gradually grew less frequent, and had now entirely ceased, so that the fundus clung around the hand in a flabby mass. At the end of an hour's hard work, and at this stage of the operation, my hand had become so benumbed and powerless that I was compelled to resign my work to Dr. Davis, by whom the reduction was soon happily completed.

"Owing to the patient's very low condition much anxiety was felt lest she should prove unable to bear the shock of operation added to the depressing effect of the necessarily long-continued administration of ether, but so far as could be determined no such ill effects were produced, and her condition at the end of the operation seemed to be quite as good as at the beginning.

"In considering this case the following points appear to be of special interest: 1. The remarkable softening and relaxation of the uterus, without which reduction of the inversion would have been impossible. 2. The absence of all hemorrhage from the relaxed uterus during and after its reduction. 3. The *order* in which the uterine tissues slowly found their way back to normal position, *the tissues nearest the cervix rolling back first.*"

I now take up the report where Dr. Packard leaves it. When I followed Dr. Packard in his attempts to accomplish complete reduction, I found the change in the condition of affairs surprising and very gratifying. The vagina was now entirely empty of any portion of the inverted uterus, the cervix well dilated, and the unreduced fundus could be felt, I should judge, two inches within the cervix as a singularly flabby and elusive mass. The latter quality prevented my making any gain in attempts at reduction, until I introduced my whole hand into the uterus. Then by grasping the uterus with the left hand through the abdominal walls, and by exercising steady pressure with the fingers and thumb of the right hand upon the tumor in its circumference rather than upon the centre, in about five minutes complete reduction was accomplished. I hesitated at first to withdraw my hand lest reinversion should take place. But this accident did not take place upon withdrawal, and there has been no symptom of it since.

The patient bore the ether well, and suffered less from shock than we had a right to expect. No hemorrhage occurred, either during or after the operation. The condition of the patient for ten days following the operation was exceedingly precarious, and then seemed so much better for a few days that hopes were entertained of her recovery. She, however, became worse again October 17th, rapidly sank, and died October 19th of pelvic peritonitis and metritis.

Epilepsy.—Every case of epilepsy subjected to operation should be kept on proper medical treatment for at least two years.—LANPHEAR.

Felon.—The application of fuming nitric acid to a felon in any stage will produce entire relief.—HIRSCH.

Snuff for Hiccough.—Dr. P. Slevin reports in the *Lancet* a case of obstinate hiccough which had resisted a great variety of remedies for twelve days. The patient was seventy-eight years of age, of good physique. Finally, in the hope of exciting a new reflex, he was ordered one evening to take several pinches of snuff. This he did, and the following morning was found free from hiccough. The cure was a permanent one.

TUBERCULAR PERITONITIS.

By C. M. LENHART, M.D.,

ZANESVILLE, O.

PHYSICIAN TO ZANESVILLE CITY HOSPITAL.

In presenting this subject, it is with special reference to the difficulties in diagnosing some cases, and also the treatment.

As is well known, tubercular peritonitis, per se, in children or adults, is rare without a previous or simultaneous manifestation of tuberculosis in some other part of the body. In the case which I will presently present, the invasion of the disease was slow and insidious, without the ordinary symptoms of this affection which are laid down in text-books, viz., tubercular disease in some other part of the body, hereditary tendency, irregular fever, diarrhœa or alternating with constipation, abdominal enlargement from gas, fluid, pus, or mesenteric glands, nausea or vomiting, abdominal pains, growing weakness, and emaciation. These symptoms may develop so suddenly in acute cases, that this disease has been mistaken for typhoid fever, which it may closely simulate, or enteritis, or simple peritonitis; or it may be so latent as to not present a single symptom of abdominal disease, only to be discovered during a laparotomy for some other disease.

Was called November 3, 1894, to attend Mrs. A. W. B——, white, aged thirty-three. Found her in her third pregnancy, between the seventh and eighth months. The previous labors had been normal, and her children, aged three and five years, are in perfect health. No history of miscarriages. The patient has always enjoyed good health, and appears healthy at this examination, except that she has had a diarrhœa for two weeks past. The diarrhœa was checked only for a day or two. She was delivered December 23, 1894, of a healthy baby. The secretion of milk was plentiful and recovery was uninterrupted. After the diarrhœa had lasted about four months a thorough examination was made. The thoracic, abdominal, and pelvic organs, as well as the rectum, were found normal. Pulse, respiration, and temperature were normal, appetite fair, no nausea or vomiting, stools from six to twelve in the twenty-four hours, but the patient is gradually losing flesh and strength. No permanent benefit has been derived from treatment. Has very slight abdominal pains, not localized, or severe enough to call for an opiate.

In the fifth month a swelling was discovered over the region of the appendix, about the size of a goose egg, slightly tender on firm pressure. The case was now thought to be appendicitis, with probably the formation of an abscess discharging into the bowels, or a catarrhal condition of the cæcum. In either case we would have diarrhœa alone or alternating with constipation. The case was watched closely, and in the sixth month of the disease this swelling had perceptibly diminished, but never entirely disappeared. An operation was proposed, but was given up for the time. Subnormal temperature was noticed at times in the morning. The baby had been healthy up to this time, but weaning was advised because a latent tubercular trouble had been thought of.

In the seventh month of her sickness the woman had become very weak; temperature from 97° in the morning to 99° in the afternoon, under the tongue; pulse, 100 to 120; takes large doses of morphine to relieve pain; bowels are now obstinately constipated.

A laparotomy was consented to and she was removed to the Zanesville City Hospital for operation. The abdomen had been repeatedly examined, but nothing abnormal was found excepting slight tenderness and a little swelling over the appendix. The operation was performed June 17, 1895, by Dr. J. G. F. Holston, assisted by Dr. G. Warburton and myself. The appen-

dix was found inflamed, and about as thick as the little finger; a particle of hard fecal matter was found in it, otherwise it was normal; it was amputated and the stump cauterized over a previous ligation; about a half-pint of fluid was drained from the peritoneal cavity and the latter was thoroughly dried out; the peritoneum was found studded with hard miliary tubercles over a limited extent. The other abdominal and pelvic organs were found healthy. The abdominal cavity was completely closed. Her recovery was uninterrupted; on the eighth day there was complete union. She has continued to improve, appetite better, bowels fairly regular, little or no pain in abdomen, and looks brighter. She left the hospital eighteen days after the operation, her health improving in every respect. It is now four months since the operation, and her health continues good.

Now, here was a case in which it was impossible to diagnose the morbid condition. The only signs we had of the existing disease were diarrhœa, growing weakness, emaciation, and a general cachectic appearance. In this case the loss of flesh and strength were attributed to the diarrhœa and defective assimilation. A subnormal temperature was frequently noted, and it appears[1] that subnormal temperature for weeks or months is frequent in cases of fibrous tubercles, where there is slight inflammation and small effusion, or there may be slight fever and subnormal temperature. It appears that my case was after this type. Tubercular peritonitis was formerly thought to be one of the most fatal of diseases. Alonzo Clark[2] says "it is believed to be uniformly fatal." Evidence, however, has lately accumulated to show that, in a certain proportion of cases, spontaneous recovery in this disease is possible both in children[3] and adults.[4] It also appears that the cases most likely to terminate favorably are those where the infection is confined to the peritoneum, and that to a limited extent. It is even possible that the disease may run a latent course and a cure be effected without any sign of existing peritonitis.[5] There is no reason why tubercles in the peritoneum may not undergo involution the same as in other parts of the body.

The anatomical changes are in brief: the tubercles undergo fibroid pigmentary induration, exudations are absorbed, and there is a transformation of the fibroid material into connective tissue with adhesions.

Osler[6] and others[7] describe three varieties of this disease—miliary, fibroid, and caseous; clinically, however, it is not always possible to classify all cases of tubercular peritonitis. Infection of the peritoneum may come through the blood, intestines, Fallopian tubes, tubercular ulcers of intestines, mesenteric glands, or pleura. We have tubercular peritoneal tumors which are very difficult to diagnose in every case; they may be omental, sacculated exudations, retracted and thickened intestinal coils, or mesenteric glands. The serious difficulty is best shown by the fact that in 96 cases of laparotomy in tubercular peritonitis, in not less than 30 ovarian disease was thought to be present. In 1862 Spencer Wells performed laparotomy for a supposed ovarian tumor, and he found a tubercular condition of peritoneum; the fluid was drawn off and his patient recovered. As we have seen above, many mistakes in diagnosis, with consequent opening of the abdominal cavity, have been made, and a cure of the patients has been the result in the majority of cases. The beneficial effect of opening the peritoneal cavity and draining off the fluid has caused this to become a generally recognized operation. As Mr. Lawson Tait[1] says, "the great majority of cases are cured by these simple means." According to Morris,[2] eighty per cent. of these cases are cured by exposing the peritoneal cavity to the air.

It is of much interest to inquire why so simple a treatment produces such radical changes in this disease. Whether the curative action is due to the removal of the ascitic fluid, or the removal of the ptomaines of the bacilli, or because the bacteria of putrefaction produce a toxalbumin which is fatal to the tubercle bacilli in the peritoneum, or because of the action of the light, dryness, and air exerted during the removal of the fluid, it is difficult to say. "The absorbent action brought about by traumatic inflammation, so common elsewhere, may make itself felt on such an occasion, and it may favor the removal of the broken-down products of the disease" (Warren). Undoubtedly the removal of the fluid and other irritating products leaves the peritoneum in a condition to remove the products of inflammation and thus favor fibroid changes, or to the "reaction processes," round-celled infiltration, phagocytosis, active connective-tissue development.

As has been mentioned before, the cases most likely to be benefited by operation are those similar to the one presented above, and also those accompanied with considerable exudation, either free or encysted. Such cases are most likely to be primary in the peritoneum, the chances of general infection are less, and the general condition of the patient is usually better. In cases with purulent exudation and large caseous masses in the peritoneum the prospect for recovery is less hopeful, but many cures are recorded, and surprising results often follow abdominal section in these cases.

In chronic adhesive or dry tubercular peritonitis, when there is little or no serum or purulent exudate, and the coils of intestines are matted together, with probably enlarged caseous masses, little or no benefit can be expected to follow an operation.

Tuberculosis is a common cause of peritonitis in children. Ashby, in 105 autopsies in children dead of tuberculosis, found tubercles in the peritoneum in 38 cases, and of 127 cases of tuberculosis noted by Woodhead, caseation of the mesenteric glands was found in 100 cases, or seventy-nine per cent. The general treatment will not be discussed here, as it is on the same plan as that of tuberculosis elsewhere in the body.

The results which have been obtained by incision and drainage are very encouraging, demonstrating the impunity with which the abdominal cavity can be opened in children, and proving that a large percentage can be benefited, and some cured, by an operation. Successful cases have been reported by Treves,[3] Knaggs, Clarke, Conitzer,[4] and many others.

The figures given by Aldibert are exceedingly interesting. Of the 52 cases in which laparotomy was performed in children, there were 45 recoveries and 7 deaths; of these 45, 9 had lived for more than one year, and 2 for more than two years. Of 32 cases of laparotomy performed for ascites, there were 29 recoveries and 3 deaths; 4 had lived for more than one year. In the ulcerative variety, if the process is generalized, the results are not so satisfactory, and it also appeared from a study of these cases that in the chronic adhesive form an operation is hardly indicated, as in the majority of cases nature is healing the tuberculosis; but even here, where there is much pain associated with adhesion, cases have been relieved by an exploratory incision.

It is to be remembered, however, that cases both in adults and children, if the symptoms are not urgent, and the patient's strength is not failing, good authority advises us not to interfere surgically, but to treat the case by medical measures and to wait on nature's efforts to effect a return to health.[5]

Other methods of treatment have been practised—thus Rendu[1] has used, with apparent success, camphorated naphthol. After draining off seven litres of ascitic fluid, he injected, through the cannula, still in the abdominal cavity, ten grains of camphorated naphthol; his patient completely recovered. Beck, in a paper read before the Eleventh International Medical Congress, reports five cases treated by injecting into the peritoneal cavity iodoform, one part, and glycerine, ten parts. Of the cases treated by this method only one resulted fatally, the others were apparently cured.

Progress of Medical Science.

Puncture of the Spinal Meninges.—Professor Fürbringer states that he has now punctured the membranes more than 100 times in 86 cases. The procedure is easy. He recommends that the patient should sit up, at the same time bending well forward, and that the needle be introduced on a level with the under surface or exact extremity of the spinous process. An anæsthetic is unnecessary. Sometimes the aspiration of the fluid was found to cause pain in the neck, back, or head, so that the author uses the Pravaz syringe almost exclusively. The amount of fluid withdrawn varied from a few drops to 110 c.c. The amount evacuated does not always correspond to the amount present or to the pressure. Occasionally a bloody or blood-stained fluid was withdrawn. Once, owing to pain in the legs, it was thought that a nerve-root had been pierced. In four-fifths of 37 cases of tuberculous meningitis the diagnosis was established with certainty by the presence of tubercle bacilli. Improvement is so rare that any curative action can hardly be thought of. In the author's opinion the symptom complex of this disease is not in any great measure the direct result of increased pressure. In 2 cases with meningeal symptoms in which no tubercle bacilli were found, the after-examination showed a serious meningitis. In 1 case of chronic hydrocephalus the fits lessened after the puncture; the necropsy eventually showed the hydrocephalus to be due to a tuberculous nodule in the cerebellum. In 1 case pus was withdrawn. In 3 cases of cerebral tumor there was slight improvement in the headache in one case. There was but slight change in a second case, which subsequently recovered under antisyphilitic treatment. In a third case sudden death occurred the day after the puncture. In a fourth case, much improved by trephining, lumbar puncture was practised owing to a relapse. The symptoms improved slightly, but death occurred twenty-four hours later. It cannot be said whether the puncture had anything to do with the sudden deaths. In two uræmic cases 90 and 50 c.c. of fluid were withdrawn without result. In one case of cerebral hemorrhage with rupture into the ventricles blood was withdrawn, as well as in a case of hemorrhage into the cerebellum rupturing into the fourth ventricle. For diagnostic purposes spinal puncture is most valuable in tuberculous meningitis and when pus is withdrawn. In hemorrhages into the ventricles or subarachnoid space it may also be of service. Therapeutic results are either absent or only rarely to be seen.—*Berliner Klinische Wochenschrift.*

Antral Empyema of Tuberculous Origin.—A case of antral empyema, apparently of tuberculous origin, is recorded by J. Kekwick (*British Medical Journal*). The patient, a woman, aged thirty, complained of the usual symptoms indicative of antral empyema. The left upper second bicuspid was extracted and a free opening into the antrum made through the socket. For twelve months local treatment combined with change of air and the administration of tonics was carried out, but to no avail, the patient's condition remaining practically unchanged. The pus being of a curdy character and the history of the patient led to a suspicion of tubercle, etc., and on the discharge being examined microscopically, the tubercle bacillus was found in large quantities. Constitutional treatment for tubercle, combined with the insufflation into the antrum every day of powdered iodoform, led to rapid improvement in the patient's condition, the discharge becoming less and the hectic condition which the patient had commenced to acquire being lost. The following reasons are given in support of the diagnosis: 1, The chronic course of the case, with no local causes, such as loose sequestra; 2, the tuberculous character of the pus; 3, the amenability of the disease to iodoform; 4, the history of the patient (uncle died from phthisis; sisters suffering from phthisis; no signs of tubercle in the patient herself, but a queried history of tuberculous cervical glands—cicatrices); and 5, the bacilli in the pus which was washed directly out of the antrum through the nose.

Acute Non-suppurative Encephalitis.—Dr. Oppenheim believes that the separation of the non-suppurative from the suppurative disease is most important. The etiology of the hemorrhagic form of the disease is not always the same. By some it has been attributed to alcohol, by others to influenza, and there are a number of cases of no known etiology. It begins with severe symptoms, but usually runs a favorable course. The author gives short details of five cases observed by him, all of which recovered. Three cases were acute, occurring respectively in girls aged sixteen and ten, and in a young woman. In two subacute cases in a girl aged twelve, and a man aged twenty-one, the lesion lay in the floor of the fourth ventricle, and a complete ophthalmoplegia developed itself. In none of these cases was there any evidence of syphilis. In the literature of this disease the prognosis has not always been looked upon as very favorable, but in recent writings recoveries have been noted. The author's experience has been most favorable. Polioencephalitis must be distinguished from disseminated sclerosis, which not very rarely takes an acute form and which, according to the author, may end in complete recovery. Acute course, rapid development, high temperature, etc., are unfavorable signs, whereas low temperature and a protracted course make the outlook favorable.—*Centralblatt für innere Medicin.*

Physometra or Tympanites Uteri.—Dr. Hermes observed this condition in a primipara, aged thirty-seven, and syphilitic. The child had evidently died some time before labor, which lasted over five days, and was mismanaged (*British Medical Journal*). The child's thigh was broken in an attempt to deliver with the blunt hook. The practitioner sent the patient into hospital. She was in a sinking condition, the abdomen greatly distended. The perineum was torn. The pelvis was slightly contracted in all diameters. On passing the finger into the os a great quantity of fetid gas escaped. The child, very large, and in an advanced state of decomposition, was extracted. The placenta, quite putrid, had to be removed manually. The uterus contracted bodily; it was carefully washed out with a solution of carbolic acid at 122° F. There was no severe flooding. The patient died about one hour after delivery. There were no air emboli, said to be the main cause of fatal results in tympanites uteri. There was perimetritis. Under the endocardium in the left ventricle were abundant ecchymoses; the pericardium contained a considerable amount of serum. The fetid air which issued from the uterus, clearly came from the dead fœtus. The frequent attempts to deliver, badly followed up, admitted air and germs from without. In other cases it has been found, that when the fœtus had died quite recently, fetid gas rapidly collects if air be admitted into the uterus.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 26, 1895.

THE REORGANIZATION OF THE CITY HOSPITALS.

THE recent reorganization of the attending staffs of the different city hospitals by the Commissioners of Charities and Correction has naturally given rise to much discussion in medical circles. Considering the radical changes effected, the manner in which they have been made, and the apparent motives that actuated them, it is no more than could have been expected. In order to understand the wide-spread character of the movement and the many different interests involved, it is only necessary to state that the Commissioners have directly under their charge a large number of important hospitals, namely, Bellevue, Gouverneur, Fordham, City Hospital, the Workhouse and Almshouse and the Randall's Island Hospitals, besides the Maternity Hospital and the Hospital for Nervous Diseases, which are in close relations with the City Hospital proper, or, as it used to be known, the Charity Hospital. The medical appointments to these institutions are entirely under the control of this Department of Charities, and the various attending staffs hold their positions at the pleasure of the appointing power. While much can truthfully be said of the political elements entering into these appointments, the latter, of late years especially, have in the main met with a general approval by the profession. The desirability of the positions, particularly those of Bellevue, in affording clinical facilities, tempted the various medical colleges to fight for what they considered their rights. By skilful wire-pulling and the ostensible exhibition of a charitable and generous rivalry in promoting the interests of medical education, the Commissioners were forced to make a deal with the colleges, and give them the lion's share of the patronage. This much was done with Bellevue, and to a certain extent with old Charity. It was then agreed, as a forced compromise, that each of the three colleges should have an equal share in three-fourths of the available positions, while the profession at large should have the remaining quarter. The colleges named their candidates when vacancies occurred in their respective divisions, and the appointments were made accordingly. The remainders, who represented the profession at large, skirmished around as best they could, and meekly dodged into the few places left.

It appeared to be a necessity of the situation that Bellevue should be so delivered to college privileges, particularly as two of the latter institutions were in such close and convenient neighborhood to the hospital. Meanwhile the positions in the other hospitals of the department were apportioned indiscriminately to different applicants with as much fairness as could be expected under the conditions of political pull and ordinary professional fitness. At all events the appointments were generally acceptable to the profession, and fairly represented its distributive interests. These latter gentlemen did their work well, and there was no apparent cause for any complaint on the part of the Commissioners, save that a few of the bolder spirits in different medical staffs rightfully protested against the bad food supplied to the patients, and the want of suitable appliances for the proper treatment of their diseases. Such men were either promptly dismissed or snubbed into submission by unnoticed appeals.

Now, with an ostensible awakening to the necessities of the reforms, so long delayed and so urgently requested by the different medical attendants, it has been decided by the Commissioners to make a clean sweep along the whole line, declare all places vacant, and model the patronage of all the hospitals on the Bellevue plan. This gives the three colleges three-fourths of the patronage of appointments to all these hospitals, and the profession at large but one-fourth.

In the matter of equitable representation of interests it is not difficult to estimate the justice of the so-called reform. If we mistake not, the voice of the profession of this city will yet be heard in no uncertain sound of earnest protest against the position taken by the Commissioners. While willing to accept the situation for Bellevue proper, there is no good reason, even on the score of better or more available clinical teaching, for expanding such a policy to the other hospitals. The Commissioners may yet learn to their sorrow that the large majority of competent medical men not connected with the colleges, have some rights for proper representation, which may yet command respect when the department itself is reorganized and new appointments in its own board are to be made.

This entirely unnecessary, unjust, and discourteous removal of medical men from positions they have so acceptably filled, involves a great deal more than the question of the outs against the ins. It is an arrogant assumption of partiality by the Commissioners that deserves a becoming rebuke. Every medical man who is not directly connected with a college consistently asks why so much favor is shown such institutions, and so little to the profession at large. Are the colleges themselves altogether innocent in the matter?

Statistics of the Antitoxin Treatment of Diphtheria in Berlin.—Dr. Behring has recently published a comparison of the results of the treatment of diphtheria in two of the Berlin hospitals. In the Charité, where antitoxin was employed, there were 299 patients with 53 deaths, or 17.7 per cent.; in the Bethania Hospital, where antitoxin was excluded, there were 249 patients with 112 deaths, or forty-five per cent.

Strychnine Delirium.—An item with this title appearing in a recent issue should have been credited to the *Therapeutic Gazette*. Through inadvertence this credit was not given.

RECKLESS SELF-DOSING.

A RECENT death in this city, directly traceable to self-dosing with nitrite of amyl, serves to emphasize once more what we have so often insisted upon, the danger in lay people prescribing for themselves and for each other. In no other condition of life is a little knowledge a more dangerous thing, and yet in none is this little knowledge presumed upon to a more reckless extent than in the treatment of disease. Sensible and prudent men, who would never think of writing their wills or even of signing a lease without consulting a lawyer, will yet take large doses of antipyrin or of some equally dangerous drug if they have but a slight bilious headache. Even babies are dosed with soothing sirups compounded of opium and other poisons, and of late years the drug which forms the text of this warning, nitrite of amyl, has acquired a most alarming popularity with the mothers of croupy children.

The responsibility for this practice of self-dosing often rests upon the physician, who puts a remedy into the patient's hands with directions to use it as occasion arises. In this way the patient acquires a knowledge of one of the effects of the drug, and when another person presents symptoms which seem to be in some respects similar to his own, he at once, with that peculiar passion for prescribing that has become an instinct of the human race, recommends the new medicine which had helped him. The other takes it and becomes in his turn a new centre of self-dosing infection.

But even if the administration of the drug went no further than the first patient, the physician takes a grave responsibility upon himself who gives a poison to a person ignorant of its dangers with permission to take it whenever his own judgment regards it as indicated.

It is quite true that nitrite of amyl will relax spasm, and if this were its only action it might be safely and pleasantly employed to put an end to the distress of an infant gasping for the breath cut off by laryngeal spasm. But unfortunately the drug is a powerful spinal and heart poison, the action of which is evanescent, it is true, yet so rapid that death may be caused almost instantaneously, before any antidote, even were such at hand, could act. And yet physicians have actually given this violent poison to mothers to use on their babies during an attack of whooping-cough, or of laryngeal spasm from any other cause! It is little wonder, when physicians are so reckless, that laymen come to think they too can prescribe drugs as though they were chocolate drops or maple sirup.

THE NATURE AND TREATMENT OF LUMBAGO.

A YEAR ago Dr. Albert Robin, of Paris, published an article in collaboration with Dr. Londe in the *Revue de Médecine*, in which he contended that lumbago and many cases of torticollis were articular affections, rather than muscular. He returns to this subject in a current issue of the *Bulletin Général de Thérapeutique*. The view, as he admits, is not entirely original with him, but he asserts correctly that most authorities look upon lumbago, at least, as essentially a muscular affection, being often described as a rheumatic myositis. Dr. Robin bases his theory of the articular nature of the trouble upon a number of facts, of which we can only summarize a few: He says, in the first place, that the points of greatest pain are usually in the median line over the vertebræ, or else over the sacro-iliac junctions. He calls attention also to the fact that the position of the patient is such as would not be easily tolerated if the muscles were mainly at fault. The sufferer stands with the body bent slightly forward, sometimes bending to one side, a position which would put the erector muscles of the back in a state of tension that should be uncomfortable and painful. On the other hand, this position is, he thinks, best adapted to relieve the articular surfaces from pressure. The muscles themselves, also, he states, are usually less painful than the joints. Dr. Robin's reasoning is ingenious, and we believe that there can be no doubt but that in many cases, at least, the joints and their supporting ligaments are really the most at fault. The more practical point connected with this subject is that of the treatment of lumbago. In most cases, of course, patients get well rather promptly by simply being put in bed, kept warm, and their symptoms relieved by local applications and the milder anodyne remedies. The old-fashioned treatment of a piece of flannel and a hot flat-iron still has its advocates. Electrical applications, blisters, and various forms of counter-irritation also are useful. Robin asserts, however, that he has discovered a drug which he thinks has a certain specific action on lumbagoes, namely, jaborandi. In acute cases, and in many of the more chronic forms, the use of the infusion of the leaves is attended, according to this writer, with the greatest success. He gives the infusion of the leaves, a form of preparation which we believe is rarely employed in this country. This infusion is taken in the morning, and repeated in a day or two, if needed. It produces profuse perspiration and salivation, with, in acute cases, immediate relief of symptoms. In the more chronic cases the dose is to be repeated three or four times. We see no reason why, if the drug is really valuable, the simpler preparations, such as pilocarpin or the fluid extract, should not prove equally serviceable. Dr. Robin cautions his readers against the use of this drug, however, in all cases where there is any heart lesion.

ALLEGED FAILURE OF NEW YORK CONSULTING PRACTICE.

IT will furnish some wonder, and perhaps amusement, to New York physicians to learn that the medical papers are publishing editorials and various comments upon the fact that the New York consulting practice has become a failure; that many consultants who have had large practices have lost them gradually but well-nigh completely.

There are ups and downs, in the course of the consulting practice, in all great centres of population. At one time, probably, the consulting gynecologist had a larger share of work, proportionally, than he does now, and this may be true of some other branches of medicine, especially among young men who started life as

consulting specialists: but where the consulting practice diminishes in one direction it increases in another, and, taking it upon the whole, we presume that there is probably more consulting work done now in New York than there ever has been in the past history of the city. The work of the general consultant, who is called upon for diagnosis and help in all kinds of diseases, has certainly not fallen off, as those who are acquainted with the few men in this city who make general consultation a specialty can abundantly testify.

Meanwhile the general practitioner is doing as well as can be expected in a city of wealthy dispensaries and palatial hospitals.

ANOTHER MEDICAL POET.

Our French contemporaries celebrate in somewhat doubtful praise the poetical work of Jean Lahor, M D. Dr. Lahor, unlike a good many medical men who are poets, indeed, unlike most medical men who are real poets, selects largely medical topics for his artistic labors. We note a poem called "Songs of Love and Death," and another, the "Drunkenness of the Lovers," a poem on the "Hospital," and a good many poems which have a bearing on emotions connected with certain physiological conditions.

> "Be then drunk, oh, my soul, and be always drunk,"

sings Dr. Lahor.

> "It is only illusion that makes things beautiful,"

he adds.

> "My thought is serene and my dream perfumed.
> Like the happy chamber where my true love died,"

is another exquisite but not very loyal verselet of the poet. The professional poem about the "Hospital" seems to be in much the same cheerful spirit. The Hospital, according to the doctor, consists of children who suffer because they were born, women who die because they had to bear them, men who are howling as though they were damned, and all begging for death and extinction of suffering. Dr. Lahor seems to have gathered all that is unpleasant and pathological and pessimistic in his medical studies, and turned it into most depressing rhymes. For our part, we hope when doctors turn poets they will take a little more as models the late Dr. Holmes, or the still later Dr. Oliver Goldsmith. It is better to be a very healthy and happy poet than to be an extremely great one, if the greatness is so intertwined with the pathological.

Typhoid Fever Prevails to an Unusual Degree in Toronto, due, apparently, to the fact of an insufficient supply of pure water. According to the returns of the Board of Health, during the first fifteen days of the present month, there were 77 cases of typhoid fever against 29 in the whole month of October last year, and 27 in October, 1893. There are many patients suffering from typhoid fever at the different hospitals. At Grace Hospital there are 36, at St. Michael's 22, and at the General 40 cases.

News of the Week.

Reorganization of the City Hospitals.—The following is the text of the resolutions adopted by the Commissioners of Charities and Correction, and providing for the reorganization of the city's hospitals:

Resolved, That the College of Physicians and Surgeons, the University Medical College, the Bellevue Hospital Medical College, and the Fourth Division of Bellevue Hospital be requested each to nominate one physician and one surgeon, who shall constitute the consulting staff of Bellevue Hospital, and who shall be members of the Medical Board of Bellevue Hospital, but without service in Bellevue Hospital proper.

Resolved, That the Consulting and Medical Boards of the Gouverneur Hospital, the Fordham Hospital, the City Hospital, the Maternity Hospital, the Hospital for Nervous Diseases, the Workhouse and Almshouse and Incurable Hospitals, and the Randall's Island Hospital be and are hereby abolished, to take effect November 1, 1895.

Resolved, That the College of Physicians and Surgeons, the University Medical College, the Bellevue Hospital Medical College, and the Fourth Division of Bellevue Hospital be requested each to make the following nominations, which, when confirmed, shall take effect on November 1, 1895:

1. For the Gouverneur Hospital, one physician and one surgeon each, making a Medical Board of eight.
2. For Fordham Hospital, one physician and one surgeon each, making a Medical Board of eight.
3. For the City Hospital, two physicians, one surgeon, one genito-urinary surgeon, one gynecologist, one ophthalmologist, and one dermatologist each, making a Medical Board of twenty-eight.
4. For the Maternity Hospital, one obstetrician each, making a Medical Board of four.
5. In the Hospital for Nervous Diseases, one neurologist each, making a Medical Board of four.
6. For the Workhouse, Almshouse, and Incurable Hospitals, one physician and one surgeon each, making a Medical Board of eight.
7. For the Randall's Island Hospital, one physician, one surgeon, one ophthalmologist, and one dermatologist each, making a Medical Board of sixteen.

Resolved, That the Medical Board of Bellevue Hospital be and is hereby constituted a Consulting Board for the Gouverneur Hospital, the Harlem Hospital, the Fordham Hospital, the City Hospital, the Maternity Hospital, the Hospital for Nervous Diseases, the Workhouse, Almshouse, and Incurable Hospitals, and the Randall's Island Hospital.

Resolved, That the Medical Boards of the Gouverneur Hospital, the Harlem Hospital, the Fordham Hospital, the City Hospital, the Maternity Hospital, the Hospital for Nervous Diseases, the Workhouse, Almshouse, and Incurable Hospitals, and the Randall's Island Hospital shall be governed and conducted in strict accordance with the plan of organization of the Bellevue Hospital adopted by this Board on May, 12, 1882.

The Hospital Sunday Association.—At a regular meeting of this Association, on the 21st, the question of uniting with the Brooklyn Association was discussed. The Hahnemann Hospital has applied for admission to the Association.

Sir Joseph Lister has been elected President of the British Association for the Advancement of Science, which is to hold its next meeting in Liverpool.

Professor Hafkine has been compelled, by ill-health, to leave India, where he has been experimenting with cholera antitoxin. It is reported that he has inoculated more than forty thousand persons, and the results of his experiments are said to have been most encouraging.

A Doctors' Stable Club.—An organization has been formed by a number of physicians, residing in this city, for the care of their horses and carriages. The services of a carriage-maker, a harness-maker, and a horseshoer will be engaged for a fixed monthly sum, and all repairs on the outfits of the members of the association will be made by these men. The cost of the whole service to each member of the association will be about thirty dollars a month.

Women Students Decreasing in Number.—At a meeting of the Board of Regents of the University of Michigan, held a few days ago, President Angell reported that the attendance of women at Ann Arbor had fallen off in percentage in the past two years.

The Committee on the Treatment of Leprosy, established by the Board of Health of the Hawaiian Islands, is composed of the following physicians: Drs. C. B. Wood, *President;* R. P. Myers, *Recording Secretary;* N. B. Emerson, *Corresponding Secretary;* G. Herbut, F. R. Day, and H. N. Howard.

The Medical Association of the Hawaiian Islands.—The officers of this association, elected at the annual meeting in May last, are: Drs. John S. McGrew, *President;* Henry W. Howard, *Vice-President;* and Robert P. Myers, *Secretary.*

Practising Homœopathy in Peru.—Despatches to the daily press announce the important fact that an American physician, after five years of struggle, has secured the right to practise homœopathy in Peru.

Death of Dr. Harry B. Conrad.—Dr. Conrad, of this city, died suddenly on October 20th, aged forty-three. Dr. Conrad was born in Philadelphia, and graduated at the University of New York, in 1877.

Dr. Abbey J. Seymour.—Dr. Seymour, one of the most prominent medical women of Buffalo, was killed by the West Shore train, on October 17th. Dr. Seymour was born in Batavia, N. Y., in 1853, and graduated from the Rush Medical College, of Chicago.

The Fifth International Congress of Otology has been holding its meetings in Florence, Italy, beginning September 3d. A correspondent of *The Lancet* describes the sessions and the discussion as being very satisfactory. Professor Gradenigo, of Turin, read a paper on the "General Treatment of Internal Otitis," and Dr. Delstanche, of Brussels, a paper on the "Employment of Liquid Vaseline in the Treatment of Affections of the Middle Ear." Dr. Macnaughton Jones read an elaborate paper on "Hypertrophy of the Turbinated Bones, and its Relations to Deafness." Dr. T. Barr read a paper on "Treatment of Intracranial Abscess following Ear Diseases," and Professor Politzer was credited with an original and "epoch-making" memoir on the "Present State of the Pathological Anatomy of the Labyrinth." One feature of the meeting was an exhibition of otological instruments and appliances. Dr. Jones showed his auto-insufflating aural bag for respired air and vapors, and also his magnifying aural speculum and nasal bougies and dilators; also his turbinotome and scale with rule for operation on the mastoid, antrum, temporo-sphenoidal lobe, and cerebellum. Professor Gradenigo exhibited an original and ingenious diapason. The Congress adjourned to meet next year in London.

The New Pirogoff Museum of Anatomy and Surgery is now being erected in St. Petersburg, with the help of the Government and private subscriptions. While the foundations were being dug, a large quantity of human bones were found in the earth, giving a somewhat grewsome appropriateness to the selection of the site. The bones are still a matter of investigation.

A Poet to the Doctors.—Sir Edwin Arnold recently delivered the address at St. Thomas's Hospital, on the occasion of the distribution of prizes to the students in the Medical School.

Presentation to Dr. Hughlings Jackson.—At the opening day of the Medical Session of the London Hospital Medical School Dr. Hughlings Jackson was presented with his portrait and a silver ewer and stand. Sir James Paget presided and made the presentation speech. Sir James referred to the statement of Mr. Jonathan Hutchinson, that the greatest work he (Hutchinson) had ever done was to discover Dr. Hughlings Jackson.

New York State Commission on Lunacy.—The Sixth Annual Report of the State Commission on Lunacy of the State of New York has just been received. It shows that there are now 20,000 insane patients under the care of the State and in city and private institutions. This means an increase, during the year, of 736. The cost to the State of maintaining the State hospitals for the year was $1,627,766. This means a reduction, per capita, during the year, of $30; in other words, it now costs the State $184.84 yearly to take care of each lunatic. The percentage of recoveries during the year was 6.03 per cent. and the mortality rate was ten per cent. Of 16,000 persons admitted to the State hospitals within the last six years, 6,000 were foreign born, and forty-four per cent. were of foreign parentage. In the New York City Asylum nearly eighty per cent. were of foreign parentage. The Commission recommend that appropriations be made to provide for the erection on the grounds of the State hospitals of some buildings designed for the specialized treatment of recoverable cases; also, that a pathological laboratory be established for the benefit of all the State Hospitals.

Reviews and Notices.

THE MEDICAL REGISTER OF NEW YORK, NEW JERSEY, AND CONNECTICUT. New York Medico-Historical Society. JOHN SHRADY, M.D., Editor. Vol. xxxiii. New York: G. P. Putnam's Sons. 1895.

A WELCOME manual, evidently printed and bound for permanency. It contains, besides the list of physicians in the three States, much valuable information regarding associations, hospitals, colleges, and executive departments. The chronological record and necrology cannot fail to throw many side-lights upon the medical history of the times. At all events, the literary terseness and compactness of the work make it very readable.

THE SCIENCE OF VITAL FORCE. Its Plan, Division of Function, and Operative Methods in Health and Disease. By W. R. DUNHAM, M.D. Boston: Damrell & Upham. 1894.

INTERESTING and well written, this little book scarcely reaches the exhaustive ideal of the preface, which is to designate and demonstrate the fundamental principles of the science of vital force, and also to revolutionize the imaginary fundamental principles upon which medical practice, both regular and irregular, is based. The four ultimate properties of vital force, the author states, are sensibility, instinct, sensation, and contractility. The term sensibility is used to represent certain life abilities comprised in all the varieties of brain functions and conscious intelligence. This vital property is implied in the ability to command and execute voluntary acts, having perceptive abilities that may recognize things, conditions, and relations both in contact with the organism and external and beyond contact. It superintends all the voluntary acts. Instinct presides over involuntary acts, superintending the construction of the organic body. Sensation is a vital property expressed by certain nerves, whose function is implied in conveying information of existing conditions and the presence of material contacts both to sensibility and to instinct. It is a kind of telegraph, and was created for no other purpose than to express feeling from contact. Contractility is an invisible instrument of motion in hands of both instinct and sensibility. It is the animal strength property. These four are the only properties by which life is carried on. Material does not act; nature—vital force—does the acting. It may act spontaneously or by invitation, as from medicine. Medicinal contact causes a sensation, to which instinct responds with an involuntary act. Medicine has no active principles of operative influence within itself; but its presence may cause the involuntary active vital principle to act differently. What constitutes physiological action? Pathological action? The involuntary active vital principle acting in relation to nutritive material for organic constructive purpose and for the elimination of normal waste and wornout tissues is physiological action. Pathological action is vital action acting on surplus nutritive material, or on foreign material not of possible use at the time. They are both manifestations of instinct for unlike purposes. Dr. Dunham's treatment of his subject is sincere and earnest. Evidently the present exposition of his views is intended as an introduction to a larger work.

THE URIC-ACID DIATHESIS Gout, Sand, and Gravel. By DR. F. LEVISON, Kreisarzt in Copenhagen. Translated from the German and edited by LINDLEY SCOTT, M.A., M.D., Aberd. New York: Cassell & Co. 1894.

THE uric-acid diathesis has of late been the subject of valuable and important research. These investigations and a plan of treatment based upon the newer view, is the subject of this interesting and valuable treatise. The theory that urea and uric acid excreted stand in constant proportion (the normal ratio said by some to be as 1 of uric acid to 33 of urea), is completely overthrown by the experiments of Horbaczewski, Bleitsen, Schultze, Hirshfeld, and Busquet. The excretion of uric acid in each individual is a fairly constant quantity, while that of urea has a wide range of variation. There exists, however, a constant proportion between the number of white blood-corpuscles and the amount of uric acid, for its production is increased in a whole set of abnormal conditions, characterized by the formation and destruction of large numbers of leucocytes, as leucocythæmia, anæmia, pneumonia, carcinoma, and extensive burns. Certain poisons increase it: Carbon, monoxide, pilocarpine, alcohol. Exercise also adds to its production. Normally present in urine, the author thinks it will one day be clearly demonstrated that uric acid is also normally present in blood. The constitution of blood and urine may be so altered that uric-acid salts are readily deposited or decomposed. If not eliminated by the kidney, the increased quantity tends to its deposition in the body as a biurate. There are only two ways in which this overcharging of the blood by uric acid appears possible: It must either be formed so abundantly that some is stored up in the blood in spite of the fact that the normal quantity is still excreted; or, the production being normal or even diminished, an abnormal quantity is retained in the blood, owing to functional irregularity of the kidney. Against this supposition that *retention* of uric acid is the origin of gout, the reply has been made that the disease would progress quickly and uniformly if this were the case. Why, when its production is influenced in such marked degree by various conditions and diseased processes, and when it may frequently return to the normal? The entire extent of the kidney is not simultaneously attacked, and the anatomical changes are very few, the primary cause being a decrease in the secretory power of the kidney, whereby certain constituents of urine are less easily eliminated. Though this pathogenesis of gout requires further proof, it has the advantage over other theories that it brings into one category all the etiological and pathogenetic factors with which we are acquainted, and gives a plausible explanation of the gout of wealth, the gout of poverty, and the gout of lead-poisoning. It also makes possible a rational form of treatment.

URIC ACID AS A FACTOR IN THE CAUSATION OF DISEASE. A Contribution to the Pathology of High Arterial Tension, Headache, Epilepsy, Mental Depression, Gout, Rheumatism, Diabetes, Bright's Disease, and other Disorders. By ALEXANDER HAIG, M.A., M.D., Oxon., F.R.C.P., Physician to the Metropolitan Hospital, etc. Second edition, with thirty-six illustrations. London: J. & A. Churchill. 1894.

THIS second edition, the *résumé* of some twenty-five papers, is in a measure a new book, as much of the earlier work required revision in reference to new discoveries. Instruments and methods receive attention in response to requests from readers of the first edition. Dr. Haig's theories are too well known to need explanation, and his suggestions in regard to the management and treatment of the uric-acid diathesis are embodied in all general practice.

THE CARE OF THE BABY. A Manual for Mothers and Nurses. Containing Practical Directions for the Management of Infancy and Childhood in Health and in Disease. By J. P. CROZER GRIFFITH, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania, etc. Philadelphia: W. B. Saunders. 1895.

THE result of much experience and observation here finds expression in plain, practical directions for persons of intelligence who are not physicians. The right way, easier always than the wrong way, is clearly emphasized and made attractive. Dr. Griffith's manual is of great value to the young and inexperienced mother who earnestly is seeking guidance. In no sense does it aim to take the place of a physician, or to do away with sound medical advice. It simply states every-day facts familiar to all acquainted with childhood, but which are unknown to others. The author's object is to diffuse necessary knowledge in non-technical form.

THE PREVENTION OF EPIDEMICS; and the Construction and Management of Isolation Hospitals. By ROGER MCNEILL, M.D., Edin., D.P.H. Camb., etc. With Illustrations. Philadelphia: P. Blakiston, Son & Co. 1895.

IN this thoughtful and carefully arranged survey of an important subject the author has endeavored to bring out points that affect chiefly small towns and rural districts, where preventive measures are far from being traditions. As long as infectious disease spreads in such localities, it will be impossible to prevent epidemics from breaking out in more populous centres. The term "isolation hospital" is used instead of fever or infectious hospital, as more acceptable and conveying the true meaning, which is that of a sanitarium where, by isolation, the patient ceases to be a source of danger to others. The nine chapters treat respectively of the dissemination of infectious diseases; the influence of effective measures against the spread of infection; the gain to the community; the nature of infection and its influence upon the construction and management

of isolation hospitals; the establishment and erection of isolation hospitals; hospital construction; disinfection; remarks on hospital management; and private sanitary aid associations. The appendix contains illustrated plans of isolation hospitals now in active and efficient operation.

THE DYNAMICS OF LIFE. An Address Delivered before the Medical Society of Manchester, October 3, 1894, by W. R. GOWERS, M.D., F.R.S. Philadelphia: P. Blakiston, Son & Co. 1894.

THIS is a reprint from *The Lancet*, with minor alterations and additions. No novelty is claimed for the ideas expressed. As their form seemed to possess some freshness when the address was first delivered, they are now given to a larger audience as of possible usefulness to others. "Life eludes our search and resists our efforts. We may, indeed, trace the relations to vitality of matter, and of the energy it bears. . . . We must be content with what knowledge we can gain, secure or insecure; and, while using it as best we may, should realize, in all humility, how much there is we cannot know, yet cannot doubt."

TRATTATO DI PATOLOGIA E TERAPIA CHIRURGICA GENERALE E SPECIALE. Del Professore FRANCESCO DURANTE, Direttore della Clinica Chirurgica della R. Università di Roma. Volume I., Puntata 3a. Roma: Società Editrice Dante Alighieri. 1895.

THIS fasciculus completes the first volume of the excellent surgical manual of Professor Durante. In the preface addressed to his students the author very modestly disclaims the intention of writing an exhaustive treatise on surgery, his aim being to provide an elementary guide to surgical practice suitable for students and young practitioners who are just beginning their work in this art. As to how well he has done this we cannot so readily judge from this first volume, which is of a general nature, dealing with the subjects of inflammation, surgical fever, traumatisms, and tumors. We can assert, however, that the learned and skilful Roman professor has written a work that no surgeon who is familiar with Italian can afford not to have in his library, and in which few, no matter what their attainments, cannot find much that is new and practically helpful. We hope before long to learn that English readers will be able to enjoy the work in a translation. This third part, which is before us, deals entirely with tumors.

STATISTISCHE BEITRÄGE ZUR PATHOLOGIE DES GEHÖRORGANS, Gewonnen aus den Daten in Bd. i.–v. des Klinischen Jahrbuches. Von PAUL KRUSCHEWSKY, M.D. Mit Acht Lithographiesten Tafeln. Jena: Gustav Fischer. 1895.

THIS is a most exhaustive collection of statistics relating to diseases of the ear, which the author has gathered from the first five volumes of the Klinisches Jahrbuch, published in Berlin, 1889–93.

UEBER DIE AUTO-INTOXICATIONEN DES INTESTINALTRACTUS. Von DR. ALBERT ALBU. I. Assistenten an der Inneren Abtheilung des Städtischen Krankenhauses Moabit in Berlin. Berlin: August Hirschwald. 1895.

AUTO-INTOXICATION the writer defines as a poisoning of the organism through the products of its own metabolism, which products may be normal but in too great amount, or abnormal; among the latter are to be distinguished those which usually undergo a further change in the body and those which are not formed in the healthy body, or, if formed at all, are in very minute quantities. Under this etiological head the author includes a great variety of affections of the blood, nerves, skin, and organs of the body. The monograph is well considered and well written, and is one that has a tendency to cause the reader to think a little closer, and to speculate a little for himself. Few books in these times have the power to do that.

MODERN MATERIA MEDICA, WITH THERAPEUTIC NOTES. For the Use of Practitioners and Students of Medicine. By DR. OTTO ROTH. Seventh edition. Revised by DR. GREGOR SMITH, Director of the Royal National and Provincial Board of Health in Wurzburg. New York: William Wood & Co. 1895.

THE first edition of this popular treatise on materia medica formed one of the series of Wood's Medical and Surgical Monographs. The present is a translation of the seventh edition, recently published in Germany, and contains references to many of the newer remedies. The work is exceedingly practical. Very little space is occupied with discussions on the physiological action of drugs, almost all being devoted to the use of remedies in disease and to the best modes of their administration. The latter are illustrated by numerous prescriptions, which add greatly to the value of the work to the practitioner.

PERSONAL REMINISCENCES AND RECOLLECTIONS OF FORTY-SIX YEARS' MEMBERSHIP IN THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA, etc. By SAMUEL C. BUSEY, M.D., LL.D., President of the Medical Society, Washington, D. C. 8vo, pp. 373. Washington, D. C. 1895.

THIS pleasantly reminiscent contribution to medical literature comprises, as its title indicates, a history of the doings of a medical society in Washington, in which the usual differences of opinions as to ethics and other matters provoked much discussion, and which is possibly of interest to some of the surviving participants. Outside of such a limited field of interest it is difficult to imagine why the book was ever written.

DR. BAILEY'S PHYSICIAN'S COMPLETE POCKET ACCOUNT BOOK. Chicago: Gross & Delbridge Co.

THIS is a very convenient and practical account book, compactly arranged, irrespective as to order of dates, and for one or more patients, on a conveniently sized page.

A MANUAL OF OBSTETRICS. By A. F. A. KING, A.M., M.D., Professor of Obstetrics, Medical Department of Columbian University, Washington, D. C. 12mo, pp. 533. Philadelphia: Lea Brothers & Co. 1895.

THE sixth edition of this useful manual within a comparatively short period proves its popularity and its well-merited success.

TRANSACTIONS OF THE SEMI-CENTENNIAL MEETING OF THE OHIO STATE SOCIETY, May, 1895. 8vo, pp. 478. Toledo: Blade Printing Co. 1895.

THIS volume contains a large number of short, practical papers on the various topics that interest and edify the general practitioner. The frontispiece is a fine steel engraving of the President of the Society.

AN INTRODUCTION TO PATHOLOGY AND MORBID ANATOMY. By T. HENRY GREEN, M.D., F.R.C.P., Physician and Lecturer on Clinical Medicine, Charing Cross Hospital, London. Seventh American, and eighth English, edition. Revised and enlarged by H. MONTAGUE MURRAY, M.D., F.R.C.P., Physician to Out-patients and Lecturer on Pathology, Charing Cross Hospital. 8vo, pp. 598. Philadelphia: Lea Brothers & Co. 1895.

THE distinguishing features of the seventh American edition of this work are, aside from numerous interpolations by the editor, made necessary by the rapid advances in pathological study; there are added sixty new illustrations and a colored frontispiece; a chapter on "Diseases of the Nervous System," by Dr. Mott; and a Section on "Tubercular Diseases of the Bones and Joints," by Mr. Boyd. The general character of the work is maintained throughout, notwithstanding the numerous additions by various collaborators, as all have imitated the admirable conciseness and lucidity of the author. From a practical stand-point the work made for itself long ago an enviable reputation. No space nor words are wasted in theorizing elaboration of the subject in hand, but the simple facts and general principles are given in the fewest possible words and in the most refreshing perspicuity of style. It is fair to say that few books within the scope of the present one could give a better idea of the present state of pathology than the one in question.

THE DISORDERS OF SPEECH. By JOHN WYLLIE, M.D., F.R.C.P. Ed., Physician to the Royal Infirmary, Edinburgh, etc. Edinburgh: Oliver & Boyd. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited.

THE text of this work has already been published as a series of articles in the *Edinburgh Medical Journal*, between October, 1891, and May, 1894. The Appendix consists of (a) Notes of three illustrative cases of speech disorders which have been under observation too recently to be available for the text of the work; and (b) a reprint of the author's graduation thesis (1865) on the physiology of the larynx, which was also published in the *Edinburgh Medical Journal*. There are twenty chapters, devoted in turn to stammering, hysterical mutism, aphonia, functional spasms; the troubles of professional voice-users; the functions of the voice; the speech of idiots and imbeciles; the development of language in the normal child; congenital aphasia; the devel-

opment of speech in the human race ; speech in its relations to insanity ; aphasia in relation to organic disease of the brain ; disturbances of speech in relation to evanescent organic affections and functional disorders of the cerebral cortex ; and dysarthric and anarthric disturbances of speech due to lesions affecting the motor speech tracts. These contain an immense amount of valuable information, and make Dr. Wyllie's book one of rare usefulness for study and reference. It is probably the most complete work on speech disorders in general that has ever been given to the English-speaking public.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Twelfth Annual Meeting, held in New York, October 15, 16, and 17, 1895.

AUSTIN FLINT, M.D., PRESIDENT, IN THE CHAIR.

FIRST DAY, TUESDAY, OCTOBER 15TH.

DR. CHARLES E. DENISON, of New York, Chairman of the Committee of Arrangements, stated that about fifty papers would be read.

Report of the Council.—DR. E. D. FERGUSON, Secretary of the Society, read the report. The Treasurer's account showed total funds, October 1, 1895, of $5,694. The net increase in the funds of the Association for the year was $443.

The question had arisen whether a member who had resigned from a branch association could remain a member of the State Association. The decision of the Council was that resignation from a branch association carried with it loss of membership in the State Association.

The Secretary, DR. FERGUSON, stated that inasmuch as he had acted as Secretary of the Association since its inception, twelve years ago, he thought it would be in the interests of the Association to elect a successor to the office.

Library.—There had been added, since the last report, two hundred and seventy-seven volumes, over two hundred of which were from the library of the late Dr. A. L. Carroll.

Amendment to the Constitution.—The constitution was so amended as to permit members of branch associations to all the privileges of the State Association, except voting on amendment to the constitution and by-laws. Dr. McLeod alone voted in favor of their having all privileges without exception, while others were opposed to this, inasmuch as full members had to pay dues to both branch and State Associations.

A Clinical Report on Orthopedic Surgery.—DR. S. E. MILLIKEN, of New York, read this paper. (See p. 581.)

DR. A. B. JUDSON thought the tendon operation would prove a valuable help in the treatment of poliomyelitis cases.

A Domestic Test for Albuminous Urine.—DR. JOHN G. TRUAX, of New York, read this paper. He first stated objections to the heat and nitric-acid tests, the picric-acid and other tests, the greatest being their inconvenience. The test which he had to propose he called the alcohol test. It consisted in pouring alcohol into a test-tube, say an inch or an inch and a half in depth, and dropping upon this a little urine. If albumin were present it would be precipitated as a white streak, not as a general cloudiness, which would result if mucus were present. If the alcohol were placed on the urine a white ring would form if albumin were present, a general cloudiness if mucus. Further, in order to exclude mucus as a cause of the precipitate, the urine could be filtered. The alcohol need not be of full strength, and a tumbler would answer for a test-tube.

Dr. Truax said he offered this method because of its great convenience, and the fact that after using it for a year he had found it even more reliable than any other single test. Like with the nitric-acid and other tests, this one required control tests in doubtful cases. It would reveal albumin present 1 to 10,000 of urine, being indeed a more delicate test than others which he had tried, some thirty in number.

DR. J. W. S. GOULEY said he had tried the alcohol test and had found it of greatest convenience. Control tests with other agents could be resorted to if thought necessary.

DR. TRUAX added that alcohol did not precipitate urates and phosphates, this element of doubt which applied to the acid test being therefore eliminated.

A Cause of Much Sickness which is Often Overlooked.—DR. W. H. ROBB, of Amsterdam, read a paper with this title. The cause referred to was dry-rot in wood, so common in damp, warm, badly ventilated cellars. Whether dry-rot in wood was due to chemical process, as had been claimed by some, or to fungous growth, had not been fully decided, but the latter cause was the more probable. From the damp, dark cellar, with its decaying substances, various disease germs were spread to all portions of the house. Where other known cause for disease in a family could not be discovered, this one should be thoroughly investigated.

Dr. Robb cited two examples. In one instance there was diphtheria and a persistent case of malaria in the house, for neither of which he could find a cause except decaying wood. The cellar was altered, with the result that there had been no sickness in the house since. The second instance was similar, except that the maladies present before the change made in the cellar were one case of pneumonia and two fatal ones of cerebro-spinal fever.

DR. A. T. VAN VRANKEN, of West Troy, thought Dr. Robb had not proven that the diseases named were due to decaying wood or old houses. They were known to occur at times in new houses as well.

DR. T. H. MANLEY thought the paper was an extremely valuable one in that it called attention to a possible cause of a great many diseases. The kinds of moulds in cellars were very numerous, and he believed that microscopists and bacteriologists would yet be able to prove their etiological relation to many diseases whose origin was still obscure or quite unknown. He cited a case of peculiar membrane in the throat which seemed to have been due to dry-rot in wood.

The Present Status of Obstetrics.—DR. HENRY MCM. PAINTER, of New York, read the paper, which will be published in a future issue.

Recent Studies on Diphtheria and Pseudo-Diphtheria.—DR. W. H. PARK read this paper. In the table constructed by Dr. W. H. Welch it was found that in 5,777 cases of diphtheria treated with antitoxin in hospitals, there was a mortality of but 18.7 per cent. These same hospitals gave an average mortality of 43 6 per cent. during the years preceding the use of antitoxin. This, he said, was too great a difference to explain by any remarkable lessening of the virulence of diphtheria all over Europe, at the very moment of commencing the use of antitoxin, nor could it be explained on the supposition that many more cases were sent to the hospital than formerly. In private practice, Dr. Welch summarized 663 cases with a death-rate of only 6.6 per cent.

It was interesting to note the effect of antitoxin in laryngeal diphtheria. With hardly an exception the statistics showed that a less proportion of laryngeal cases came to operative relief now than before the use of antitoxin. The mortality in cases coming to operation was also reduced in all hospitals. In 1,016 cases there was a mortality of less than thirty-eight per cent., as contrasted with the average mortality before the use of antitoxin, of over seventy per cent.

In New York City the mortality statistics were very interesting. The average mortality for the past four

years for all cases reported had been over thirty-four per cent. During the past nine months the mortality had been only seventeen per cent.

Dr. Park believed that if antitoxin had been used in all cases the mortality would not have been more than ten per cent. In Willard Parker Hospital the mortality had been reduced one-third, and, lately, one-half. Regarding the ill-effects, in some the injection caused a slight temporary rise in temperature. In about ten per cent. a local or general urticaria or other form of rash made its appearance between the fifth and twentieth days, and lasted twelve to forty-eight hours. In a few this was accompanied by a rise of temperature. In about one per cent. of the cases with this rash one or more joints became tender; the temperature might be considerably elevated. As a rule these symptoms subsided within forty-eight hours, but in a few there was swelling of the joints some weeks or even for months, as in one case. In a small per cent. albumin appeared in the urine, but with this there were no other symptoms showing any deleterious effects on the kidneys. He had seen at the hospital during the past nine months no serious effects upon the heart, kidney, or nervous system which seemed attributable to the antitoxin. Those who had read Dr. J. E. Winter's remarks might wonder at this, but as a matter of fact he had not seen, after careful observation, the evil effects mentioned by him.

Regarding the use of diphtheria antitoxin in preventing, by immunization, the development of diphtheria, he referred to its use in four asylums in the city, where outbreaks of diphtheria had occurred, the entire number of inmates being over six hundred. In every instance after commencing the injections no further cases of diphtheria developed. The following is an example: At the Reception House of the Juvenile Asylum four cases of diphtheria developed during the week ending April 11th. On the 12th the children (about seventy) were injected with from 200 to 400 units. No cases occurred afterward except that an attendant and an engineer who handled the clothes from the diphtheria children, and who had not received immunizing injections, developed diphtheria.

Dr. Park said to him these results seemed conclusive as to the immunizing power of injections of from 100 to 400 units of antitoxin. About one-sixth of the children developed albuminuria, and a much smaller percentage developed it to a greater extent. In none, however, were there any other symptoms pointing to any deleterious action on the kidneys, and in none was the albuminuria more than transitory. On the blood there was noticed a slight temporary diminution in the number of the red blood-cells. No other changes were noticed.

Dr. Thornton, of Buffalo, had noticed in a good many cases, after the pseudo-membrane had disappeared, that recurrence took place in a few days.

Dr. Park answered questions put by Dr. Didema and Dr. Ferguson, and stated that the antitoxin was manufactured by the Health Department, and was supplied to the poor, free.

The Emergency Treatment in Acute Diseases and Injuries of the Eyes.—Dr. John E. Weeks was the author of this paper. The subject was considered systematically under the headings acute diseases of the lids, of the conjunctiva, of the cornea, etc. Abscess of the lids should be treated as abscess in other parts of the body is treated; when it pointed, make an incision parallel with the edge of the lid. In this and various other conditions and operations antiseptic irrigation was employed, solution of boric acid, or bichloride, 1 to 5,000. In purulent conjunctivitis, whether gonorrhœal, diphtheritic, or other form, every precaution should be taken to prevent spread of the disease to other persons and to the other healthy eye. A watch-glass might be sealed over the healthy eye, leaving ventilation at the lower edge. As a wash, use boric acid by pipette or absorbent cotton. Sponges should not be used about the eye, solution of nitrate of silver, one or two per cent., once or twice during twenty-four hours. If much swelling of the lids, cold applications. But continue the cleansing. In phlegmon of the lachrymal sac, apply moist heat (not over the entire eye), and when fluctuation developed make a free incision into the sac, remove the contents, scrape with curette, wash with bichloride. In cellulitis of the orbit, remove cause, apply cold, then heat, when pus, open. In bruises or contusions, the first six to twenty-four hours apply cold. Then absorption of serum or blood would be hastened by hot water. In burns with acids, neutralize the acid by alkaline application. Foreign bodies should be removed if possible by cotton probang, or, if embedded, with knife, or be dislodged with pointed instrument. Carefully cleanse wound with bichloride, 1 to 5,000.

The whole paper was not read.

Some Unusual Cases of Orbital and Intra-ocular Tumors, Emphasizing the Necessity of Careful Differential Diagnosis.—Dr. C. S. Bull read the histories of the cases. The first was one in which, placing too much importance upon the family history of cancer, he made a diagnosis of malignant disease, while operation showed the case to be one of abscess of the ethmoid cells. In two weeks the patient was discharged, at the end of a month diplopia and exophthalmos had disappeared. In the second case the diagnosis was made of tumor of the lachrymal gland, probably malignant. Removal was advised, and done. It proved to be an adeno-sarcoma of the gland. There had been no recurrence. The next case proved on operation to be a fibro-sarcoma instead of an hypertrophy of the lachrymal gland. The patient subsequently had a suspicious tumor in the neck, and died of exhaustion.

The next case was one of sarcoma of the sphenoid and ethmoid bones. It extended after removal. Still another case was cited of malignant tumor involving the bones of the orbit and dura mater, and extending backward, causing optic-nerve atrophy. A cystoid angioma of the orbit was removed in another case; no recurrence.

Notes on the Diagnosis of Interstitial Cerebritis.—Dr. Neil J. Hepburn read a paper, giving the histories of two cases.

The Practice of Medicine in the Light of Bacteriological Researches.—Dr. A. A. Smith, of New York, read the Address in Medicine. (See p. 577.)

Empyema of the Antrum.—Dr. William Carr, of New York, read a paper on this subject. In considering the question of the causation of this condition the author referred to the research of Fletcher, who found that out of fifty-seven cases of ulcerated teeth only four had perforated into the antrum. From this, this observer inferred that suppuration of the sinus was usually the result of some nasal affection, and not from diseased teeth. To this view, however, the reader of the paper took decided exception, believing that in about eighty per cent. of the cases the empyema was due to disease of the teeth and their alveoli. The first step in the treatment of this condition is the establishment of an opening into the antrum, either by way of the nose or through the alveolus. The latter method he preferred, and where possible, the opening would be made at the second molar tooth. Having made the opening, a flexible probe should be inserted, and the cavity carefully explored to determine the existence of foreign bodies or of septa. The cavity is next irrigated with some weak antiseptic solution, and a plug of sterilized gauze placed in the opening that has been made. Silver drainage-tubes, the speaker said, became corroded very quickly, and in general it might be said that drainage-tubes were unnecessary and harmful in the treatment of this condition.

General Suggestions Regarding the Diagnosis and Treatment of Acute Aural Inflammation.—Dr. Ed-

WARD B. DENCH, of New York, read the paper. He said that primary inflammation of the external auditory meatus was exceedingly rare in infancy, while acute otitis media was quite common. In cases of acute inflammation of the external canal the onset of the pain was usually sudden and severe, and there was associated with it more or less fever. In the mild cases a serous discharge appeared in the course of a few hours, and quickly gave relief, but in the severer form of the affection the pain and constitutional disturbance rapidly increased in severity. It should be remembered that while tenderness on moving the auricle, or by pressing near the meatus in an adult, was almost pathognomonic of inflammation of the external canal, it would indicate in a child, with almost equal certainty, the existence of an inflammation of the middle ear. In a case of external otitis in an adult, examination with a speculum showed the drum-membrane to be of normal color, and the deeper portions of the canal of normal size, but the introduction of the speculum was often a difficult and painful procedure. If seen early, the local abstraction of from one to four ounces of blood often gave marked relief, and checked the inflammatory process. One dose of morphine was allowable, but it should not be repeated. Further relief was obtained by the application of dry heat, which could be conveniently done by the use of the miniature salt-bags made out of glove-fingers, or, more elegantly, by the use of the Japanese pocket-stove. The use of moist heat should be avoided, as its tendency was to favor tissue necrosis. If these simple measures failed to relieve the urgency of the symptoms, no time should be lost in making a free incision with the object of depleting the tissues and controlling the inflammation. This little operation does not require the aid of the specialist; it can be safely done by the general practitioner if he will take care to use sterile instruments, and to have the canal thoroughly aseptic both before and after the incision. There is very little pain connected with making this incision, and the previous application of cocaine is unnecessary and useless. When the case is seen later on, when there is already a discharge from the ear, the physician should see that the discharge is kept free and aseptic.

SECOND DAY, WEDNESDAY, OCTOBER 16TH.

Preamble and Resolution on the Late Reorganization of the Harlem Hospital Staff and the Ethical Questions Involved.—DR. THOMAS E. MANLEY offered the following:

Whereas, As the action of the Bellevue Hospital Medical College and the University Medical College in the late reorganization of the Harlem Hospital medical staff, whereby the members of the said staff were displaced without charges of any description having been preferred against them, after years of faithful and gratuitous service, has seemed in wide contravention to the spirit of the Code; and

Whereas, This action is without precedent, and involves a principle which concerns the entire profession, and has imposed an injustice on members of this Association; therefore, be it

Resolved, That the Council of New York State Medical Association be instructed to institute a searching investigation into this transaction and report their conclusions thereon before this annual meeting adjourns.

On motion of DR. FERGUSON the matter was referred to the Council with power.

A Case of Extra-uterine Pregnancy; Death of Fœtus; Unusual Complications.—DR. GEORGE E. MCDONALD in this paper gave the history of a case in which he had made the diagnosis of extra-uterine pregnancy; no operation. Pains appeared connected with gall-stones, some of which were passed; hepatic abscess developed which opened into a bronchus; later peritonitis killed the patient, and autopsy confirmed the diagnosis. The fœtal bones were in the broad ligament, and evidently had not been the cause of the peritonitis. The sinus communicating between the hepatic abscess and bronchial tube had cicatrized. Peritonitis was present.

Foreign Bodies in the Œsophagus.—DR. H. M. SILVER, of New York, in a paper on this subject, related two or three cases coming under his own observation, and reviewed certain statistics in relation especially to the treatment. The first patient, a man, had swallowed a bone with his food, which stuck in his throat. A physician was called who tried to push the obstacle on into the stomach, but failed. Dr. Silver being called had the man sent to a hospital for external œsophagotomy. The graduated metallic bougie à boule was introduced, and came in contact with the obstruction eight inches from the upper incisors. The œsophagus was opened on a sound introduced within a distance of an inch, and the foreign body was found an inch below. It was impossible to extract it because of a sharp point embedded in the soft parts above, nor could it be pushed down on account of a similar penetration of the tissues below. It was necessary to enlarge the incision, after which the tissues were pressed away from the sharp edge, and the bone, measuring one inch and a quarter by five-eighths of an inch, was extracted.

Statistics were given of 165 cases of œsophagotomy. Of this number 127 recovered, 38 died, a mortality of twenty-three per cent. The causes of death were starvation, perforation and abscess, secondary hemorrhage, pneumonia, etc. In four cases gastrotomy was performed—four recoveries.

The author's conclusions were: 1. That neglected bodies should be removed at once by operation without making an attempt at extraction through the mouth or to push it down into the stomach. 2. A foreign body of moderate size should be removed by operation as soon as impaction is considered complete. 3. Where a small sharp body has been swallowed the œsophagus should at once be opened; and where difficult deglutition is present and constitutional symptoms point to septic inflammation. 4. The use of small catheter, bougie, and sponge probang should be condemned. A metal-capped œsophageal sound, with graduated scale, was the only reliable instrument. 5. Where the foreign body was less than thirteen inches from the upper incisors it should be removed by œsophagotomy, if farther down, by gastrotomy. 6. Stitching the wound was unessential, yet if it was healthy sutures could be passed, but only through the muscular and subcutaneous coats. The external wound should be left open, although a few sutures could be introduced at the upper corner, leaving it open below. 7. Absolutely no food should be taken by the mouth the first twenty-four hours, thus giving the planes of the tissues opportunity to become glued together and prevent infiltration and infection of the deeper tissues. Feeding by tube, whether through the mouth, wound, or anus, was unnecessary, although rectal injection of water might be given the first twenty-four hours if there were thirst. After the lapse of twenty-four hours liquid food could be given by the mouth. To prevent its escape through the wound he would advise resort to Dr. Bryant's plan of making firm pressure with cotton over the wound while swallowing.

Dr. Silver said surgeons had at times made the mistake of continuing rectal alimentation until the patients had been actually starved. One very serious objection to passing a tube through the wound for alimentation was the great pain. It also endangered sepsis by allowing the patient to swallow after the first twenty-four hours. The wound healed eight or nine days sooner than when other methods of feeding had been resorted to.

A Case of Carcinoma Ventriculi, with the Continued Presence of Free Hydrochloric Acid and the Absence of Lactic Acid.—DR. CHARLES G. STOCKTON, of Buffalo, read the history of the case. For two years the

patient had complained of disturbance of the stomach, suffering from pain and vomiting at times. Two months before he saw her the attending physician began rectal alimentation. She was greatly emaciated and cachectic. The diagnosis of cancer of the stomach had been made, and Dr. Stockton concurred in this diagnosis and regarded the condition as beyond relief. The patient then weighed only eighty pounds. The stomach was extremely dilated, and there was a movable, kidney-shaped tumor in the epigastric region. Examination of the stomach contents under different conditions revealed a high degree of acidity, which depended mostly upon hydrochloric acid. No lactic acid was present. It was one of the rare and interesting cases in which advanced malignant disease of the stomach was accompanied by free hydrochloric acid while lactic acid was absent. Under these circumstances he was able to prescribe a diet and medication by the mouth which markedly increased her weight and comfort for some months, or until the tests showed that hydrochloric acid had disappeared from the gastric secretions. He now recommended surgical interference. Dr. Roswell Park operated, found carcinoma of the pylorus, and performed gastro-enterostomy. The patient soon became able to take food, which she did with avidity, and increased her weight to one hundred and thirty pounds, and was still improving in health. Hydrochloric acid was still absent, lactic acid was present. Discussion on this paper was taken up with that on Dr. Einhorn's, which was next read.

Gastro Succorrhœa Continua Chronica.—Dr. Max Einhorn, of New York, read a paper with this title. It will be published in full in a future issue of the Medical Record.

Dr. Stockton thought the class of cases referred to by Dr. Einhorn were sufficiently numerous to have been seen by most practitioners. He was of opinion that they were usually of nervous origin or due to a neurosis, and it was important to give attention to the patient's general nervous state, as well as to any local nervous irritation. While the author had found benefit from the continuous galvanic current, Dr. Stockton had thought this agent caused the succorrhœa to be aggravated and therefore he had discontinued its use notwithstanding its efficacy in relieving pain.

Dr. Jones's experience with galvanism had been similar to that of Dr. Stockton's. He thought pyloric stenosis was in some instances only temporary, and due to a tumor-like state of the folds in the neighborhood, caused by stimulation and irritation of condiments.

Dr. Gallant, of New York, believed that eye-strain was often the primary factor in the neurosis leading to the conditions of the stomach under consideration, and he was accustomed to send such patients to Dr. Weeks for treatment of hypermetropic astigmatism. Regarding washing out the stomach, he thought the necessity for it, except for diagnostic purposes, could be obviated by giving ichthyol, which patients regarded as the less disagreeable of the two remedies. Dr. Weeks had supposed the ichthyol produced beneficial results as an antiseptic, but Dr. Gallant believed it also restored function.

Dr. Austin Flint, commenting upon the cases of Dr. Einhorn, of the great amount of gastric secretion, said that while this juice might possess some of the qualities of gastric juice, it could not be considered as entirely normal. He believed that any person with absolutely normal digestion could occasionally commit gastronomic indiscretions with impunity. In the same way that nature had provided two kidneys for extra work; in the same way that she had provided more lung substance than was absolutely required for ordinary respiration, had she also provided for extra demands upon the digestive functions. He did not believe that she would regard an occasional gastronomic indulgence as an unpardonable sin, calling for prolonged punishment of the sinner. But one of the greatest difficulties which he had encountered in treating persons with digestive disturbance was to get them to observe regularity in eating and to avoid taking more than they wanted. With such errors he could imagine the stomach saying, in the condition described by Dr. Einhorn, I will comply with your demands and supply you with enough gastric juice, but I doubt whether any stomach can secrete such an amount of normal quality.

Cases of Atresia and of Stenosis Vaginalis, with One Hundred Tabulated Cases in Labor.—Dr. J. J. E. Maher recited a few cases of atresia or stenosis of the vagina seen by himself, and then made use of a tabulated list in considering the site of the constriction, its calibre, thickness, resistance, etc. In 3 the whole canal was said to be involved; in 57 the narrowing was in the middle third; in 81 below the middle third; in 15 no opening had been found, while in the remainder it had varied from the size of a pin-head up to only a slight amount of constriction. Its nearness to the vulva should exclude the error of mistaking it for the os and cervix uteri. As to etiology, post-partum cicatrization had been responsible in 42 out of 86 cases, difficult operations on the vagina in 2, traumatism in 5, 31 were congenital. It was surprising in how large a number there had been complication of pregnancy, such as unusual presentation, etc. Dr. Maher was of opinion that the constriction should be penetrated in the presence of pregnancy, or if this were not possible he would, in opposition to the teaching of Breisky, apply forceps. In 13 cases of death the fatal result was, no doubt, due to dilatory treatment.

Discussion on Malignant Tumors.—This discussion was in the nature of a number of papers prepared and read by different authors on sub-titles.

The Prognosis of Malignant Tumors as Modified by their Management.—Dr. Joseph D. Bryant opened the discussion. He advocated, as did the authors who followed him, early removal of all malignant tumors, and indeed of all tumors of whatever nature as a form of prophylaxis. Tabulated statistics were given, showing that malignant disease was on the increase in the human family. In the United States the mortality from this cause in 1850 was 9.0 for 100,000 living; in 1860 it was 11.7; in 1870 16; in 1880 26; in 1890 33.5. This difference could not be entirely due to a fuller report of cases for the later decades. The death-rate from malignant disease was greater in the cities than in the country. The increase had been shown in all parts of the body, but not in equal proportion. In the parts most commonly affected, as the genitals and breasts of women, the increase had not been so rapid as in the alimentary tract. The organs of most physiological significance were most involved. The increase was greatest with increasing years, which was against the theory of infection as more than a rare cause at best. Germans were more often affected than Italians or Irish in New York.

The importance of removing enlarged or neighboring lymphatics while removing the tumor was shown by earlier recurrence and earlier death where this was not done. The advantages of removal by the knife over caustics were that it could be done quickly, cleanly, completely, circumscribedly, securing early healing of the wound, and avoiding irritation and spreading of the disease. The patient should be impressed with the necessity for remaining under observation, and of speedy removal should there be recurrence. Everything lowering the health should be avoided. After removal, special internal remedies might at times be used with discretion—arsenic, mercury, etc. They should never be employed as a substitute for the knife, but simply as an aid.

The Early Detection and Prompt Ablation of Tumors.—Dr. J. W. S. Gouley discussed this phase of the subject. He thought the question was one which could not be too frequently discussed. Early removal

had for its object not only possible radical cure and prolongation of life, but also of rendering life more comfortable even in cases hopeless of cure. In 1885 he removed the breast of a patient which contained two hard nodules in an old scar, microscopical examination showing them to be typical carcinoma. There had been no recurrence. Similar cases could be multiplied. It was possible for tumors of different kinds to exist at the same time, as in Bryant's case, where the patient had in different localities a benign, carcinomatous, and a sarcomatous tumor, and on whom sixteen operations were done at different times, counting also those performed for recurrences. At last accounts he was well.

Dr. Gouley regarded it as of prime importance for physicians to understand that partial extirpation and caustics favored spreading the disease. Benign tumors were liable to become malignant, and should be removed. It was possible, he thought, for a malignant tumor, or one of low organization, to take on the higher organization of the benign forms, or at least to become so far transformed as to remain quiescent a long time. Yet the oft-repeated dictum, that so long as a tumor remained stationary and caused no inconvenience it should not be removed, was contrary to the true principles of conservatism, and was fraught with the greatest danger to the patient. Early removal was likewise indicated whenever recurrence took place. None of the so-called specifics for malignant disease had ever been of any service. Dr. Gouley formulated his points in fourteen conclusions.

The Nature, Modes of Propagation, and Commoner Sites of Tumors.—Dr. Edward K. Dunham discussed the metastatic nature of tumors, which he made out to be peculiar to those of malignant form alone; their mode of extension and transplantation, which he attributed to cell transplantation and growth under new surroundings; also the commoner sites of tumors, which he explained in the case of recurrence on the basis of the usual channels through which the cells were transported. While cases of metastasis of benign tumors, such as cartilaginous tumors which had a high cell organization, had been reported, Dr. Dunham had come to the conclusion on studying these that they were really-mixed tumors, containing sarcomatous elements, and that therefore they did not constitute exceptions to the rule that metastasis was a sign of malignancy. He regarded the susceptibility of malignant tumors to metastasis to be dependent upon their cellular structure, with little or none of the inter-cellular substance characteristic of other tissues. In a great many instances the transported cells would die, and to this fact was to be attributed the usual failure of inoculation experiments, especially in animals of different species. In the same individual the time of metastasis appeared to bear no relation to the duration of the primary neoplasm nor to its size. As soon as the tumor formed, it was liable to metastasis. No more conclusive argument could be offered in favor of prompt operative interference.

Dr. Dunham also discussed the greater liability of certain malignant neoplasms to metastasis than others, basing the explanation upon their difference in structure.

Dr. Charles Phelps, of New York, also read a paper on "The Early Detection and Prompt Ablation of Tumors." To those who held that all tumors should be removed at once, diagnosis of the nature of the growth was not so important; to those who held that only malignant tumors should be removed at once, early diagnosis was extremely important. The contention that removal stimulated growth or extension of the disease seemed to him most irrational, and was not borne out by experience with radical operations. The possibility that all tumors might degenerate was admitted. It was a logical necessity that if malignant tumors required removal, safety demanded equally radical treatment of those other structures which might assume the character of malignancy even while we hesitated. It was hard to remove the breast of a young unmarried woman when it contained an adenoma, but an experience like one which he related, of a change to carcinoma within a few months and death after prolonged and severe suffering, would convert one to the surgical treatment.

Means of Eradication of Tumors: the Knife Versus Caustics.—Dr. Parker Syms, of New York, arrived at the following conclusions in a paper on this subject: 1. Malignant neoplasms were the result of cell-proliferation. 2. Their development was frequently caused or determined by local irritation or trauma. 3. It was purely a local condition, confined to the seat of the growth. 4. Any general infection arose from the original local focus. 5. If this were completely removed while localized, the patient could be completely cured. 6. Distribution was through the lymphatics. 7. When the growth was situated where the anatomy would permit of complete removal, along with removal of the lymphatics, the resulting operation was most likely to be successful.

From the foregoing the following deductions were drawn: 1. Thorough removal of all visible disease. 2. Thorough removal of all invisible disease. Hence, removal of tissue surrounding the growth. 3. Removal of the neighboring lymphatic system. 4. Removal of the disease *en masse* as far as possible, so as to avoid cutting into and liberating infectious elements. 5. Save the patient's strength as far as possible. 6. Ablation of the disease in the early stages.

How could these objects be best accomplished? Decidedly by a well-carried-out surgical operation. Among the advantages of the knife over caustics was that it caused less deformity.

The Necessity of Complete Extirpation of Tumors, and the Importance of Rapid Cicatrization of the Wound.—Dr. Frederick H. Wiggin, of New York, read on this subject. He first showed why the older surgeons had less favorable immediate and remote results from their operations on malignant disease than did modern surgeons. The mortality had been reduced from twenty-five per cent. before the introduction of antisepsis to practically *nil* since. Less frequent recurrence or prolonged life obtained by recent surgery was due to a cleaner, more radical operation, as well as to an earlier one. Sir Astley Cooper had pointed out the fact that the radicles of the disease spread out, and that the lymphatics were involved, and he advised removal of these, but many years elapsed before this advice was followed. Halsted, Curtis, and Meyer had reported little deformity or disturbance of function from so radical an operation as removal of the pectoral muscle in addition to the tumor and lymphatics.

As to rapid cicatrization of the wound, while it was important that the wound should heal as rapidly as possible, yet it was secondary in importance to removal of parts adjacent to the tumor.

The Value of Subsequent Constitutional Treatment, and of Long Surveillance of the Patient After the Operation.—Dr. Frederic S. Dennis, of New York, said in this paper that some regarded constitutional treatment as absolutely valueless, but the practical surgeon could not adopt this view, although he might have doubts. There were some who had published statistics apparently proving the value of certain internal remedies, as arsenic, bichloride of mercury, Lugoll's solution, pyoctanin, gold, etc. Dr. Dennis thought there was little to be hoped or expected from the administration of constitutional remedies, and believed that where there had been a result, it had been due more to the radical character of a preceding operation than to the drug. If the drug produced an effect, it was probably as a tonic, enabling the patient to resist the advance of the disease. It was a question whether iodide of potash had not some influence on sarcomas,

but disappearance under its use might have been spontaneous, as sometimes occurred with no treatment. Cicatricial contraction was not to be confounded with disappearance, a mistake which some made in lauding a remedy.

The remainder of Dr. Dennis's paper was devoted to impressing the necessity of keeping an accurate systematic history of every case of tumor from the beginning. A photograph should also be taken. The condition present after operation should be recorded at stated intervals. Prompt removal should be the rule in cases of recurrence, and the need of this should be impressed upon the patient. Like Dr. Wiggin, he placed three years as the period after which recurrence was not likely to take place, say in only two per cent. of the cases.

The Management of Cases of Recurring Tumors: Indications and Contra-indications of Repaired Operations.—Dr. Stephen Smith having been called away, Dr. Ferguson read his brief paper. After quoting Virchow and Cohnheim, he said it thus appeared that every tumor was developed from a pre-existing cell or cells by proliferation, and that the tumor was not an independent being, but was a part of the body, and subject to the laws which covered the body. The mere statement of these facts seemed to indicate very clearly what should be the management of every accessible tumor. Common sense dictated that the only method to eradicate a growth which had its origin in a germ, was to destroy the germ itself, and such was now the universal practice of surgeons. This rule applied no less to tumors at a distance from the parent growth than to the parent growth itself.

The Indications for Non-Operative Local Treatment; the Therapeutic Value of Toxins.—Dr. W. B. Coley, of New York, gave his experience with toxins, mostly mixed toxins of erysipelas and bacillus prodigiosus, in the treatment or malignant tumors. The number of patients so treated exceeded one hundred. The greatest benefit had been in sarcoma. He said that he did not propose to discuss the theories on which the treatment of cancer by toxins is based, but he would give the results of his practice in that direction during over four years, which he had spent in the application of the treatment at the New York Cancer Hospital. I do not say that all cases of cancer can be cured by the toxin treatment. I can only give to the profession the results which have been reached by the use of the erysipelas serum and other toxins. I have had good results in many cases of both sarcoma and carcinoma. In some cases the patients have been greatly benefited by the treatment, and their lives have been certainly prolonged, if an entire cure has not been achieved. In the most successful cases the malignant growths have been entirely abated, no symptoms of their presence can be detected by the most rigorous examination, and the patients are in apparently perfect health. There has been no recurrence of the cancerous growth since the cessation of the treatment, although the time from the cessation of the treatment in the different cases ranges from seven months to three years. The reason that other practitioners have not been as successful and have not achieved such good results as I am able to report, can probably be traced to the fact either that the treatment has been slip-shod or has not been sufficiently persisted in. All the cases which I have treated successfully have been pronounced inoperable by the best authorities in this and other cities, owing to the position of the malignant growths or other conditions. Several of the patients had been operated on previously, and came under my care at the hospital on a recurrence of the cancer. In cases where the toxin treatment was successful, the patients are now going about apparently in perfect health.

Dr. Coley then enumerated eight cases which had been treated by him with success. He detailed at length the condition of the patients when they came into his hands, the exact nature of the malignant growth from which they suffered, and the course of treatment pursued in each case. Six of Dr. Coley's patient's who had been successfully treated — four women and two men—visited the hall, and the doctors subjected them to a rigorous inspection.

The President's Annual Address.—The President, Dr. Austin Flint, of New York, chose for the subject of his address "The Coming Rôle of the Medical Profession in the Scientific Treatment of Crime and Criminals."—Society, he ventured to say, was not prepared to accept Rondeau's view, that crime being, as he claimed, the outcome of disease, its penalty should be nothing else than medical treatment; but it must be admitted, Dr. Flint said, that the treatment of crime and criminals, under existing laws, and their execution is a failure, and a failure so serious in its results that it is difficult to imagine what will occur before a revolution takes place, and scientific criminology and penology become established as part of the social fabric. The chief object of a penal system is the protection of society, the quoted fact which showed, he said, that the protection of society against crime and criminals is becoming more and more alarmingly inefficient. The United States census showed in 1850 ratio of prisoners to population, 1 in 3,442; in 1880, 1 in 855; in 1890, 1 in 757.

Sentimentality in questions of criminology and penology should be put aside. It has no more place in criminal law and penal administration than in medicine and surgery. Crime is a disease of our social organization. It is true that it is ineradicable, but it may be restricted within much narrower limits than at present exist. While crime cannot be abolished, all criminals are not hopelessly affected with crime. It has been abundantly shown that criminals may be divided into two great classes, the curable and the incurable, and society needs the aid of competent men to undertake the task of separating the two classes, to restore the curable to usefulness, and to protect our social organization against the incurable. In Dr. Flint's opinion, the only hope is in the medical profession; yet he feared the profession can have little direct influence in the making or repeal of laws. Our chief hope at present is to induce judges, lawyers, and law-makers to study law in the light of modern scientific knowledge. In its application to the treatment of crime and criminals, the idea of the word law, in the minds of jurists and legislators, needs revision. Law existed, and was only discovered by man, not created. Scientific progress will lead us finally to abandon the ancient idea of punishment of crime, and to substitute for it treatment and correction. The only punishments will be those necessary for the enforcement of discipline in prisons and elsewhere. The treatment of criminals will resolve itself into measures to reform the curable, to protect society against the incurable. To his mind, it should not often be difficult to distinguish between criminality and insanity, provided the data were sufficient. There are the criminal insane and the insane criminal; the one an insane person who commits crime under an insane impulse; the other, simply a criminal who has become insane.

In the scientific study of crime, the physician has to do mainly with the occasional criminal, the habitual criminal, and the born criminal; and in this study, the first thing is to separate these from the offender who is not a criminal and the occasional criminal. The born criminal is seldom without physical evidences of what is now called degeneration. The criminal by occasion may lack physical and moral characteristics of criminality and have no criminal heredity, being simply a weak and pliable organization. This unfortunate should be treated most carefully, and be protected, as far as possible, from influences which may render him an habitual criminal.

The President then discussed some of the character

istics of the different classes of criminals. On conviction of a criminal, he should be turned over to the State for treatment. The judge should not fix the so-called punishment. Fortunately, laws were not wanting in the State of New York to render possible this beginning of an intelligent criminal administration. All will admit the value and saving to society of the reformation of criminals; and all criminologists, without exception, regard the indeterminate sentence as indispensable to proper reformatory measures. The good results of the reformatory method were shown in the Elmira Reformatory. Prisoners should be under the supervision of physicians.

Speaking of capital punishment, he said we certainly should be able to prevent a murderer from repeating his crime without committing a legalized murder. The only argument to his mind that remained in defense of capital punishment was, that it may be deterrent.

In conclusion, he said that while it would be desirable to adjust our criminal laws so as to bring them in accord with the present scientific status of criminology, existing laws admit of important reforms. A scientific spirit might be infused into the prison commission, if it included members of the medical profession. Physicians to prisons should study criminals, according to modern methods, and not simply prescribe for their bodily ailments.

Observations on the Minor Degrees of Contracted Pelvis.—Dr. Austin Flint, Jr., read the paper. (See p. 583.)

Dr. George T. Harrison said the impression had seemed to prevail here that pelvic deformities existed chiefly in foreign countries. He thought Dr. Flint had done a good service in showing the frequency of minor contractions of the pelvis in New York. He could not understand how any person could prefer high forceps to version. Version was much safer.

Dr. W. T. Lusk said the subject of pelvic deformities was one of such importance that it had been set down for special discussion at the next meeting of the International Obstetrical Congress. He had been assigned the work of tabulating statistics from America, and the paper of Dr. Flint would be of great service to him. Contraction of the pelvis in this country was usually slight in degree compared with that in Europe. If the contraction were not below three inches and a half for the true conjugate, spontaneous delivery might take place, or it might be necessary to resort to version or forceps. Dr. Lusk would not condemn high forceps entirely, as it would seem Dr. Harrison would do. He hoped craniotomy on the living child would give place either to one of the methods just mentioned, or to symphyseotomy on Cæsarean section.

Notes on the Diagnosis of Interstitial Cerebritis.—Dr. M. J. Hepburn, of New York, related two cases bearing upon the early recognition of this affection, or as it is generally termed, general paresis.

The first was that of a physician who was under observation for two years and whose earliest symptoms were discomfort in or about the eyes, followed by gradual lowering of vision, and periodic dilatation of the right pupil. The ophthalmoscopic appearances were slight creamy redness of the optic disk, later pallor, going on to the appearance of primary atrophy of the nerve, the retinal vessels showing no signs of change. A gradual narrowing of the visual field accompanied the change in the nerve, mostly confined to the temporal side. The general symptoms of the disease appeared as the eye symptoms increased, and he died in an asylum.

The second case was that of an artist who presented similar changes in the earlier period of observation, and later developed lines of change in the retina near the disk. The general signs of beginning paresis began to manifest themselves some months later, and the affection of the optic nerve being considered an interstitial neuritis, he was put under treatment for that affection, with the result that not only was there entire recovery so far as the eye was concerned, but the general symptoms also disappeared, and there was apparently complete restoration to health.

These cases would seem to support the theory that the earliest stage of what is called general paresis is a low grade of interstitial inflammation, with slight and transient exudation which, however, when undisturbed may go on to the destruction of nerve tissue and cells, yet not leaving much if any traces of the first deposit.

Third Day, Thursday, October 17th.

Dr. Darwin Colvin, of Wayne County, was elected President for the ensuing year: Dr. E. D. Ferguson was re-elected Secretary and Treasurer.

A New and Original Method of Obtaining Material for Skin Grafting.—Dr. Zera J. Lusk read a paper describing his experience with a method of skin grafting which he first employed rather by accident. The dry epidermis hanging from the skin after a burn was used successfully for grafting a large raw area. The method could be carried out on any occasion by raising the epidermis through the application of a blister. The epidermis, when dry, was cleansed and moistened, a piece an inch square was cut into perhaps twelve pieces and applied on the wound. Little islands were formed which spread and covered the entire surface.

A Study of Hysteria and Hypochondriasis.—Dr. Charles E. Lockwood, of New York, in this paper enumerated about fifteen conditions favoring or causing hysteria or hypochondriasis. Some were, hereditary neurosis, unfavorable environment, improper mental and physical training, physical defects, lack of definite purpose in life and mental occupation, superstitious notions, especially as to one's own ill health and remedies therefor, tobacco, alcoholic, and opium habits, lack of physical exercise, circulation in the blood of poisonous germs and toxic matters, syphilis, uric-acid diathesis, etc.

The author emphasized the importance of mental occupation, of having the patient forget himself and take an interest in other people's welfare. Diet and medicinal treatment were also considered.

The Technique of Maunsell's Method of Intestinal Anastomosis.—Dr. Frederick Holme Wiggin, of New York, described the method and cited its results. Maunsell's original description was recognized as somewhat obscure, and Dr. Wiggin wrote him, suggesting that he rewrite it. Maunsell having died, at the request of his wife Dr. Wiggin had undertaken the work. Diagrams were used, and the third patient ever operated upon by this method, by himself (1893) was shown. There had been no pain, no evidence of contraction. The operation was done as an emergency, by lamplight, with a woman domestic administering ether. In all, nine successful cases of anastomosis by Maunsell's method had been reported, and two unsuccessful ones, death in the latter being readily explained. The method commended itself for simplicity, rapidity, and safety, and applicability under any conditions. Objection had been found to be without basis.

A Review of the Treatment and Results in Nine Cases of Fracture of the Neck of the Femur.—Dr. Douglas Ayres, of Montgomery County, took occasion to impress the fact that much damage might be done by manipulations carried to the extent which might be necessary to establish the diagnosis of the exact condition present, whether the fracture was within or without the capsule. Much manipulation made for this purpose was especially reprehensible, inasmuch as the treatment would be the same in either case. Much injury was liable to arise from trying to obtain crepitus. The cases treated by him were nine in number, the first one having been seen in 1882. All of the patients recovered with a useful limb. Four were treated without extension, five with. Most of the

patients were aged. The shortening was from half an inch to an inch and a quarter. If there were doubt as to whether fracture really existed, especially at the age when very slight force was sufficient to produce it, it was best to give the patient the benefit of the doubt and immobilize the limb. Regarding the indications for extension, if there were much shortening it should be overcome by moderate extension. In the young, extension should be the rule.

Diseases of the Ankle-joint.—Dr. Thomas M. Ludlow Chrystie, of New York, in this paper considered the anatomy and function of the ankle-joint, related some cases of disease, stated that they usually gave a history in the commencement of some wrenching or trauma, and finally in connection with the treatment showed a steel shoe which he preferred to plaster of Paris in immobilization.

A Brief Contribution to the Therapeutics of Diabetes.—Dr. J. Blake White, of New York, expressed the view in a paper on the above subject that diabetes could be classed among the neuroses. Indeed, he thought the disease obviously arose in the sympathetic chain which controlled certain secreting functions. His own experience coincided with that of others, that the best response came from treatment directed to the digestive tract, but he thought it was owing to the influence upon the nervous system. In addition to dietetic management he had found intestinal antisepsis of value, and dwelt more upon the administration of benzoazol. Fifteen grains a day was sufficient, given in capsules. It was aided by carbonated lithia and Fowler's solution.

Dr. J. G. Truax added his testimony to the influence of the nervous system in causing sugar to appear in the urine. He had witnessed it in shock from trauma and operations. Diabetic patients were troubled, too, with some form of indigestion, and it was this which usually first drove them to the doctor.

The Criminal: His Social and Legal Status, and the Philosophy of Reformation.—Dr. William A. White, of Broome County, read a paper of considerable length on this subject, in which he expressed views similar to those contained in the President's Address. There was no subject of a medical nature in which the public was taking so much interest at present as criminology. And it was well that it should be so, for our defective, dependent, and delinquent classes were largely constituted of degenerates, and statistics showed that it was being increased from year to year. Society thus seemed threatened, but let us hope that science would be able to organize efficient methods of attack upon this form of disease in the body social.

Upon the potent causes in the production of the degenerate were such economic disturbances as had been illustrated by the recent financial crisis and the war going on between labor and capital. The deleterious effects always fell with greatest force upon the poor.

There were many classes of criminals. There was the criminal by passion, the criminal by force of circumstances, and with these we had less to do. Then there was the occasional criminal and the habitual criminal. These required more serious consideration on the part of physicians. Attempts had been made to recognize the signs which separated them from the rest of society, and of recent years with considerable success, special mention being made of the Italian school headed by Lombrosi. It was in the brain that one would expect to find the clearest evidences of degeneracy, but while defects doubtless existed here, we knew as yet little of their nature owing to the complicated and delicate structure of this organ. It was rather in the skeleton that we found variations from the normal readily appreciable. Thus, in criminals there had been recognized anomalies of cranial, orbital, and other cavities, strabismus, arching of the palate, etc. In proportion as one possessed these anomalies of structure, was he less highly organized than should be, and predisposed to commit crime. Lombrosi professed to be able to recognize the criminal by his chirography, and even to tell the character of his crime thereby.

The true criminal was a degenerate, and this being so, what should be our attitude toward him? Before answering this question we should first decide that of responsibility. The question of responsibility was one of degree, depending upon knowledge of the nature of the act, of the character and forces which impelled to the action, and of the character and forces restraining from action.

Dr. White thought it ridiculous for a jury of laymen to pass judgment upon the testimony of expert medical witnesses. He thought the latter should be appointed by the State, and should investigate the case impartially, in a scientific spirit, and hand their report to the judge. In the treatment of criminals, reformation and restriction should be held in view, while retaliation should take no part. To inflict legal murder was no less than brutal and barbarous.

Dr. White thought our prison system, while an improvement on the past, should be still further changed. The best example of what it should be which we had at present was the Elmira Reformatory, where over fifty per cent. of the inmates were discharged as cured of criminality.

Dr. John G. Truax wished to say a word for the New York Juvenile Asylum. All the reformatory measures referred to as desirable by the author were carried out there except that isolation of different classes was impracticable for want of room. Ninety per cent. of the criminals sent to this institution were permanently reformed.

Dr. Austin Flint said there was an essential difference between the New York Juvenile Asylum and the Elmira Reformatory, for in the former the inmates were young and had committed their first crime, while in the latter they were older and more confirmed, having been sentenced to State prison.

Committee to Consult with the Prisoners' Association.—Dr. J. W. S. Gouley moved that the Council be instructed to appoint a committee on the question of criminality, to confer with a similar committee to be appointed by the Prisoners' Association, and to report at the next meeting of the Association. The resolution was adopted.

Some Fractures of the Upper Extremities in Children.—Dr. John F. Erdmann, of New York, read the paper (see p. 585).

Dr. Austin Flint introduced his successor in the presidential office, Dr. Darwin Colvin, who thanked the Association for the high honor conferred upon him. The Association then adjourned.

Tumors of the Mammary Gland.—1. Mammary carcinoma submitted to operation before infection of the axillary glands should promise fifty per cent. of cures. 2. Although the axillary glands seem not to be involved, the axilla should be opened in every case and thoroughly cleared of glands and fat. 3. Infected axillary glands are of bad prognostic import, but a radical operation that removes them and, at the same time, the supra-clavicular glands, may cure eleven per cent. of the cases. 4. The complete operation should be practised in every case of malignant disease. 5. The mortality following the complete method is doubtless somewhat greater than is that of partial operations. The difference in results, however, is so conspicuous, when the question of "cure" is considered, that the radical operation is the only one to be countenanced. 7. Statistics gathered many years ago are as valueless as are those made use of in estimating the mortality after amputation of the extremities.—Rodman.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, October 15, 1895.

W. H. PORTER M.D., CHAIRMAN.

Morphinism in the Old: Cases at Threescore and Ten; Recovery.—DR. J. B. MATTISON read the paper on this subject.

He said morphinism in the old was rare. Most cases of that neurosis occurred between thirty and forty, the number steadily declining in later decades. In a paper, "Morphinism in the Young," he had called attention to the rarity of that disorder in children, as evidenced by reported cases, but he believed it prevailed more than records or mortality tables showed. In children there were many cases of unsuspected heritage from maternal ancestry tainted along narcotic lines, death usually coming before the fourth day. Also many acquired cases resulting from ignorant or indiscreet opium giving. In the aged this toxic factor was more patent. Some of the genetic factors of morphinism in middle life played a part in the old, but the absence of the most common cause, pain, might be put down as the main reason for its infrequeney in the old.

Dr. Mattison said, in his experience neuralgia was the most prolific cause of morphinism, but as that was a disease of the first four decades mainly, unless from structural lesions or morbid growth, morphinism would not be caused so often in the old. Of the two cited in the paper, pain was the cause in both. One was due to sciatica, the other to melancholia. Both patients were laymen, one seventy, the other seventy-two, years of age. In the former the disease had persisted four years, the opiate used was laudanum, and sometimes rum, to excess. The other had used morphia twenty years, but reaching only four grains, subcutaneously, per day. His physical condition was impaired. The one that used the hypodermic was under treatment eleven weeks, the other twelve. Both recovered. The one that had used morphia lived fifteen months after complete cure, and died of albuminuria. The other survived four years, free from opium, and died of old age.

Regarding the results of morphinism in the old, they are not as disastrous as in earlier years. This is mainly due to the less lavish use of the drug, the old seldom taking it to excess. The writer said he believed a moderate use of opium, in a not small proportion of cases after threescore and five was salutary, and conducive to length of life. In addition to the supporting effect at this time of life it undoubtedly exercised a prophylactic power against inflammatory diseases. This power obtained in opium habitués in early life and diminished as the drug was withdrawn.

Dr. Mattison cited a case of a woman who lived to be eighty-six, but suffered from sciatica. At his suggestion she had used opium, in the form of deodorized tincture, in doses seldom exceeding ten to twelve drops per day. It worked well, she did not suffer, so enjoyed life much more, the demand did not increase, and life was surely lengthened.

Among cases eligible for treatment, the prognosis for morphinism in the old was good. The proportion of permanent recoveries in patients above sixty under his care had been greater than in those below that age.

This was due to the liability of recurring causes in ex-morphinists of middle life, and a lack of time taken in the post-active treatment. This was especially true of medical men. In these there was the danger of premature return to professional work, and this, in his experience, had been the most frequent cause of the return of the disease. The author said the remote future of his patients gave him most concern. Even physicians did not seem to realize that it took not only months of hygienic care and environments, but even years in many cases, to secure a lasting cure.

There was some cases in the aged not eligible for treatment, and in these cases it was best to give that form of the drug which was the least destructive. This he thought was the crude drug or the deodorized tincture. Morphia, subcutaneously, was the most disastrous.

In cases where it was deemed best to entirely withdraw the opiate, the treatment must be adapted to each case. The patient as well as the disease should be treated. In proper cases the Mattison method could be used with full promise of good result. In others a more gradual withdrawal of the drug was best. To abruptly withdraw the drug was brutal, and need be mentioned only to be condemned. It sometimes caused fatal collapse in the vigor of middle life, and was much more likely to do so in the weakened organism of the old.

On Hæmogallol, and the Assimilation of Iron by the Organism.—DR. L. H. FRIEDBURG, read the paper on the above subject. He said of the normal iron of the body which was excreted by metabolism about ten per cent. appeared in the urine and about ninety per cent. in the fæces. Iron injected hypodermically or intravenous appeared in a few minutes in large quantities in the urine, but it was not firmly linked to organic material. The iron received by the mouth and assimilated by the system was represented by this ten per cent. in the urine, and this ten per cent. then must be considered the amount of assimilated iron. The average amount voided in twenty-four hours was one milligramme. To determine the amount of iron assimilated when given as a compound it must be determined whether this normal ten per cent. in the urine had been increased or not. It had to be stated that none of the existing iron medicines sensibly increased the mentioned amount, and, hence, could not be considered as having been assimilated.

Bunge had said at the May meeting of European naturalists at Munich, that the best place to buy iron was not at the drug store, but at the vegetable and egg market, referring to yolks and spinach. He was right as far as in those substances the iron is linked in such a form as to be assimilated, but he forgot that successful research had been made to find compounds in which iron was firmly linked to albuminoid substances.

Kobert satisfied himself that none of the iron compounds were assimilated, but faced the fact that from their administration there were certain beneficial results, which he explained was due to its secondary action in combining with the intestinal gases, mainly hydric sulfid, eliminating it as one of the poisonous gases, and rendering its action upon the iron contained in the blood impossible.

Kobert found that the blood was the starting-point for the administration of iron to be assimilated. All the blood iron preparations existing heretofore had two objections: first, they consisted of pure dried blood, which was objectionable as covering the intestinal track with a tarry mass; or, second, such blood was mixed with iron salts, which as such had no other effect than to neutralize the H_2S, but, eventually, this impaired digestion or produced metal kidney after prolonged use.

After long experiment Kobert discovered that the reductive action of pyrogallol upon blood resulted in a substance called hæmogallol. By different manipulation of the primary impure reddish-brown precipitate, a pure, tasteless, non-smeary powder, dark-brown in color, and insoluble in water, was obtained, 9.7 grammes of iron in the form of hæmogallol increased the amount of firmly linked iron in the urine to one hundred and fifty per cent.

Dr. Friedburg cited experiments by which it was positively proven that free pyrogallol did not exist in the hæmogallol. The use of hæmogallol upon chlorotic or anæmic patients was invariably an extraordinarily favorable one.

The profession of Austria, Germany, and Russia, had decided favorably in regard to the action of hæmogallol, and the profession of this country need no longer look upon its use as an experiment.

The author said hæmol as well as hæmogallol was the form of iron, par excellence, which had no detrimental action whatever, and allowed successful application in the gravest forms of anæmia.

Kobert also prepared compounds of hæmol with the heavy metals, iron, copper, mercury, and with the halloids, iodine and bromine. Also, a mercuro-iodo-hæmol had been prepared.

Professor Koch had experimented with copper hæmol upon lupus patients with good results. The mercuro-iodo-hæmol and bromo-hæmol were recommended for the double action of blood reconstructors and specifics, the former being a positive specific against syphilis.

Rille, one of the most reliable European syphilidologues, said we could not thank Kobert enough for his preparations containing mercury and iodine, which produce less undesirable secondary results.

Dr. Friedburg closed his paper by giving the history of a number of cases treated by these preparations of iron.

In discussing the last paper, the Chairman, Dr. Porter, said that he had used hæmogallol for a considerable length of time, and was convinced that its therapeutical advantages were fully established. It did not have the irritating effects that many preparations of iron had. The iron in this form satisfied the sulphides, etc., of the intestines, and permitted of the assimilation of food.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE OPENING OF THE WINTER SESSION—NOTES ON THE INTRODUCTORY LECTURES.

London, October 4, 1895.

The traditional 1st of October was celebrated by the opening of the medical schools. As this occurred on Tuesday, we are already in full working order. Those schools which continue the introductory lecture show no falling off in the ability displayed by the lecturers, some of whom took up subjects of public interest.

The London Hospital College had perhaps the most memorable opening. For the public presentation to Dr. Hughlings Jackson of his portrait in oils and some silver plate was an event to interest not only his own sphere of labor but all earnest members of his profession. Sir James Paget presided with his usual inimitable felicity. He spoke of Dr. Jackson as a former pupil of his own, and said it gave him consolation as he grew old to find a former pupil who had gone so far beyond him in knowledge. He said the subscribers to the testimonial had vied with each other in their expressions of esteem and gratitude for Dr. Jackson's person and work, and he concluded with the hearty wish that Dr. Jackson might live long to enjoy the supreme happiness of doing good and prolonging the life of others.

The portrait, a striking one, was here unveiled amid loud cheers, and Dr. Jackson, acknowledging the gift, said he could not express how much he appreciated the kindness. He had been thirty-one years connected with the hospital, and made many friends. Sir James Paget afterward presented the prizes to the successful candidates.

At St. George's Hospital the lecture was delivered by Mr. George Pollock, who took occasion to urge the public to come forward and enlarge and modernize the buildings so as to make them worthy of the noble site they occupy. He advised students to bear in mind the temperaments and idiosyncrasies of patients, and gave some interesting examples of peculiarities. A relative of his own, he said, was unable to take the smallest quantity of rice without suffering, and yet that was a most wholesome food. On one occasion the friends of that gentleman, unknown to him, made some biscuits, placing a single grain of rice in each. He took one or two, but became ill enough to leave the table, declaring that if he were not morally certain he had not taken rice, he should think he had been poisoned by it. He had heard of a gentleman who could not take gooseberries without inducing a rash, and on one occasion, at a fashionable party, after the champagne had gone round, turned up his sleeve and showed his friends the peculiar rash coming out. Idiosyncrasies as to drugs, such as calomel, opium, and belladonna, were not so uncommon, and the lecturer warned his hearers against disbelieving the statements of their patients and giving drugs which they said disagreed with them.

Lord Byron had said, in his rather exaggerated way, that what would cure one man would kill another, but the lecturer objected to the word cure, and said we do not cure—we treat "the ills that flesh is heir to." Some credit was due to nature, and cure is the expression of empirics.

At University College Professor Bradford urged the necessity of scientific training, and held that the science selected for this purpose should be one in which students could see for themselves the data on which its deductions were founded. Biology was not suitable on account of the great claim it made to study it properly. Human anatomy he held to be by far the most appropriate, and it afforded great facilities for students to become accurate observers. Students must become careful clinical observers to attain success.

At the Middlesex Hospital Dr. Julius Mickle devoted his address to discussing the manner in which we obtain knowledge of external objects, and thence deducing the natural and proper methods of studying medicine. Study and research should be one honest, consistent, persistent search after truth.

At the Westminster Hospital Dr. Monckton Copeman passed in review the steps through which we had arrived at the bacteriological diagnosis and treatment of disease, and then gave a brief account of his own researches in connection with small-pox and vaccinia. His results seem to indicate that the specific organism of both these diseases is a small bacillus, which is demonstrated with great difficulty. It can be cultivated in a special medium, though with very great difficulty, and calves have been successfully inoculated with these cultures, so that in the future we may have the means in vaccination not only of preventing, but of combating, small-pox after its invasion of the system.

At St. Mary's Hospital Mr. A. P. Laurie took for his subject "The Medical Profession and Unhealthy Trades," and unfolded a scheme for utilizing the work of the medical staff of the Factory Department in a scientific manner, from which valuable information would be obtained and the health of the operatives improved.

At the School of Medicine for Women Miss Ellaby, M.D., addressed the students, urging them to "make haste slowly," and to put on a triple armor—courage, wisdom, speed. But she warned against overworking, and recommended her audience to take time for recreative thought, meditation, and even dreaming.

At Guy's Hospital an excellent example was set by bringing up a former student from the Provinces to inaugurate the Physical Society. This was Mr. G. H. De'Ath, Medical Officer of Health for Buckingham, who spoke many wholesome truths on "our profession, our patients, our public, and our press." Many racy remarks of his must, I fancy, have touched some of his

London audience, and will, it is to be hoped, bring forth fruit in the more rigid adherence to ethical conduct. He would have us see men and things as they really are, rather than as they appear to be, for he declared that no man and no thing is what he or it seems to be. So many subjects were crowded into this address that it is impossible to do more than say they were all dealt with incisively and in a manner that separates it from the other lectures.

At the Leeds School Dr. Leech, of Manchester, devoted his address to "Our Forefathers," and traced from the earliest times the use of remedies, and held against Spencer that our art did not arise in magic or priestcraft, but in observation on the effects of various foods and herbs. This view is supported with much learning.

At Birmingham Professor P. Frankland traced the story of Pasteur's wonderful work from his first discovery of the difference between the two forms of tartaric acid to the close of the great savant's career, which has just plunged science in mourning for her greatest son. Nothing could have been more timely.

At Liverpool Mr. Hutchinson undertook the duty of the day, and discoursed familiarly of "the examination system" of the present day, pointing out many of its effects, both good and bad, on education, both general and professional.

At other schools the time-honored Introductory has fallen into disuse, but the Dinner holds its ground almost everywhere, though there are not a few who fail to see the use of the convivial meetings. The distribution of prizes is interesting to both students and teachers. At St. Thomas's Hospital this year it was particularly interesting, as it was undertaken by Sir Edwin Arnold, who expressed in happy terms the obligations and sympathy with which the successes of scientific medicine are followed in the sphere of literature and journalism, and put in a plea for animals condemned to vivisection for the benefit of humanity, for an enhanced regard and a special consideration toward creatures thus doomed to perish for human good.

APPENDICITIS DURING PREGNANCY AND LABOR.

To the Editor of the Medical Record.

Sir: A reluctance to trespass on your valuable space and the good-nature of your readers for a third time on the subject of "Appendicitis during Pregnancy and Labor"[1] was the reason why I refrained from sending you a few remarks on the very interesting and instructive paper on this occurrence by Dr. J. W. Thomason, of Huntsville, Tex., published in your issue of September 21st last. But an exceedingly typical case of this kind which has since come under my observation leads me to again ask your indulgence.

I will premise by saying that Dr. Thomason quotes the delay in operating in the case reported by me in the Medical Record for December 1, 1894, which apparently has set this particular ball rolling, as a part justification for his delay in operating in the case related by him, where the patient recovered without operation, and was delivered at term of a healthy child. While this result undoubtedly warranted the delay, and eventually the non-performance of an operation, I would not be understood as advising such delay in operating in other similar cases. In the case I saw with Dr. Hochheimer, in September, 1894, to which Dr. Thomason refers as "now famous in medical literature," we delayed the operation only four days (not "about six days," as Dr. Thomason says), and I expressly stated at the end of my article, in regard to the time when the operation should be performed, as follows: "I think that in a future similar case I would open the abscess at once, as soon as a reasonable probability of its existence could be settled, without reference to the pregnancy or the impending or completed delivery. I would rather take the chances of puerperal infection from the abscess than of its unexpected rupture at any moment into the peritoneal cavity."

The above statement makes my position as regards the time of operation in such cases sufficiently clear and positive. Would that the question of diagnosis were as easily settled! Dr. Thomason refers to this point, and quotes several authors who have written since my article appeared, and who report difficulty in diagnosis and unfavorable results from early operations, the women aborting and dying several days later. They do not say, however, nor can they say with any certainty, how long the acute inflammation of the appendix (probably with perforation already accomplished) had existed before the patient was seen by the operator. These questions of difficulty of diagnosis, and time of operation when the diagnosis has been suggested or made, will be brought out in the case I am about to relate.

On October 2d last I was asked by Dr. David Franklin, of 17 East 129th Street, to see, with him, Mrs. H. S——, forty years of age, mother of nine children, who had been confined by a midwife two days before of a dead anencephalic fœtus at term. There had been an unusual amount of amniotic fluid, and the placenta failed to come away. Hence Dr. Franklin was sent for, but not being at home, Dr. Charles M. Ford, of 218 West 135th Street, was called in his place, and detached and delivered the completely adherent placenta. It was attached to the right side of the uterus. (Compare with Dr. Thomason's statement as to the site on the right side and the calcareous degeneration of the placenta in his case, with a healthy, living child, p. 408, December 1, 1894.) The patient at that time complained of no more than the usual after-pains. Within twelve hours, however, she began to vomit, and as the vomiting increased the abdomen became tympanitic, and pain was localized in the right iliac region. There had been a large alvine evacuation from castor-oil before delivery, but none afterward.

When I saw her, at three o'clock on the afternoon of October 2d, she was retching and vomiting incessantly, the stomach being empty; the pulse was 63, fairly strong, but dicrotic; temperature and respirations normal; tongue moist and clean; extremities warm; no particular sign of collapse. Abdomen much distended and very tense. Pain chiefly in right iliac region, but no perceptible dulness or resistance at that spot. Vaginal examination showed nothing abnormal. On questioning the patient as to her health just before confinement, she said it was good, and that she had no pain then. But on asking her whether she had ever had similar attacks of pain in the right iliac region, she said that during her last three or four pregnancies she had, up to the fourth or fifth month, more or less pain in that region, which gradually wore away and did not return until the next pregnancy. Her husband added the information that sixteen years ago she had been very ill with pain in the right side.

Judging from the present symptoms and the history, I felt justified in making the diagnosis of recurrent appendicitis, with probable rupture of an adhesion during this confinement, produced either by the uterine contractions, or possibly by the manual detachment of the placenta. The diagnosis and former probability were imparted to the husband, the latter possibility to Drs. Franklin and Ford privately. The probability of a perforation of the appendix was not then entertained since there was as yet no sign of general peritonitis. The vomiting, however, I decided to be undoubtedly reflex from a local peritonitis in the right iliac region, and I gave as my opinion the necessity of first controlling the vomiting by hypodermics of morphine administered over the epigastrium, and of reducing the tym-

[1] Medical Record, December 1, 1894, and March 23, 1895.

panites by oxgall, glycerine, and turpentine enemata, so as to enable us to arrive at a more positive diagnosis as to the actual presence of an appendiceal abscess and the advisability of operative interference. The patient certainly at that time did not seem in a good condition for anæsthesia and laparotomy. Nutrition by the rectum was also recommended.

On the 5th, three days later, I received a note from Dr. Franklin that the patient had improved very much up to that morning; the vomiting had ceased, large quantities of gas and considerable fæces had been passed, the abdomen was soft and much less distended, and her general condition good. On that morning, however, the fifth day after confinement, the tympanites returned, and temperature and pulse began to go up a little, to 101° F., and 112°, respectively. I saw her again, with Dr. Franklin, that afternoon and found her as tympanitic as ever. The stomach was good, but the tongue coated. Strength still very good. No decided dulness or resistance on right side. Lochia offensive. I advised that decided efforts be now made to empty the intestines of gas and whatever fæces they might contain by means of doses of one-half grain of calomel every half-hour until twenty had been taken, followed by drachm doses of Rochelle salts and oxgall enemata if necessary. In any case to let me know in the morning, and if there was no improvement an exploratory incision into the right iliac region should no longer be postponed.

On the next morning, Sunday, October 6th, word was sent me by Dr. Franklin that the tympanites still persisted, and that there had been no movement. I recommended puncturing the most distended coils of intestine with several hypodermic needles (a proceeding repeatedly employed by me with benefit and no danger), and arranged to meet the doctor at 3 P.M. prepared to operate. But little gas escaped through the needles, and at three o'clock I found the abdomen still quite distended. No more than a trace of dulness in the right iliac region. At 3.30, with the assistance of Drs. Franklin, E. Sternberger, Ford, and Richards, I made the usual right lateral incision and soon discovered from the infiltration of the tissues that there was deep-seated inflammation. On incising the peritoneum a large quantity of gas and solid and fluid fæces escaped, showing that a perforation of the appendix had taken place. The general peritoneal cavity was apparently entirely shut off by the adherent intestines. Turning the patient on the right side, I gently irrigated the abscess cavity with warm sterilized water, and packed it loosely with iodoform gauze. The patient rallied from the operation remarkably well, and during the next twenty-four hours enormous quantities of gas escaped and fluid fæces oozed through the dressing, and were passed per anum. On the next day the temperature was normal, and the patient's condition fairly good, except an unpleasantly rapid, although good, pulse. The deep dressing was not disturbed for fear of rupturing fresh adhesions. Stimulants *ad lib.* were ordered, chiefly champagne. On the next day, however, after a good night, a change for the worse took place. The temperature remained normal, but the pulse went up to 140 and became thready, and when I saw her at 2.30 P.M. she seemed almost moribund. The dressing was changed, oxygen inhalations were ordered, and of course stimulation hypodermically, etc., resorted to as much as feasible. Still, I hardly expected that she would survive the night, but she rallied and lived nearly three days longer, dying from exhaustion.

How long the appendicitis had existed in this case I cannot say. Probably, as the history states, there had been a number of attacks during a period of years. In consequence of these attacks, undoubtedly the appendix was adherent, and in a soft, friable condition at the time of the last labor; and during, or immediately following, the labor perforation took place, and fecal matter was discharged into a cavity sealed off by the previous attacks. This perforation was the cause of the reflex vomiting and the intestinal paresis causing tympanites.

If the diagnosis of perforation could have been made with absolute certainty at the time it occurred (the diagnosis of appendicitis was made thirty hours later, when I first saw her), that, in my opinion, would have been the time to open the abscess. The next best time was, the perforation being certain, when I saw her thirty hours later. Whether she would have survived the operation in her then collapsed state is the question. And still I think the sooner after perforation the operation is performed the better, supposing, of course, that the patient's condition is good enough as to warrant moderate delay. And even then, one never knows when an internal perforation may take place. The diagnosis of the occurrence of perforation is, after all, the chief difficulty. With a well-defined dull tumor in the right iliac region, and the usual (it is true, rather vague) history of appendicitis, the advisability of immediate operation need not be discussed.

But it is these doubtful, obscure cases, with questionable history of previous attacks, or with the present illness masked by the distention of the abdomen during pregnancy and labor, by labor pains during the confinement, and after-pains and tympanites afterward, which render the diagnosis so difficult and the indication for operation so uncertain.

The insidious character of recurrent attacks of appendicitis and the possibility of recovery after perforation were illustrated to me in a case this summer, that of Professor Worthen, of Dartmouth College, whom I was asked to operate upon while I was delivering my annual course of lectures at the Medical College. He had been a perfectly healthy man (even an athlete) up to about two years before, since which time he had complained of occasional colicky pains in different parts of the abdomen, and had lost some flesh. Nothing of the nature of appendicitis had been suspected. About ten days before his illness he lifted a heavy log to show his strength. He felt a pain in the right side of his abdomen at the time. He thought nothing of it, however, until about a week later, when, returning from a visit to the Wild West Show at White River Junction, on dismounting from the stage he was seized with so severe a pain in the right iliac region that he went to bed. He was seen by Dr. C. P. Frost, his physician, the next day, and the diagnosis of probable appendicitis was made. The following day I was asked by Dr. G. D. Frost, who was attending the patient with his father, to operate. I agreed to do so, if I found the case a suitable one. I saw the patient at the Mary Hitchcock Hospital, where he had been moved from his house, at three o'clock that afternoon, found a decided swelling in the right iliac region, and operated as soon as the patient could be prepared, that is, about forty-two hours after the severe attack of pain on descending from the stage, when I think the perforation occurred. On opening the peritoneum, gas, fecal matter, and pus escaped. The appendix was found loosely adherent, and on attempting to tie it off, it broke away piecemeal. The abscess-cavity seemed closed off except below, where Dr. G. D. Frost, who assisted me, and I both thought the finger reached into the open peritoneal cavity. I did not, therefore, irrigate, but rapidly packed the pocket with iodoform gauze. This was removed in part three days later, being then soaked with fecal matter, and under the subsequent care of Dr. G. D. Frost the wound gradually healed and complete recovery took place. Here, I think, the early operation saved the patient's life, since probably a perforation of the abscess downward into the open peritoneal cavity would soon have taken place.

I have no hesitation in mentioning the patient's name in this case, as a report of his illness and the operation appeared in the Boston papers at the time, and since then in the Dartmouth *College Journal*, of course without my connivance.

In conclusion, I think that the numerous instances of appendicitis, with and without suppuration, occurring during pregnancy and labor, which have been reported since my paper appeared nearly a year ago, should induce us to watch for this accident at those times quite as much as on other occasions, and to treat the disease entirely regardless of the existence of pregnancy. I do not agree with those gentlemen, therefore, who would induce abortion or premature labor during, and on account of, appendicitis.

I think the cases of appendiceal abscess occurring during labor and the puerperal state particularly interesting, and difficult to diagnose and manage.

PAUL F. MUNDÉ, M.D.

20 WEST FORTY-FIFTH STREET. October 14, 1895.]

"MATERNAL IMPRESSION."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Does not Dr. F. W. Maloney, of Rochester, N. Y., in his report in the MEDICAL RECORD of September 28, 1895, of a case of "maternal impression," where a whitlow on the thumb of a woman, six months pregnant, is said to have caused a supernumerary thumb on her unborn child, mistake cause for effect? Isn't there about as great a likelihood that the supernumerary thumb caused the whitlow as that the whitlow caused the supernumerary thumb? Is it not quite probable that "a supernumerary thumb fully formed with nail, apparently grown out of the primary articulation of the first phalanx," had its origin about as early as the thumbs that weren't supernumerary had theirs; or, at all events, long before the whitlow was thought of?

When it is remembered that there is no more connection between the nervous system of the mother and the nervous system of the child *in utero* than there is between the nervous system of the setting-hen and that of her unhatched chick, is it not nearly inexcusable for anyone to assert that maternal impressions of any sort can produce malformations in the fœtus, especially as late as the fifth or the sixth month?

E. T. SHELBY, M.D.

ATCHISON, KAN.

POTASSIUM PERMANGANATE IN MORPHINE-POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I feel it my duty toward the profession to comment upon a case of morphine-poisoning, reported by Dr. McDonald in the MEDICAL RECORD of September 28, 1895. One of the conclusions arrived at by the writer is "the apparent inefficiency of potassium permanganate." Now, the latter, intrinsically, cannot possibly be inefficient in antidoting morphine. One may just as well state that a strong alkali is incapable of neutralizing a mineral acid. In the case reported by Dr. McDonald, the patient had taken, at 5 A.M., the enormous quantity of twenty grains of morphine. At 6.30 A.M. he was given ten grains of the permanganate, partly internally and partly hypodermically. As the patient showed no improvement in the course of an hour, the doctor evidently concluded that the permanganate was inefficient. In my opinion the potash salt was eminently instrumental in saving the patient's life, as will be readily understood from the following: As soon as opium begins to exert its narcotic influence, gastric and intestinal activity is greatly reduced, and, consequently, the absorptive power of the gastric mucous membrane is very much lessened. It is, therefore, not surprising when we hear that considerable quantities of opium or morphine have been found in the stomach of persons who have died from this poison. Applying these facts to the case in question, we may take it for most probable that at the time when Dr. McDonald administered potassium permanganate, a large quantity of morphine was still in the patient's stomach. The doctor states ten grains of the antidote were given partly by the mouth, partly hypodermically. Even if the quantity given by the mouth did not exceed five grains, it will be seen that, most probably, at least five grains of morphine were decomposed by the antidote. The final issue of the case might have been quite different had Dr. McDonald not administered the permanganate. Every physician may well be satisfied if his patient regains consciousness one hour and a half after the ingestion of twenty grains of morphine!

Permit me to call once more the attention of your readers to the mode of administration of the antidote to opium:

1. One grain of permanganate of potassium decomposes one grain of morphine (six grains of opium or one drachm of laudanum).

2. If the quantity of the opium or morphine ingested is unknown, eight, ten, or fifteen grains of the potassium salt, diluted in one pint of water, should be given, and repeated twice or three times at intervals of thirty minutes. In cases of poisoning by opium (laudanum), a teaspoonful of diluted sulphuric acid or white vinegar —preferably, diluted sulphuric acid—can be advantageously added to the antidotal solution.

3. Hypodermic injections of a well-diluted permanganate solution should be administered at short intervals. One grain in one ounce of water, injected with an antitoxin syringe or an aspirator, will probably give better results than the use of concentrated solutions.

4. One grain of the antidote dissolved in a cupful of water should be given from time to time, in order to decompose the morphine, which the glandular lining of the stomach continues secreting for many hours.

I take this opportunity to express my hope that the day is not distant when our representative medical bodies, for the sake of science and humanity, will investigate the relation between potassium permanganate and opium. Academical committees have studied atropine in its relation to opium; why should the permanganate receive no attention?

WILLIAM MOOR, M.D.

103 WEST FIFTY-EIGHTH STREET, NEW YORK, October 10, 1895.

NUCLEIN IS NATURE'S ANTITOXIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read carefully the interesting dissertation on "Nuclein," written in your issue of September 28th, by Dr. J. Mount Bleyer, of New York. Not only have I found it well written, but its contents are entirely in accord with reason. I am of the opinion also, that from his point of view, it will be the end and the natural explication of the Brown-Sequard theory, and it explains the *rôle* of the leucocyte in phagocytosis.

I think, also, that nuclein is certainly the best way to destroy the infectious virus; although I think that nuclein and protoplasm must be constantly together, and it will not be possible to consider either apart from the other. But however correct his theory may be, I do believe that although nuclein is the best, it is not the only and single way to destroy the infectious material. I think antitoxins, single and alone, when attenuated, will be also capable of destroying the infectious virus, although that may be through the modifications impressed to the potoplasm and nuclein.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 19, 1895.

	Cases.	Deaths.
Tuberculosis	98	104
Typhoid fever	57	13
Scarlet fever	42	3
Cerebro-spinal meningitis	2	1
Measles	53	6
Diphtheria	137	12

The Infantile Causes of Epilepsy.—In Gower's latest book, "Clinical Lectures on the Nervous System," some careful observations on this subject are elaborated in detail. The most frequent infantile cause of epilepsy is rachitis. Clouston has also emphasized its influence in the production of other nervous diseases. It was Sir William Jenner who demonstrated that the condition of rickets is a general retardation of development, with various secondary necessary results, and of the association of convulsions with this general state. Backward teething is also a manifestation, but is now fully understood not to be a cause in itself of the convulsions of infancy. These are a consequence of the retarded development which occurs so often toward the end of the first year. It is the epoch at which the character of the food-supply undergoes change, or does not undergo the change that is natural. It is also a period when much functional capacity passes into functional use. The influence of rickets in causing the convulsions of infancy are of great importance in connection with epilepsy. They leave behind a residual disposition to a like morbid action, which may be continuous in its results, or may become active at a later period of life. Every variation of interval is met with. It is impossible to doubt that the convulsions of dentitions are a definite element in the causation of epilepsy. And it is also impossible to doubt that the prevention of rickets would have a considerable influence on the prevention of epilepsy.

Convulsions due to retarded development are general; so also are the epileptic attacks that follow them. This is an important point to remember. Moderate in severity, when continued in epilepsy, the attacks often become slighter, until they are merely minor attacks with loss of consciousness. There may be only the slightest indication of spasm or no trace of it after a time. Minor attacks may continue a few years, and thus muscular contractions may be added to loss of consciousness. There are two other forms of epileptic attacks that can be traced to the convulsions of infancy. In the first, the spasm can be observed to commence locally, in the hand or face; and appears on one side before it does on the other. The attacks during babyhood in these cases were also of this nature, the first seizure being often of great severity. Such convulsions mean unilateral instability of the motor structures of the brain, and the local change excludes a general cause that would act on the whole brain. There is organic disease in the cortical region. If profound, and in the motor region, hemiplegia is the result. This may be slight or severe, lasting a lifetime, or passing away in a few months. The third class of cases in which epilepsy has its origin in infancy is found among first-born children who make their entrance into life under great difficulties, and the symptoms of their convulsions are due commonly to the effect of meningeal hemorrhage. A small number of cases dating back to infancy, and not belonging to these three classes, are those associated with congenital brain defect. Underlying all the phenomena of epilepsy, whatever its cause and its features, there is one fact which it is important to recognize. Convulsions are far nearer normal action than this startling aspect suggests. In health, nerve-centres are always ready for the instant vigorous liberation of nerve force. A perception of danger induces in an animal, and often also in man, motor activity as intense as that of an epileptic fit. By their nutritional state, the nerve-structures hold, ever ready for release, in vast amount, the latent energy that excites the muscles. Considered from the dynamic point of view the amount is, no doubt, trifling, not to be measured by its manifestation in the muscular contraction it excites. The perfect readiness which underlies its instant release in health, underlies also its instant liberation in disease. Thus may be explained the fact that the apparent causes of epilepsy are often such as seem inadequate.

Dead Chinamen as Freight.—A curious freight which is shipped exclusively from San Francisco to China is "fish-bone," which pays $20 a ton. It is sent in large boxes consigned to the Tung Wah Hospital at Hong Kong, but the contents of the boxes are really the bodies of dead Chinamen sent home for burial. Most of the Chinamen who come to the United States are under the care of the Six Companies, who sign a contract guaranteeing to return the bones of the dead for burial with their ancestors in the Celestial Empire, and the Tung Wah Hospital acts as the agent on this side in carrying out the agreement. They are shipped as "fish bones" in order to evade the rule of the steamship companies, who charge full first-class passenger rates for the dead. Nearly every ship leaving San Francisco for China carries among the steerage passengers a number of invalids who hope to live until they reach their native country, but several usually die on every voyage. There is an agreement between the steamships and the Six Companies which forbids the burial of these bodies at sea, and the latter furnishes coffins of the peculiar Chinese pattern for use in such emergencies. They are made of slabs, the first cut of the log, so that the sides and bottom and top are rounded. A dozen or more are carried on each ship, and the surgeon is furnished with a supply of embalming fluid. When a Chinaman dies at sea, the surgeon embalms the body, which is then placed in a coffin, sealed up, and lowered into the hold. The expense is paid by voluntary contributions from the other Chinese passengers, the crowd, and the stewards of the ship—all of whom belong to that race. No subscription paper is passed around, but a pan containing Chinese sugar is placed beside the coffin, and every Chinaman on board drops in his contribution, from a dime to a dollar, and takes a piece of sugar from the pan, which is supposed to bring him good luck and prolong his life. When the ship reaches Hong Kong, the coffins and the belongings of the dead are delivered to the Tung Wah Hospital, which disposes of them to the surviving friends in China. Every Chinaman in the United States is supposed to be registered at the Tung Wah Hospital and with the Six Companies at San Francisco.

Empyema in Children.—1. When pus is found to be present in the pleural cavity, the proper treatment is to remove it. 2. The best method is simple incision and drainage. 3. The best site for the operation is the fifth space in the mid-axillary line. 4. Irrigation is unadvisable, and is indicated only in cases of fetid effusion. 5. Exploration and scraping of the cavity are not necessary. 6. Resection of the rib is practically never necessary in children as a primary procedure to procure efficient drainage, but may be required to secure the closure of the sinus, subsequently, by allowing the chest-wall to fall in. 7. Collapse of the chest-wall is not a result to be desired in the early stages of the treatment. 8. Rapid and complete expansion of the lung is the great object of treatment. 9. The tube must be removed early.—CAUTLEX.

ON THE DEFORMITIES AND MALFORMATIONS RESULTING FROM ACUTE INFECTIONS IN BONE.[1]

By ROSWELL PARK, A.M., M.D.,

BUFFALO, N. Y.

PROFESSOR OF SURGERY, THE MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

It is apparently the depth and the concealed location of the bone-marrow which has prevented a more general and wide-spread recognition of the readiness with which the internal structure of bone succumbs to infection and to destruction. The clinical consequences of this internal disease have long been recognized, but accurate notions regarding its pathology have not been in vogue until comparatively quite recently. At the very outset it is well to make an abrupt distinction between those alterations in texture, contour, density, etc., of bone which are the result of perverted nutrition, of alterations of trophic-nerve influence, etc., and which are distinctly not infectious, and another series of changes similar perhaps in gross results, very dissimilar in etiology, which are the consequences of acute infectious processes, which have their analogies in various of the soft structures of the body, where they have been longer recognized and more carefully studied, because more easy of access. Indeed, as Savory some years ago showed, bone and lung react in a very similar way to infections, the analogy in some respects being even striking. Both bone and lung are surrounded by a firm, investing membrane; both have a more or less spongy texture: both are extremely liable to tubercular invasion, while in either case the disease usually selects the apices for its primary manifestation; both are in close relation, the bones especially by their joint ends, with serous cavities which become secondarily involved in the majority of instances—in the one case as a pleuritic effusion or an empyema, in the other case as a joint effusion or a pyarthrosis: while the picture of miliary tubercle in either structure is beautifully distinct and clear. Savory did not point out, however, that which I would like to emphasize here; for instance, that bone as a tissue is, nevertheless, subject to an acute miliary invasion of tubercle corresponding to an acute miliary tuberculosis, as well as to certain streptococcus and staphylococcus invasion, producing a condition of affairs corresponding materially to acute lobar pneumonia, in which the whole structure of an epiphysis or a shaft is involved, and in which, owing to the intensity of the process, local gangrene may result, producing in the one case a gangrene of the lung, in the other a gangrene of the bone, a fulminatingly acute necrosis which means death of the patient if not speedily attended to.

We need not hesitate, then, to compare bone and lung, if only we take the view concerning the former that students are not generally enough taught, that the calcareous infiltration of bone is simply an incident favoring its physiological function, and that it may become inflamed and act in every other way like any of the soft tissues. When we cease to make artificial distinctions, which nature does not make, we shall have much clearer ideas of bone pathology. The acute phases of these infectious processes are not usually considered in works on orthopædic surgery, nor do they often come under the observation of orthopædists, who are so often concerned with their remote consequences. Nevertheless, in order that the matter may be the better appreciated, I deem it wise to say a little more about the acute condition first. That acute inflammation (*i.e.*, infection) of all or any of the structures which go to make up the bone is possible, is now a well-established fact. Inasmuch as each one of these tissues comes at least into close contact and relation with the others, even if it does not insensibly merge into it, it is not often that one meets with an infection of one which is not conveyed to the others. Clinically, however, there are three locations in which these manifestations are most commonly met with: *a*, Beneath the periosteum; *b*, in the epiphyses; *c*, in the diaphyses.

From the pathological side, infections are of four main varieties: *a*, The tubercular; *b*, the staphylococcus; *c*, the streptococcus; *d*, the pneumococcus. To these may be added, *e*, rare instances in which other organisms are primarily or secondarily present.

Of these certainly the more common is the tubercular form, whose manifestations, however, are usually not acute. The other three may be grouped in a general way as pyogenic forms of invasion in which pus is practically invariably produced, providing only that sufficient time has elapsed.

Although it is not exactly germane to my subject, I cannot let this opportunity pass without calling special attention to one manifestation of tubercular bone disease, which I grant is rare, but, nevertheless, which is not sufficiently recognized. I allude to the acute miliary tuberculosis of bone which corresponds in most essentials with similar invasions of the lungs, and of which I have seen occasional examples. This is not generally described, even in the most recent literature, and would deserve more space than I can give it here were this the place in which to consider it. It is not quite so rapid as the pyogenic forms, and it may take two or three weeks to produce such destruction of the bone as to necessitate operation. It stands, therefore, in intermediate position between the acute infections and the slower (*i.e.*, usually the tubercular) lesions. Nevertheless, it is sufficiently acute to demand prompt recognition, and when recognized may often be relieved by prompt operative interference.

The course of a bone disease, then, will depend first upon the location of the lesion, and secondly upon its character. If it assume a very acute type, and if prompt evacuation of morbid products be carried out, such a bone disturbance will usually subside with very little deformity, there remaining perhaps only a scar marking the site of the operation. Take, for instance, a subperiosteal infection of the ulna or fibula. If, now, this be recognized during the first day or two, and if a long incision be made down on the bone, there is ample opportunity for escape of pus and of other morbid products, and there will be prompt reapplication and reunion of periosteum and bone with a minimum of loss of function, occasioned only by the occurrence of a cicatrix. If a deep and acute bone abscess form in the

[1] Read before the American Orthopædic Association, in Chicago, September, 1895.

shaft of a bone, and the same be promptly opened, it corresponds to an acute abscess in the neck or elsewhere, and only a scar will remain to indicate what has happened. If, however, prompt recognition and immediate incision do not occur, the consequence will be extension of the disease, increasing destruction of bone, possibly necrosis of the entire bone shaft between epiphyseal junctions, possibly spontaneous perforation, with sinuses through which sequestra may protrude, or at least be recognized. These usually come to the surface by a reasonably direct route, which affords exit with a minimum of disturbance of surrounding soft parts; but this is by no means always the case. Finally, if the acute focus be located in an epiphysis, there is usually prompt involvement and infection of the joint, loosening of epiphyseal connection, with a resultant pyarthrosis and necrosis of a bone end, which will require something more than a mere opening and evacuation of a joint, which may call for resection, or even amputation. In such a case dislocation finally occurs. I have seen this condition most often at the hip, and have repeatedly known of an acute osteomyelitis of the upper epiphysis of the femur, which has pursued a rapid and unbroken course until such destruction has occurred as to permit of spontaneous luxation during the act of lifting the patient, with the production of two inches of shortening within half an hour. Such a case is an aggravated one, to be sure, not illustrating the common phases of this disease, yet, nevertheless, not so rare as could be wished, and not one whit overdrawn. I have, moreover, repeatedly seen such absorption of calcareous stiffening—in other words, such an artificial and pathological flexibility of bone produced—that torsion of the shaft of long bones or more or less angular deformity was produced, either rapidly, in some instances by mere muscle spasm, or in other cases by too early or indiscreet effort to support the weight of the body.

Osteomyelitis may be a tedious and long-drawn-out disease, which may also be characterized by acute exacerbations. It is well to keep this fact in mind, for it does not follow that every bone fistula or sinus is due to tubercular disease, though it is always open to the presumption of having become tubercularly infected. Albert, for instance, has called attention to the confusion between the two conditions, especially in the latter part of certain cases. The anatomical picture about the joint involved in the one case is not materially different from that of the other.

Concerning the character and extent of possible destruction in these cases, one meets with all degrees of destructive changes, from the mildest appreciable up to total destruction of an entire bone, or even to gangrene of an entire extremity. Other things being equal, the most destructive lesions are those which produce the greatest deformity. Yet, of the inveterately deformed cases, it is sometimes those which are least involved which will be subjected to orthopædic treatment, while those in which deformity is very great would be subjected to resection or amputation.

If one seek for the reason why one bone is involved oftener than another, it may possibly be explained by the normal rapidity of bone growth in different bones. According to the investigations of Langer, the co-efficient of growth in the femur is 4.38, in the tibia 4.32, in the humerus 3.97, in the radius 3.83. This scale perfectly coincides with the frequency of disease in the bones mentioned. Studying for a moment the prevailing localities in which remains of lesions are found, and basing this study upon 181 patients collected by Helferich, we find that the lower end of the femur was involved in 40 instances, the upper end of the tibia in 29, the tibial shaft in 19, the lower end of the tibia in 18, the upper end of the humerus in 16, the remainder being scattering. These, to be sure, were cases of necrosis as the result of the disease; and, nevertheless, they serve our purpose in showing relative frequency of location of foci.

As showing also the relative frequency of parts involved, of 30 cases observed by Kocher the disease occurred 13 times in the tibia and 11 in the femur. Of 98 cases collected by Leucke and Volkmann, the femur was involved 36 times, the tibia 34, and the humerus 11. Disease in the immediate neighborhood of the hip-joint is about five times as common as in that of the knee. Comparing epiphyses with diaphyses, and accepting Schede's 67 cases, we find that of 28 cases in which the femur was involved, half of them were in the shaft and half in the diaphysis. In the tibia, of 27 cases only 9 concerned the epiphysis, and of 7 cases of the humerus, 2 involved the epiphysis.

Arrests of development in bone as due to bone inflammations have long been known. Blasius, for instance, described a case in which an adult arm never passed beyond the dimensions of that of a child; and numerous such cases are on record. Mild differences of this kind have been often overlooked, as Helferich emphasizes. As between the two femora and the two humeri considerable changes may often be noted, which will be explained if one gets a careful history of the patient's life. I may also remind this Association of that form of increase in the length of long bones spoken of by Ollier and Mondan as "atrophic elongation," to which I called attention a few years ago in a paper to which I would refer those who are further interested.

Relative to persistent joint lesions which may result from acute bone infections, we may get very interesting statistics from the memoir of Haaga. Out of 28 cases in which the upper end of the femur was involved, in 22 there were more or less well marked persistent lesions. Of these 22, in 14 mobility was diminished, and in 10 of these there was absolute anchylosis, twice in the straight line, 8 times with more or less flexion of the thigh. In the other 8 cases there was spontaneous luxation to a greater or less extent. Out of 28 cases involving the arm, the humerus was involved 7 times, and of these 7 cases one presented a subcoracoid luxation, and in another a very marked limitation of movement existed. In 2 others there was a persistent hydrarthrosis. Of 19 cases involving the elbow, the humerus was involved in 10, the radius in 6, the ulna in 3; the elbow-joint was destroyed in 2 of them, was anchylosed in 4, and presented distinct lesions in all the others. Of these 19 cases the immediate neighborhood of the joint was involved in only 7; in the other 12 the lesion was more or less remote from the joint. In 7 cases involving the wrist, the radius was involved in 4, the ulna in 3; in each instance anchylosis was complete, and in 4 others there was marked restriction of motion.

Haaga has epitomized 470 cases of distinct osseous foci altogether, in which 189 showed distinct joint lesions, which were more or less persistent.

Out of 24 cases involving the ankle, the lower extremity of the fibula was involved in but 1. Of these 21 were more or less anchylosed; in 1 case there was a flail joint; in two instances the joint was destroyed; and in one there was chronic hydrarthrosis.

Secondary affections of the knee were extremely frequent. Of 107 cases of disease of the lower end of the femur, the knee was involved in 71. Of 54 cases of involvement of the upper end of the tibia, the knee was involved in 21. Studying 109 lesions of the knee, Haaga found luxation forward once; subluxation, 9 times; flail joint, 11 times; articular destruction, 5 times; late suppuration, 6 times; while motility was diminished in 77 cases, of which in 20 the difficulty was caused by anchylosis, and in 57 by a contracture.

Another kind of deformity is that produced by arrest of growth of the joint end of one bone and compensatory hypertrophy or parallel alterations in the other and participating bone. Absolute arrest of de-

velopment occurs naturally only in growing children or adolescents: and these deformities will at least arise during youth, although they may be met with much later. I have, for instance, in my possession a specimen illustrating arrest of growth of the lower end of the tibia, while the fibula continued to grow, so that its lower end assumed a literally circular shape, the lower two and one-half inches constituting 90° of a circle of four or five inches in radius. In a case, for instance, reported by Marchant,[1] the region of the knee was greatly enlarged and deformed by the presence on the inner side and posteriorly of the head of the fibula, whose upper styloid process was on a line with the upper border of the patella, having been pressed there by the weight of the body and lack of growth in the tibia. The upper half of the fibula was greatly thickened, but flexion was possible to a right angle.

One should also speak in this connection of that class of deformities which are produced by muscle contractures, which have at the time seen not yet proceeded to the point of anchylosis, except so far that motion beyond certain degrees was impossible because of these same contractures. In other words, these are joints whose function is much interfered with and in which extremes of motion are not permitted, and which, nevertheless, serve still a useful purpose in most respects. I do not know that there is any marked difference in the frequency with which the various joints present lesions of this kind. In more or less mild degree, and for greater or less length of time, these conditions obtain in the neighborhood of any joint which lies in proximity to a focus of acute bone infection.

Torsion and flexion of bone which has been the seat of previous disease is not at all infrequent. Even muscle pull alone is sufficient to account for many of these cases. Richter has reported from the Breslau Clinic a specimen of diseased bone in which fracture had been diagnosed because of the deformity. Diesterweg has also described a similar case from Volkmann's clinic, in which there was such remarkable curvature of the trochanteric part of the femur as to permit of luxation.[2]

In a general way I would divide the deformities which are due to inflammatory bone changes, into those which pertain to juxta-articular lesions and those which have their anatomical seat in the shafts of the long bones. This is a classification purely for purposes of convenience, and implies nothing regarding pathological differences. Of the former class, the most conspicuous are, first, those produced by anchylosis. This will be readily appreciated as due to the intensity of inflammatory change and to organization of solid exudate, to cicatricial contraction, etc. It is usually of the spurious or fibrous type, but is occasionally of true osseous character. I could show, were it desirable, numerous specimens indicating the rigid consolidation and stiffening of such joints by osseous tissue.

There is a variety of change, of which frequent expressions are seen, which is due to compensatory enlargement of one bone in order to atone for more or less weakening of another. This, of course, is met with only in the leg and forearm, where we have paired bones. I have seen several instances where, after serious weakening of the tibia, the fibula has enlarged almost to the previous size of the tibia, and has gradually prepared itself in this way for sustaining the weight of the body and assuming the functions of the tibia. Along with these changes in the bone-shaft there are also changes at the extremities, which would be difficult to describe in a few words, and which hardly call for it, the present paper being concerned rather with statement of facts than with minute description of cases. One may see the same condition in milder degree in the metacarpal and metatarsal bones. I am not aware of similar changes having been noted in the ribs, although I consider them possible.

Dislocations and subluxations constitute another variety of joint deformities which may have been produced either by muscle spasm alone, as in the slower forms of tubercular disease; by destruction of the ligaments and removal of opposition to displacement; or by epiphyseal separations, which sometimes occur in connection with acute cases of the pyogenic type.

The dislocations met with as the consequences of bone infections may be described, first, as of the distention form—that is, they are permitted through the great distention of the joint as the result of outpour of products of inflammation and infection. These are the most genuine of the spontaneous luxations. A remarkable case of this kind was observed at the shoulder by Stromeyer.

A second form is due to the early consolidation between epiphysis and diaphysis, and the consequent cessation of growth at this point. When, for instance, this occurs in the tibia, the corresponding fibula end will continue to grow, and subluxation must be the result. I have now under occasional observation a young lad whose radius was nearly destroyed by an acute infection of this character, but whose ulna has continued to grow. The styloid process of his ulna now presents nearly half-way down on the outside of the fifth metacarpal, and great displacement and deformity of the hand result. In this case I have advised, and expect to perform, a resection very soon.

A third case of osteomyelitic dislocation is due to overgrowth of the ligaments, due to hyperæmia of the parts and increase of nutriment conveyed toward the seat of activity. Ligamentous bands thus overgrown, stretch and give rise to flail-like conditions of the joints.

Albert has also alluded to the spontaneous fracture due to epiphyseal separation. In most of these cases the epiphyseal cartilage will be found normal, and it is rather in and about the shaft of the bone that one would look for most evidence of disease.

Epiphyseal separations, accurately speaking, are among the most serious of complications. According to observations made by Garre, in Tübingen, they occur in from twelve to fifteen per cent. of cases. These occur most frequently of all at the lower end of the femur, then at the upper extremity of the tibia, and then at the hip.

Epiphyseal separation without suppuration is rare, but has been distinctly established. Until further investigations clear up its pathology, we must hold it to be due to alterations in nutritive supply and vascular conditions of the involved bone; that there is solution and disappearance of those calcium salts which are usually regarded as cementing by their deposition the union of epiphysis to shaft.

Ullmann reports a twelve-year-old patient with eight centimetres shortening of the thigh with angular deformity. Here it was very evident that spontaneous fracture had taken place at the site of an old bone focus. Fracture may also occur as the result of rarefying ostitis without the necessary presence of a sequestrum. Spontaneous fractures also occur sometimes after operations made necessary for removal of large sequestra, and I have myself twice seen the tibia break in this way. Such cases constitute in effect a sort of infected compound fracture, and it is not to be expected that recovery will ensue without considerable shortening, distortion, or other changes.

Some special manifestations of osteomyelitis are met with in somewhat novel and unusual places. Thus Froehner has published a unique case of infectious osteomyelitis of the nasal bones. It occurred in a young man, aged seventeen, and was followed by fever with tumefaction of the region involved. The jaws are known to be occasionally involved as well, and perhaps most often in those instances of multiple lesion

[1] Revue d'Orthopédie, March, 1893.
[2] Ueber die Verbiegungen der Diaphysen nach Osteomyelitis Acuta, Inaug. Diss. Halle, 1882.

which are of pathological, rather than of orthopædic, interest. In one instance, mentioned by Gangolphe, the jaw was involved along with both tibiæ, a metatarsal bone, and the sacrum. This form of osteomyelitis of the jaw is to be distinguished from the post-febrile form of periostitis, to which Salter has particularly called attention, as following measles, scarlatina, etc. While the latter is distinctly a secondary infection, it, nevertheless, has an etiology somewhat different from that met with, for instance, in Gangolphe's case.

Osteomyelitis of the skull is usually followed by acute necrosis, and will frequently terminate within a short time by meningitis, sinus phlebitis, pneumonia, endocarditis, or other pyæmic manifestations; it has for us, as orthopædists, only a remote interest at this time.

But osteomyelitis of the vertebral column, although rare, may concern us very deeply. Such a case has been reported, for instance, by Lannelongue as one of primary infection of the vertebral column, with metastatic lesions in the leg and in the forearm. The result in his case was death; but the fact that these lesions may occur in this location should by no means be forgotten.

So, too, in the clavicle, osteomyelitis is usually followed by acute and total necrosis. In some instances there has been a very tardy reproduction of bone, due to activity of the osteoblasts which remained upon the periosteum. Such disease in this bone may give rise to great disfigurement about the shoulder, as well as loss or disturbance of function. So, too, in the ribs and in the sternum. One meets in literature with isolated cases which are not without considerable interest. Thus, Froehner observed a case of this kind in a young child aged four, in which suppuration occurred and necrosis followed. Considerable attention has been paid to this matter in two or three recent French theses, as by Berthomier,[1] by Hasle,[2] and by Barbacci.[3] As in the other long bones, the favorite locations in the ribs appear to be close to their terminations. The disturbance and swelling due to lesions of this character, near the head of a rib, may give rise to a great deal of uncertainty in diagnosis. Berthomier has in his paper discussed the physical signs, differential diagnosis, etc. Salomon has reported the case of a man, aged twenty-one, sick for ten days, who, on the sixth day complained of pain in the right sterno clavicular region with swelling and fluctuation. On the tenth day inflammation of the lower lobe of the right lung was evident, and delirium, followed by death, occurred. On autopsy it was shown that there had been osteomyelitis of the sternum with perforation of pus into the right sterno-clavicular joint. I have myself seen three cases of acute or chronic lesion of this kind of the sternum, in which there was more or less disfigurement of the chest, though I cannot say that it attained a degree of deformity which would attract attention when the patient was clothed. Several cases of considerable deformity due to this cause are, however, on record.

In the pelvic bones these infections occur rarely, but give rise to most serious symptoms when they do occur. According to the part involved and the arrangement of muscles, we will have posture deformity of the thigh with fixation by muscle rigidity, etc. This posture deformity may even become permanent. Deformities from this source would be probably more often met with were it not for the fact that acute osteomyelitis of the iliac bones is followed by death in more than half of the cases.

Acute infection of the patella is by no means unknown, and has been seen in very young children, even to such an extent that almost total necrosis has resulted. In some instances, and very slowly, new bone has been reproduced to take the place of that which has been thus lost. It would appear in these instances as if the posterior cartilaginous surface of the patella served as the barrier by which perforation into the joint were prevented.

It is perhaps more often in the larger bones of the tarsus, particularly the calcaneum and the astragalus, that we meet with multiple but small foci, each of which is followed by limited necrosis, and which gives rise to what Ollier has spoken of as "disseminated necrotic ostitis."

Necrosis forms, by all means, the most common result of osteomyelitis. It may assume either of the following types, with corresponding variations in resulting deformity (Ullmann):

1. Peripheral necrosis or cortical necrosis, in which a more or less thick scale is detached from the external portion of the bone.

2. Central necrosis, connected with the marrow cavity, at least, connecting that part of the bone which comes into direct contact with the bone-marrow.

3. A lamellated form, in which an intermediate portion of the compact substance dies and a sequestrum results which extends neither to the surface nor to the interior cavity.

4. Penetrating necrosis, where to some extent the entire thickness of the bone is involved, *i.e.*, from periosteum to centre.

5. Transverse necrosis; the same as 4, except that it extends completely around the bone.

6. Total necrosis, where the entire shaft is separated as a sequestrum.

7. A disseminated form, particularly described by Ollier.

Necrosis concerns us here as orthopædists mainly in this, that it produces in many instances a weakening of the bone which may lead either to fracture, deformity, or curvature. Spontaneous fractures of necrotic bone have occurred under my observation; and I remember one case of necrotic femur which broke as we were lifting the patient upon the operating-table.

Incidentally, there is danger of cancer in some of these cases, for Volkmann collected thirty-two cases in which old and fistulous passages became the site of epitheliomatous changes, and in which cancer was the final result.

SOME GENERAL CONSIDERATIONS ON PARESIS—IS IT A MICROBIC DISEASE?

By LOUIS C. PETTIT, M.D.,

WARD'S ISLAND, NEW YORK CITY.

The following paper is the result of the study of the clinical histories of over thirteen hundred cases of paresis, and is supplemented with a few of the great changes observed in over fifty autopsies. In such a large number of cases of paresis an observer is necessarily and perhaps unwillingly impressed by frequent anomalies in the clinical and histological features of a disease progressively involving the entire cerebro-spinal system and directly or secondarily interfering with every function requisite to life.

Paresis as already defined is a disease tolerably uniform and specially classified among the insanities and differentiated from other forms not only by somatic signs, but by an almost constant dementia and a general enfeeblement of intelligence; a disease of the body and of the mind, a morbid connecting link between the "material basis of mind" and immaterial entity; a disease that steers its own way in the whimsical classifications of insanities, and at the same time embodies every conceivable psychical type, with true dementia as a basis, and affective and intellectual disorder in bas-relief.

The etiology of paresis has not as yet revealed to us much that really enlightens as to the direct source of

the disease. We have only the complex conditions under which it may occur. In our present state we can say that two-thirds of the paretics have been immoderate drinkers; at least one-fourth have had syphilis; a small proportion have indulged in sexual excesses, and the remainder have been moral and temperate, and acquired the disease in the legitimate pursuits of life. Many have indulged in the entire category of supposed inciting causes. A rationalist will ask, Why should alcohol or syphilis or both cause paresis in man, and almost never in woman? or, Why should such causes produce in one paresis and in another a dementia wholly different? Syphilis and intemperance have existed almost since the advent of man upon earth. Paresis has grown upon us, or rather we have grown to recognize it, during the last few decades. Even admitting that the above mental strain and a rapid exhaustion and stasis of nerve force may cause or produce similar early symptoms or the prodromic disease, what causes its progression after these supposed causes have ceased to exist? The cerebro-spinal system needs only touching by this disease and the rest is done. A possibly novel or at least not generally known fact is, that paresis occurs frequently among the robust children of phthisical parents. Without any effort on my part, or special object in view, knowledge of this fact was impressed upon me by the very large percentage of phthisical relatives in the families of over thirteen hundred patients dying of paresis. Again, contemporaneous heredity, and its occurrence in two or more brothers or other members of the same family, where attributed inciting causes were not sufficient, may argue toward a predisposition. Paresis and phthisis may in some manner be related to each other in some mysterious etiological sense. Paresis is no respecter of persons, at least of men, neither does it select persons already infected with disease, unless the forerunner be either syphilis or phthisis. At times the materies morbi of these two diseases are interchangeable, and may not these impose their duties upon others, or could the already present schisomycetes undergo an autochthonous evolution and thereby produce a new micro-organism, the cause of paresis? While much may be found in the present etiology of paresis to substantiate the theory of micro-organisms, vastly more is shown at the necropsies and will be treated of later.

The characteristic or pathognomonic somatic signs of paresis are not many, neither are they uniformly and collectively present. While there is the widest range of disturbance of the intellectual sphere, the physico-motor phase of the disease in a large majority of cases is manifested by rather few but usually well defined symptoms. The psychical symptoms are first to attract attention; friends of the patient recognize something wrong, a change from the normal state; the physician recognizes the physical signs and the diagnosis is complete. The early recognition of psychical symptoms by friends and relatives is no criterion by which we can judge of the time of appearance of physical signs. It must be assumed that the psychical and motor symptoms of this disease appear simultaneously; clinical history substantiates this, and our present knowledge does not permit us to say that the disease selects preferably the "basis of mind" to that of motion.

Among the earlier manifestations of paresis we study the physiognomy. One long associated with paretics grows to recognize them almost at a glance. The expression in addition to being an index to the mind is accompanied by more or less permanent physical change, an asymmetrical lack of muscular and dermal tone. There is a lack of expression, a want of stimulation from the brain. A slight dropping of the lower jaw, a tendency toward roundness, especially when there is delirium of an expansive type present; or there may be a fixed, stony expression, a lack of that reaction which gives character to mental acts; later there is an increase of ideo-motor reflex action. The face at rest once put into motion brings out an entire new feature of the disease, a physical lack of proper co-ordination. Probably of all the physical signs of paresis none are more pathognomonic than a slight clonus of the upper lip on retraction, not in all cases observed, but when present needs fewer associative symptoms than any other to establish a diagnosis. The presence of fine fibrillary tremor in the upper eyelids on easy closure will reveal remarkably slight loss of co-ordinating power. Tremor of the tongue is rarely absent. Any or all may be present; at times they are transitory, disappearing after treatment. Leaving the face we examine the hands by placing the finger-tips on the dorsal surface of the interdigital folds, and the same distinct fibrillary tremor is felt and is frequently accompanied by a fine crepitation. Lastly comes the knee-jerk; be it either exaggerated or diminished it has weight in the general phenomenon, and is of much more value when increased than diminished. In testing the knee-jerk in this disease the free hand should be placed lightly upon the quadriceps and its contraction estimated; the arc subtended by the foot does not always fairly represent the increased irritability, and depends on the tonic state of the muscle at rest. There may be a violent contraction of the muscle and but little response in the foot. The foregoing symptoms must be associated with some evidence of mental disturbance, transitory or permanent, or with vertiginal attacks, or temporary loss of speech, or hemi-paresis, and the diagnosis will be positive. There is a diagnostic value in this association of symptoms that cannot be overestimated, no matter how slightly developed. Out of five thousand cases of insanity in the male, the nearest approach to this chain of symptoms was exhibited in a few paranoiacs, about the only difference being in the character of tremor, which in the latter was coarse and more general in distribution, and obviously due to emotional disturbance and a maligned feeling. Acute alcoholism may confuse one for a short time; in such cases the diagnosis should be in abeyance. Pupillary symptoms usually come later in the disease, and little early change may be sought for other than a slight akinesis and decrease in range of action in the iris. Myotic and spastic pupils are of serious import and may be prodromic; if "pin-holed," a long course of disease may be premised. Probably not more than five per cent. of cases will present this symptom, usually alcoholics or rheumatics over forty; at times it appears to be merely concomitant and from a different cause. There is a remarkable acuteness of vision in such patients, but they require more light.

Some detail of the psychical disturbances in the early or prodromic stage of the disease will not be out of place, as we assume that mental reductions must always be present; they are the result of external psychical stimuli and the increased reflexion from spontaneity of thought. The prevailing impression is, that paresis is accompanied by expansive morbid delirium; this to a certain extent is true, but misleading; probably more than one-fourth of all paretics pass entirely through the disease without manifesting l'alienation ambitieuse; once exhibited there is no symptom, psychical or motor, of more diagnostic value. Transitory expansive alienation, in fact a single sentence in this tenor, has given many a clew; "this clew once found unravels all the rest." The early psychical symptoms are commonly a mere absent-mindedness, not wholly inconsistent with perfect health; at times mental restlessness or unrest, broken by a painfully acute perception of something being wrong or a morbid fear of death.

At the present time public knowledge of paresis is so wide-spread that it is not unusual to receive patients who knowingly are afflicted. Such patients are given at times to a painful self-consciousness, and pitifully appeal to the physician for help. A recent case said that his greatest ambition was to die, and prayed that his life might be speedily taken. Transitory al-

ternating states of depression and exaltation, however, soon flicker and are smothered by progressive dementia. Leptomania, where the morbid desire is accompanied by an irrational act, is common. A sense of confusion is present with a bewilderment, during which mental inhibition is lost and ludicrous; sometimes marvellous feats are performed. Vague and indescribable sensations and hallucinatory sounds are often prodromic. One patient spent months trying to grow a pansy to the size of a sunflower, and ransacked Jersey for rich earths; finally he became irritable and morose, and a menace to his family. Another purchased six clocks. A third, after many wonderful experiences and hair-breadth escapes, extending over a period of one year, presented himself at his mother's door at one o'clock in the morning with two red lanterns swinging on his arm; so on *ad infinitum*. There is a change in demeanor or habits toward spendthriftiness or demoralization; attempts toward insuring one's life without appropriate means; gamomania and the consummation of the desire by the act: the predicament of having more than one wife is pleasing enough when one's turrets are armored with dementia. Rarely is there anything like distinct sexual perversion. Expansive ideation (megalomania) is usually a later manifestation, but may be present from the beginning. The ordinary psychical course is first an indefinite period of mild mental deterioration with some confusion of ideas or apathy; during this stage purposeless acts are performed. Then follows a short period of depression during which homicidal or suicidal tendencies develop. Mental stasis followed by an æstheticism and delirium of grandeur complete the cycle.

It is impossible here to detail at length the premonitory symptoms in many cases. I will refer merely to those of a single case. A patient at present thirty-seven years of age, whose mother died of phthisis, and whose sister is suffering from melancholia, had syphilis nineteen years ago. He was treated in the Hamburg (Germany) City Hospital, and was informed that he was "cured," as the profession at present accepts the term. He married nine years ago and has three healthy children; has been a moderate drinker, and states as follows: "I was apparently in good health four years ago, but began to suffer from insomnia and headaches to a slight degree only, when previous to retiring one night I felt a heavy feeling around my chest and went to the window to get more air and then to bed. I did not sleep; was sitting up in the bed when suddenly everything seemed to pass out of sight; then I felt a burning sensation as if I was being cut in two lengthwise with a knife. I lost consciousness for a few seconds; on regaining it I felt an intense burning all over my body, which I could not cool with water. I was then weak on the right side and unable to speak distinctly, and my head felt as if an iron cap were being pressed down upon it. In two days I had recovered my usual strength and went to work. I continued to suffer from insomnia, and began to worry about my future and family, and suffered from headaches and pains in the right leg and knee and over the spine; these symptoms lasted over two years." The patient's friends state that during the past two and a half years he has been more or less at times confused, mildly excitable and emotional, and during such periods has had difficulty with his speech. He lost his position, and through unreasonable jealousy became a source of apprehension and a menace to his family. With the above premonitory symptoms of nearly three years' standing the patient was admitted to this institution one year and a half ago, presenting the following somatic signs: His pupils responded to both light and accommodation sluggishly, were regular, and the left showed a slight paradoxical reflex. There was a marked tremor of the upper lids on closure, a slight clonus of the upper lip, and a fine fibrillary tremor around the margin of the tongue, which was moist but deeply fissured. There was a crepitation of the hands and the usual tremor. The knee-jerk was slightly diminished. The above conditions continued to exist in spite of antisyphilitic treatment. The grandiose ideation was shown in a single letter which he wrote to a friend; in this he characterized himself as "like to Him." The dementia was seen in the accumulation of trash in his bed. It is needless to state that he is well on in the trodden path, far beyond "old sheet-anchor iodides." There are many reasons why I have chosen such a case for illustration: First, the typical paretic is represented; secondly, those who believe in a pseudo-paresis will find solace in syphilis; again, the long period of prodromes furnishes almost every prominent psychical symptom of paresis to a certain degree. Such cases have been called syphilitic peri-encephalitis. If there is any positive means of demonstrating that this patient's disease is syphilis, then I shall believe that syphilis and paresis are convertible terms. Similar cases to the above are of common occurrence. The danger in diagnosing syphilis will only be fully appreciated by those who have seen identical cases without either syphilitic, phthisical, or neurotic predisposing or contributing causes. Is paresis an atavistic anomaly of syphilis, or can we differentiate supposed causes until we are compelled to individualize a new micro-genesis? Again, is it not possible that the specific virus of syphilis in passing through generations of men has been modified so as to become the progenitor of a xenogenitic cause of paresis?

The tabetic type, and in fact all other "types," of paresis are, as we progress in knowledge, being absorbed by the disease proper. At one time there existed in the minds of some a co-relation between paresis and tabes. It is a notable fact that in less than three per cent. of paretics do we find the classical symptoms of tabes, and in the male asylum of this city there are at present as many melancholiacs and terminal dements as paretics with such symptoms. Their co-relation is certainly not semeiological. Paresis is accompanied by no "type" of cord affection. The cord as a part of the cerebro-spinal system is nearly always subjected to the ravages of this disease, and may be primarily so affected; but there cannot be a co-relation in the degenerative or sclerosed sense. There may, however, be a common etiology, by which cord disease (not necessarily tabes) and paresis are related; if so, it is a mere chance in a hundred that the posterior columns are the first foci of infection. Paresis is no more a respecter of the cords columns than it is of men; the morbid appearances after death indicate this and exclude no part of the cerebro-spinal axis. Looked at in the sense of a localization of a general disease, the concurrence of tabes and paresis is a mere coincidence. If paresis attacks the cord first it will attack the cortex eventually, just as certain as when it attacks the cortex only the intervention of death prevents the disease from involving the cord. All that necropsies have yet shown indicate that paresis attacks through the circulation and not through psychical nonentities.

Duration of Disease.—This is not at variance with the other general features of the disease and shows the widest range. Thirteen hundred cases were under asylum care an average period of eleven months each, and had an average duration previous to admission of fifteen and three-fourths months each; this would make a total average duration of twenty-six and three-fourths months, and may be considered as the minimum average, it being difficult to obtain accurate data as to the invasion of the disease in some cases. A less number of cases with more accurate histories raised the average to about twenty-eight months. The duration of treatment, or period of asylum restraint, in the total cases does not equal the period of duration previous to admission, a unique feature, and argues that the greater portion of the paretic's diseased life is spent in a state of quiet dementia, motor disturbance predomi-

nating throughout the disease. In the entire number the duration was under five years in twelve hundred cases, from five to ten years in eighty-six, from ten to fifteen years in twelve, and for twenty-five years in one and thirty-five in another. It might be a source of "professional pride" to know that fourteen years ago some of our expert alienists were called to testify in a then well-known case brought into court on a writ of habeas corpus and discharged as sane, in spite of their testimony of existing paresis; that the patient died only a short time ago after an attack of fifteen years' duration. After having passed through a complete cycle of mental phenomena he settled down into a state of quiet self-contentment and dementia, for years manifesting no other somatic signs than spastic myosis and a very slight fibrillary tremor of the tongue, hands, and lips. Approaching deterioration was observed several months previous to death by increased loss in co-ordinating power only. He was suddenly attacked with convulsions, apparently of the respiratory and cardiac type, the temperature rapidly reached 106° F., and death ensued in a few hours. Owing to a liability at any time to convulsive attacks, dural hæmatomata, or hydro-meningitis, it is difficult to prognosticate the duration of the disease. Younger men seem to suffer more acutely and to give way to the disease earlier and easier than men of forty years and upward; likewise, they are more liable to maniacal attacks and morbid impulses. Affection of speech and expansive delirium, accompanied by motor excitement, paralysis of sphincters, and the "Romberg" symptom, mean progression and an early termination, although such extreme cases may remit and pass into a state of quintescence and life be prolonged for years.

Thirty-two nations and over two hundred and fifty occupations are represented in the death-roll from this disease in a single asylum. America takes the lead with 436 white and 48 colored; Germany furnishes 335; Ireland, 244; England, 71; France, 31. The balance is about evenly divided between twenty nations, and includes two Chinamen. This is not a very bright showing for the native-born in an institution where over two-thirds are of foreign birth and over eighty per cent. of foreign parentage. There may be a greater morbidity at home; this we will not discuss at present.

There is a general impression among the laity and some of our profession that paresis prevails largely among those who follow the stage; this cannot be substantiated by facts. While that profession cares for its own to a greater extent than does any other, a large portion of its paretics go to private institutions. I may state that the medical profession and that of law furnished equally as many cases for the great charitable institutions. In the entire number of cases of death from paresis only 8 were actors, 7 lawyers, and 5 physicians. The ministry was not represented.

Without going into any extensive detail, I will state that no profession, trade, or occupation, predisposes to paresis. Investigation shows that the out-door and sedentary occupations each furnish their quota. The ordinary laborer takes the lead with 109 cases, followed by 59 clerks, 45 tailors, 37 drivers, 35 bartenders, 32 painters, 32 cigarmakers, 31 carpenters, 29 salesmen, 28 shoemakers, 26 waiters, 23 merchants, 20 machinists, 16 printers, 16 butchers, 17 bakers, 16 barbers, 16 engineers, 15 pedlers, 14 cooks, 13 musicians, 13 porters, 12 blacksmiths, and so on down through over two hundred different pursuits, with a single representative of the Rogues' Gallery, No. 1,878. Vital and mortuary statistics show that man's means of livelihood is not an etiological factor in this disease, and leaves an inherited tendency as highly probable, and a common cause staring us in the face.

Age at Death.—It will be seen by the following table that paresis rarely occurs during adolescence, and while it frequently attacks early manhood, it usually selects its victims from those mature in years. Thirteen hundred deaths were distributed through the various periods of life as follows:

Age at Death.	Cases.	Age at Death.	Cases.
20 to 25	4	50 to 55	152
25 to 30	72	55 to 60	89
30 to 35	173	60 to 65	53
35 to 40	250	65 to 70	20
40 to 45	272	70 to 75	2
45 to 50	212	75 to 80	1

Making due allowance for the duration of disease, it will be observed that paresis occurs most frequently between the thirty-fifth and fortieth year, and the greater number die between the ages of forty and forty-five. Statistics in this country vary but little from those already taken from abroad in this respect. If there really was a greater morbidity with us, it would probably be exhibited by an earlier manifestation of the disease. The above would indicate that paresis does not usually begin until the age at which acute diseases most frequently occur is passed. The immunity of nerve structure against disease is well known. The frequent occurrence of paresis among the robust—those "never sick a day"—would hint at immunization of those who had suffered from other acute infections against paresis. The effects of acute infection of the cerebral cortex from disease, as ordinarily seen, are deliria of transitory nature. What is there in paresis that prolongs that state and adds to it a destruction of every accessible part of an entire nervous system? No disease manifests the persistent progression of paresis; its function is to destroy. There may be an acquired immunity that we have not yet discovered. Paresis gathers in the phthisical and syphilitic human residuum of prolonged subsidency, and well on in the road of life, beyond the age where sexual excesses most weaken and nerve-cells least resist.

Finally, it may be well to offer more substantial aid to the cause by a few microscopic observations on the paretic brain. It is these, more than all others, that tend to convince one, after frequent autopsies, that paresis is micro-genetic in origin. It is a remarkable fact that in this disease there is a characteristic uniformity in the morbid appearances of its earlier stage (when death occurs through intercurrent disease), while the late appearances are in a true sense panoramical.

Only a small percentage of paretics die in the extreme stage of the disease. Exhaustion from maniacal excitement, frenzy, and depression, malnutrition and insomnia, epileptiform convulsions, dural hæmatomata, and morbid accumulation on one hand, and intercurrent diseases on the other, carry off nearly ninety per cent. of the cases. The final typical paretic stage is rarely seen; that is where the entire cerebro-spinal axis has been extensively involved. In such cases the fœtal posture is assumed, the extremities become atrophied, and are rigidly flexed; decubitis appears over the prominent parts; paralysis of the sphincters has occurred long since, and with a spark of intelligence there remains only the more invincible trophic centres to complete the annihilation. In this stage even, they may greet you with a smile, a mere consciousness excited by a presence, and possibly an attempt at speech; the eyes seem bright, and there seems to be a playful, flickering mind quietly carousing with and cajoling death. Consciousness, or the mind we associate with a material basis long since destroyed, loathes to leave a body now inert. The destruction of cortical substance in two such cases was almost complete, and apparently caused by advanced and extensive lepto cerebro-spinal meningitis. The sub-arachnoid trabecula and the spinal canal were almost filled with pus. The cauda equina was simply macerated and the posterior nerve-root sheaths were dripping with pus which had evidently originated within the spinal membranes and percolated downward. The sulci over the vertexes

were filled, and in places the gyri were decorticated by the distention from pus within the epicerebral space. In the second case the pus was confined to the subarachnoid space, and in a third it was subdural. The inflammatory effusion had not yet appeared in the basilar cisternæ; they contained only congested capillaries. The cisternæ fossæ Sylvii were filled with pus. The arachnoid over the interpeduncular space was opaque and thickened, but no pus was observed; the subarachnoid sinus was empty. The spinal and cerebral meningeal affections appeared to be contiguous; the disease was equally advanced in both brain and cord, with a strong possibility of the cord disease being either metastatic or having had an independent foci of infection. I have not as yet found a case in which leptomeningitis of the cord alone existed. In one case alone was there pus in the cerebral sulci and none in the spinal canal.

It is probable that the disease when well established eventually involves the entire cerebro-spinal membranes. In the most advanced case the lateral ventricles were dilated to three times their normal capacity, their ependyma much thickened and shrivelled, but very tough and leathery, and not granular or latticed over the surface as is usually the case in ependymal inflammations. Two of the cases apparently presented three independent foci of infection—the cortex, spinal membranes, and ependyma. Almost every advanced case of paresis presents some marked or peculiar pathological appearance.

The above were cases in which there was an extensive purulent exudate seemingly of inflammatory origin. In wide contrast I may mention two cases in which the changes were apparently degenerative and necrotic; clinically they did not exhibit the trophic disturbances, so marked in the former cases; there was no decubitus, no muscular atrophy, no contracture of the extremities. The cords presented little to the naked eye other than thinness of the meningeal vessels. The degenerative changes were far advanced over the cerebral vertexes. On removal of the dura the cortex presented diagonally across the vertex an undermined and sunken appearance. The gyri in some places retained their full rotundity, but were depressed to a much lower level than the surrounding parts. In places the membranes were entirely absent and the gyri presented nude. The disease extended in this manner from the left supra-marginal gyrus to a width of 75 mm., and proceeded forward and upward toward the vertex; reaching the paracentral lobule it cut several wide, deep notches, and completely destroyed the gray cortex in this region; reaching the cerebral falx it seemed to ricochet, leaving the cingula intact, and appeared again on the opposite (right) side in the exact location on the paracentral lobule, proceeded about the same distance and width, and ceased at the gyrus frontalis medius. The meningeal remains over the entire diseased surface was of a rusty color and extremely thin and pellucid. In this case the lateral ventricles were filled with a clear, straw-colored albuminous fluid, specific gravity 1.010, and of slightly alkaline reaction. There was no ependymal granulation or sclerosis. In the second terminal case of this type of late degeneration the disease appeared to have exhausted itself along the pars horizontalis of both hemispheres; a double chain of depressions, necrotic softenings following cystic degeneration, reached the entire length of the fissure, and each angular gyrus presented gelatinous cysts about the size of a hazel-nut, beneath which the gray cortex was entirely perforated by the necrotic degeneration. Over such necrosed spots there was in many instances a mere pellucid film sometimes encysting a transparent fluid.

In the above cases both an inflammatory and degenerative terminal state of the disease are shown, and these in the cortical envelope. I would here desire to show from a pathologico-anatomical view another type of the disease, viz., that in which the disease locates itself upon or beneath the ependyma and within the ventricles. In such cases only the earlier cortical changes were observed. The ordinary granular ependyma occurred in about ten per cent. of the cases, and included both the syphilitic and non-syphilitic. It is possible that this granular state may be an early manifestation of another form of ependymal disease. In two cases where the ependymal changes were prominent, there was an entire absence of anything like granulation. The morbid processes were exerted in the floor of the lateral ventricles, usually in the anterior horns or the cella media. In one case there was a large area of necrosed neuroglia implicating the stria cornea and the tail of the caudate nucleus: the morbid process had obviously begun on the under surface of the ependyma and proceeded downward into the basil ganglia; the membrane itself was thickened and on its surface presented a latticed appearance, and there was an entire new connective-tissue-like formation; this state of affairs also existed in the floor of the fourth ventricle in both cases, but was not accompanied there by necrotic changes in the ganglia beneath: there was a true heteroplasia extending over the whole ependymal surface. The necrosed cavities were empty; the serous membrane above not distended but somewhat shrivelled and sunken into the space caused by the absorption of the products of disease.

Throughout the whole number of autopsies the advanced cases more frequently showed degenerative than inflammatory changes; the suppurative conditions were probably consecutive. However, it must be apparent to one making many autopsies on paretics that the disease is not strictly cortical, and may first select the cord, or, perhaps rarely, the serous lining of the ventricles. There is no reason why paresis, if it is the localization of a general disease, might not as easily first locate itself within the inner vascular cerebral system as in the cortical envelope. The common-cause theory will eventually assert itself. The cases described were all said to have been "fast livers;" two had stricture of the urethra, one gave history of specific disease, and two were negative. I am not prepared to say that all or any were free from syphilitic infection; but there was an entire absence of gummatous deposit in the nerve structure. If syphilis presents all the pathological manifestations of paresis, then our present knowledge of cerebral syphilis is wofully meagre. It is said by some that syphilis causes pseudo paresis. I have noticed that the "pseudo-paretics" are subject to iodism and die in the allotted time given to the true disease. There can be no neutral ground; paresis and syphilis may be convertible terms; but it is difficult to believe that syphilographers have been waiting for a century or more on students of paresis to discover the brain lesions of their disease. Syphilis may present different types of virility, if so the "paretic type" is the most virile.

The theory of a psychical paresis has long since been discarded by investigators. The common and constant vascular changes seen on the autopsy table tend to relieve one's mind of theorizing on the mysteries connecting psychical reduction with paresis in an etiological sense. It was not "that which has escaped" that acted on the living matter to produce paresis. It is also time that the Rolandic area and paresis were divorced. The motor cells in this area suffer no more than other cells suffer in other areas; and we certainly cannot connect a general loss of voluntary muscular control and co-ordinating power with this specialized cortex, its clusters, or its laminations.

In conclusion I would reiterate that the future of paresis depends on the discovery of a common cause; that preserved, sterilized, and hardened specimens of the paretic brain will be searched over as ruins only, and their value will be in the sense of a connecting link between paresis and what was once physiological.

THE ALLEGED PARASITE OF MALARIA.

By W. MOSER, M.D.,

PATHOLOGIST TO ST. CATHARINE'S HOSPITAL, BROOKLYN, N. Y.

THAT the red blood corpuscle is not always round in shape has long been known. Quincke saw peculiar-shaped corpuscles in pernicious anæmia and called them poikilocytes, and at one time regarded them as characteristic of that disease. While it is true that these peculiar shapes are best seen in pernicious anæmia, they do occur in many conditions. Their exact nature being unknown, they were simply denominated poikilocytes. Friedreich and Mosler were first to see distinct amœboid processes in a few instances in the red blood-cells of pernicious anæmia, and Jaksch too made this observation and says: "Ich möchte geradezu behaupten, dass durch die Eigenschaft der rothen Blutzellen, in abnormen Masse contractil zu sein, das Bild der Poikilocytose entsteht."[1] And this theory of Jaksch I regard as the proper one. Owing to some poison in the blood the cells are stimulated to abnormal contractility, while ordinarily they remain more passive; in the same manner in which the white blood-corpuscle, ordinarily round, may under certain influences as heat, acids, etc., be stimulated into activity and show varied shapes. I saw and described amœboid processes in healthy blood while experimenting with methyl blue in 1893.[2] And again I saw and described contractions in red blood-cells—see articles, "The Pathology of Pernicious Anæmia," and "Have the Red Blood-corpuscles Amœboid Movement?"[3] Contractions in the red blood-cells and distinct amœboid processes were seen and described by me as physiological processes, and for this I claim priority.

Further observations on this subject only tend to confirm those previously made. In about fifty examinations from the blood of a patient now lying in St. Catharine's Hospital I saw time and again, and likewise demonstrated to several colleagues, the polymorphic picture represented in the figure. The blood was examined fresh without the warm stage, and strange to say, many of the cells exhibited motion. A bird's-eye view of the figure will show many cells which have sent out prolongations in different directions, such as occur in the white blood-corpuscles, and which cannot be anything else but amœboid processes. The cells in this blood varied much in size; some were small, while others were large, only a few retaining their rounded outline and inactive, motionless state, while most cells were very irregular in contour and showed distinct movement. A few of the smaller cells were actively mobile, constantly changing shape and exhibiting inherent contractions, while in some cells only the prolongations—the amœboid process—could be seen faintly yet distinctly moving back and forth.

In No. 1 of the figure the artist has sketched the different shapes which he saw under the microscope within one minute, which we regard as quite active movement. I placed the cell in the centre of the field and let him sketch what he saw after that—and ask no questions. The two last cells in No. 1 show what took place within thirty seconds. In No. 2 we reproduces what he saw within one minute in another cell which I placed in the field for him. In No. 3 we reproduces different cells which I placed in the field successively, and we note their irregular outline and peculiar bodies in the protoplasm of the cell. In some cells we see small round bodies, while in the other cells we see larger irregular-shaped bodies. In No. 4 we see peculiar-shaped cells, and a few showing these irregular bodies within them. No. 5 shows irregular-shaped cells, a few containing round or irregular bodies, and the last contains a large irregular body partly within, partly without the cell. This body is nothing more or less than a red blood-cell itself lying on, not in, another cell, and may be mistaken for a parasite. In No. 6 a few of the cells in this series show long and distinct amœboid processes. The peculiar body in this series, partly within and partly without the cell, is merely another red blood-cell undergoing movement and could be mistaken for a parasite. In Nos. 7, 8, and 9, cells may be seen in different phases of amœboid movement, and a few contain irregular-shaped bodies within them. No. 10 shows a small red blood-cell which was actively mobile. I placed No. 1 in the field, and within thirty seconds it had assumed the changes in shape depicted in Nos. 1, 3, 4, 5, and 6, and the artist endeavors to show the relative change in position which it took within that time from No. 1 to No. 6. The larger body in the centre is a red blood-cell only slightly altered in outline as compared to the others. Now, in looking at the

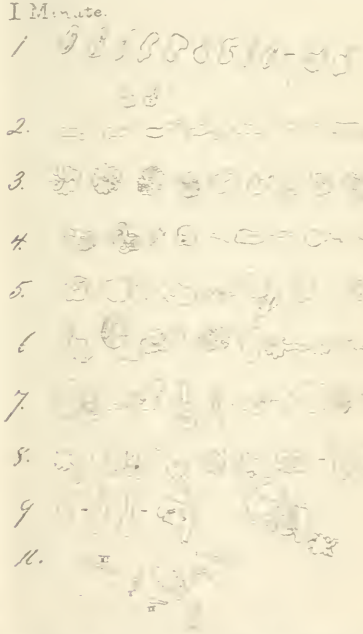

figure we have a very polymorphic picture, one which we are not accustomed to see in ordinary blood examinations. In No. 10 the cell is so altered in shape, or rather it is undergoing such alterations during life, as to be mistaken for a worm or parasite.

The question arises, What are the peculiar bodies within the cell? I regard them as degeneration products and not a parasite. In fact, when we compare these bodies with what has been described as the plasmodium malariæ, and when we consider how actively mobile a few of these cells and how altered their appearance may become, there may be a suspicion that that the life history of the cell has been confounded with that of a parasite—the plasmodium malariæ of Laveran.

In reviewing the literature on the plasmodium we see that no two authors are agreed as to what constitutes the parasite. It is true that oval bodies varying in size, some within the cells and some free in the blood, exhibiting active amœboid movements, have been described. But the red blood-cell itself may vary much in size and exhibit active amœboid movements. It may become oval, semi-lunar, or crescent-shaped,

[3] New York Medical Journal July 21, 1894.

[4] MEDICAL RECORD, August 11, 1894.

scythe-like, etc. In short, it manifests the same polymorphism as does the plasmodium malariæ, and we fear that possibly we may have confounded, at least in some instances, these two, and naturally ask which is which? The presence of pigment simply means that degenerative changes are taking place in the cell, but shows no relation to a parasite. The patient from whom the blood examination was taken has been in the hospital some three months. The case in question, to be brief, has been diagnosed by different physicians as pernicious malaria. She was very, and is still slightly, anæmic, has had irregular chills, and now and then vomiting. No enlarged spleen or liver. Whether the case is one of malaria or not, microscopical examination of the blood showed what the figure represents. The blood at times contained free pigment. Now, until the plasmodium malariæ of Laveran is demonstrated outside of the blood or outside of the body, we become perplexed and hardly know which is which. The question naturally is asked, if what I describe are the varying phases in the life cycle of the red blood-cell, why is it we do not see them oftener or ordinarily when examining the blood? The red blood-cell generally is round and exhibits no amœboid motion unless it be placed on the warm stage, and there the motion is slow. But is not the white blood-cell ordinarily round, in a passive condition, unless when stimulated by certain factors it becomes active? And so here, in the case in question, owing to some poison or "noxa" in the blood, the cells are stimulated to abnormal activity, and retain this activity when we examine the blood, and, as in this case the cells retained their vitality for an incredible length of time (in some cells over five hours, and in a few over twenty hours), and I repeat the blood was examined fresh without the warm stage. Now, this activity in the cells, coupled with degenerative changes with the cells, and the presence of pigment, may have led us to believe we were dealing with a parasite. At least, I feel as though I may have been mistaken in my previous observations, and I am at a loss now to say which is which. Let me ask why do we not see karyokinetic changes in the nuclei of the red blood-cells as often and as constantly as we see them in infantile pseudo-leucæmia, or why do we see them at times in the nuclei of the white blood-cells in the leucæmia of adults? Are these not physiological processes, part and parcel of cell life? And yet ordinarily the nucleus, like the cell itself, is round, or, as in the case of the white blood-corpuscles, at most a little irregular, but not in process of mitosis. This subject is a little large and requires a little review.

My thanks are due Mr. Charles Perpente, who made the drawings, and who would not be so apt to draw on his imagination as I might have done, had I made them.

158 Ross Street.

Another Quarrel between Hospital Staff and Board of Managers.—We are informed by the *Medical Sentinel* that the entire medical staff of the Portland (Oregon) Hospital resigned recently in order to uphold one of their colleagues, whom they evidently thought was in the right. The Board of Trustees accepted all their resignations, and promptly appointed a Homœopathic staff instead of the previous regular one.

Mercury in Heart Disease.—A correspondent of *The Lancet* reports the case of a patient who, in the course of fourteen years, took over twenty thousand blue pills of three grains each. The patient was suffering from heart disease, and had been given up by his physicians. The persistent use of mercury, however, brought him out of his moribund state, and he continued to take his three grains or more of blue pills every night for fourteen years. Whenever he stopped the use of the drug the symptoms began to return. He asserted that his continued use of mercury never produced any diarrhœa or salivation.

TWO CASES OF AN UNUSUAL PAPULO-PUSTULAR AND FUNGOID BROMIDE OF POTASSIUM ERUPTION IN BABIES.[1]

By GEORGE T. ELLIOT, M.D.,

Professor of Dermatology at the Post-Graduate Medical School, New York.

The question of cutaneous eruptions, the result of the internal administration of drugs, is one of peculiar interest to both the dermatologist and the general practitioner. The former sees many artificial conditions of such origin, which simulate in their clinical phenomena well-known skin diseases of entirely different origin and causation, and the latter is often confronted by cutaneous processes of his own making, which he fails to recognize, as the result of the drugs given by him, but he refers them rather to some peculiar and unknown cause, and regards them as an unfortunate complication of an existing disease. In consequence, I do not think an excuse is necessary in calling attention to such a *banale* subject as bromide of potassium eruptions, in view of the severe and exaggerated examples of the effects of the drug to which I would call your attention in this paper.

Case I.—E. M——, female, aged nine months, came under my care June 5, 1894. Though born at full term and well nourished, she had always been susceptible to catching cold. When four months of age she had had tonsillitis, followed by a bronchitis, which had persisted for several months. During that time she had received some medicine, the nature of which could not be ascertained. When five months old she had developed a tonsillar abscess, which was opened four times. In the beginning of March an abscess, originating apparently from the same region, was opened externally on the left side of the neck, and a little later another one was operated upon on the right side. Prior to the opening of the first abscess the baby had been taking syr. ferri iodidi, gtt. xv. t. i. d. for two weeks, and shortly after the operation a diffuse erythematous eruption had appeared over the trunk. The exact duration of this "rash" was not ascertained, but it was stated that the iodide of iron was continued until March 30th, and the first eruption had been gradually succeeded on the body, the face, and the scalp, by crops of small pinhead-size pustules, which had dried up into small crusts and had left no trace of their presence.

Owing to an increase in the bronchitis the iodide of iron was discontinued March 30th and a mixture containing in each dose bromide of potassium, grs. iiss., acetat. of potass., gr. i., and a few minims of buchu, hyoscyamus, and Elixir of Calisaya was given every four hours. The pustular eruption then became more abundant and appeared on the legs, the arms, and over the body generally. These new lesions were larger and more deeply seated than the former ones; they did not dry up into crusts, but tended to increase in size and to become more prominent. The same medicine was continued until May 7th, and then the bromide was increased to grs. vss. every four hours. May 13th a further increase was made, and the baby received grs. xiss. every four hours, and this dose was kept up until June 5th, when she came under my care. The mother of the child was a very sensible and conscientious woman, and she told me that she had followed literally the instructions and had given her baby the mixture every four hours, or six times daily. She also furnished me with copies of all the prescriptions, and from them I have calculated that the baby had received from March 30th to June 5th, 2,376 grains of bromide of potassium.

The child was fairly well nourished when seen by me. Her mother nursed her. There were no gastro-

[1] Read at the meeting of the American Dermatological Association, held at Montreal, September, 1895.

intestinal disturbances and the bowel movements were normal in regularity, consistency, and color. She still had some bronchitis, however, and was decidedly anæmic. The eruption was very generally distributed over the body. Its primary lesion was a tense, deep-seated, and prominent papulo-pustule, varying in size from a pinhead to a small pea, and round, oval, or elongated in shape. It was surrounded by a narrow red zone, and sharply delimited toward the surrounding healthy skin. In the course of its existence it enlarged slowly to the size of a three-cent piece or larger, became prominent and covered with a yellowish, clear, glazed coating, beneath which yellow miliary points of pus could be seen, or progressing still further, it became elevated and fungoid in character, and covered with thick, soft, black or greenish, crumbly crusts. The base upon which these rested was fungating and studded with miliary abscesses. Many pigmented and dark-red stains were also present, the sites of lesions, which had already undergone involution. On the scalp papulo-pustules and crusts were alone present. On the face small and large pustules were noted, and on the cheeks a few prominent, champignon-like growths. Only few of the lesions had attained this development on the trunk, and here only pinhead and a little larger papulo-pustules were seen. The extensor surfaces of the extremities were severely affected, and the flexors to a very much slighter extent. On the arms a large number of fungating growths were grouped together, though still remaining discrete, but on the legs confluence had taken place, and diffuse patches were found extending from the ankles nearly up to the knees.

To judge by the behavior of the child, itching was not a feature of the eruption, though it is possible that it was painful, in view of the baby's restlessness and insomnia. In treating the child, absolute discontinuance of the bromide salts was primarily directed. Its functional health and its hours of nursing were properly regulated, and a tonic suitable for the existing anæmia was ordered. Externally an ichthyol ointment was applied to the lesions. Retrogression began very quickly and continued steadily, though for some weeks new pustules appeared, but were, however, of ephemeral duration. By the end of August no traces of the process remained except numerous scars marking the sites of the former growths.

Case II.—F——, male, aged six months, was brought to me June 15, 1894. He had been born at full term, was healthy, and well nourished. He had been, and was still, nursed by his mother. No gastro-intestinal or other functional disturbances existed. About the middle of May he had developed a bronchitis, and had become restless and sleepless. May 21st his physician had given him

℞. Kali bromidi,
Sodii bromidi.....āā ʒ iss.
Syr. acaciæ..... ʒ iss.
M. Sig.: One-half teaspoonful every hour until the cough was quieted.

Calculating the dose ordered as representing thirty minims, the baby received three and three-fourth grains of each of the bromide salts each time the medicine was administered. This mixture was continued for four days, but was stopped May 25th, the baby's temperature having risen to 103° F. It then received

℞. Aconite..... gtt. xij.
Tr. opii. camph.
Spts. nitrosi dulc.
Spts. mindereri,
Syr. scillæ ..... āā ʒ ii.
M. Sig.: Fifteen drops every two hours.

At the end of a few days, the temperature having fallen and the baby's condition being improved, the original prescription of bromide was substituted for the aconite, etc., mixture, and given up to June 4th. On June 7th, the bronchial symptoms becoming worse, the child again received kali bromidi, two grains in syrup, every two hours, and this was continued until the 12th, or three days before I saw him. The cutaneous eruption had begun about June 1st, but had been slight and received little attention. It had subsided somewhat when the first bromide mixture had been stopped, but it had increased in quantity and in severity after taking the one given on June 7th.

When examined by me the baby was found to have an eruption distributed quite abundantly over the scalp and the face, and also here and there on the extremities. It consisted of papulo-pustules, about the size of a small pea, or smaller, which on the scalp had formed around a hair-follicle. Many of these lesions were pierced by a hair. These primary lesions had enlarged on the extremities to the size of a penny, and they were prominent, sharply defined, surrounded by a narrow red margin, fungoid in appearance and covered with a glazed coating, below which minute miliary pustules could be seen clustered and aggregated together. In some instances thick crusts had developed.

In treating the child all the bromide salts were discontinued, and ichthyol was used locally. In a few weeks the skin was again normal. No perceptible scars remained even at the sites of the larger lesions.

The histories of these two cases thus show that an eruption of a severe type and of wide distribution, consisting primarily of papulo-pustules, and later of discrete, aggregated, and confluent fungating and crusted lesions, appeared after the ingestion for a more or less long period of time of a certain drug—bromide of potassium—and continued cropping out during the entire period of its ingestion, but subsided after its discontinuance. These particulars of origin, course, and involution represent the crucial tests determining the relation between a drug and an eruption, and being so decidedly apparent as they were in these two cases, it is perfectly proper for me to connect together the cutaneous disturbances observed and the bromide of potassium in the position of cause and effect. The great differences noted in the severity and the extent of the eruption in each of these cases are not of importance, in view of the fact that in Case I. the bromide was given for several months and in excessive doses, while in Case II. it was administered for only a short time and in such quantities as could or would be given with entire safety in the majority of cases. Besides, it must not be forgotten that the first baby received daily, for more than a month prior to the administration of the bromide of potash, forty-five drops of the iodide of iron, an inordinate dose for its age.

It is a well established fact that a bromine following an iodine compound will lead to exaggerated and intense cutaneous effects, and it is therefore not surprising that in this case the baby was so severely affected, so much more so than was the subsequent case which came under my care. Independently of the bromide of potash effect, the eruption which occurred while Case I. was taking the iodide of iron is most interesting. There are few cases mentioned in literature of the iodide of iron producing any cutaneous manifestations of iodism, though there is no reason why it should not do so, since it is not a very stable iodine compound, and the union between the two is easily dissolved, each then existing free in the solution. The eruption which did occur in the case (Case I.)—an erythematous rash followed by one which was papulo-pustular—was such as iodine produces, and the increased bronchial symptoms which developed with the administration of the drug certainly suggest that the baby was suffering from general iodism. It may be claimed, however, that the early erythematous rash was a toxic erythema unconnected with the iodine, but resulting from the tonsillar abscesses through absorption of toxines; or it might be regarded as one developing from shock after

the operation of opening the abscesses. Such occurrences are perfectly possible, and rubeloid, scarlatiniform, and papulo-pustular eruptions have occurred very commonly under such circumstances. Such eruptions are, however, accompanied by febrile temperature, systemic symptoms of grave import, are usually of short duration, and very commonly followed by desquamation of the epidermis at the end of a very few days. None of these features were, however, met with in this case, but the rash persisted for a while and then disappeared, being followed by a higher type of eruption—the papulo-pustular—and this remained until the new drug—the bromide of potash—being administered, the subsequent symptoms, as already detailed, developed and existed until the medicament was discontinued. I do not think it is necessary to insist further on this point, as it cannot but be apparent to any one familar with eruptions produced by drugs that there is no question but that the symptoms referred to were the result of iodine and not of any septic intoxication or of other cause.

The manner in which bromine and its compounds, or, in fact, any drug, produces its effects on the skin is a mooted point. In regard to the former, with which we are particularly interested, owing to the cases reported in this paper, there are many who regard the cutaneous manifestations developing after its administration as the result of an exaggeration in its physiological effects, believing that individual idiosyncrasy plays a small part and has little influence. There are as many others who attribute the eruptions to the local effects of the drug upon the glands of the skin, which seek to eliminate it from the system; and there are again others, who, believing in a more recent theory, find an explanation for the occurrence of the lesions in a supposed foreign material generated in the blood by the drug, which then acts directly upon the skin.

There is no question but that authorities can be found substantiating either one of these opinions, but in view of our practical ignorance of the mode and manner in which the drug does in reality produce cutaneous disturbances, it would seem to me to be preferable to leave the choice of theoretical conviction to the prejudices or to the pre- or post-conceived desires of each individual observer, rather than by speculation to support one side or the other. I do this owing to the fact that positive proof in favor of one view or the other of the question is entirely wanting, and all that can be said is that the drug, when given to certain or perhaps the majority of individuals, does produce cutaneous lesions of greater or lesser severity, but how it does it, I frankly confess that neither observation nor theory has yet been able to satisfactorily explain.

The action of bromine and its compounds upon the cutaneous surface are manifold and multiform. Though the most common type of eruption produced by the drug is the so-called bromide acne, represented by papulo-pustular or tubercular lesions, occurring particularly on the face and the scalp, but also more or less generally over the body, yet even this *banale* type may develop into furuncular-like lesions and ulcers leaving scars. More rarely the eruption may be erythematous in character, and occur in either a diffuse form, and then especially on the lower extremities, or it simulates a roseola. Urticarial lesions have been observed, and it has even been possible to produce them by rubbing or irritating the surface. A maculo papular eruption has also been seen, and it has led to the mistaken diagnosis of syphilis, while cases of nodular, furunculoid, anthracoid, and carbuncular lesions abound in the literature of the subject. Seguin has described, admirably, a peculiar elevated ulcer due to its long-continued use, and Amidon has called attention to an "epithelial" ulcer observed by him. Veiel reported a verrucous or warty eruption, strictly resembling ordinary warts, and others have recorded bullous, squamous, and seborrhœic manifestations.

I find it rather difficult to include the cases reported in my paper among any of these, owing to their peculiar type, one evolved from an ordinary papulo-pustular lesion. Jacquet reported a case which, beginning as a bullous eruption, became fungating in character after rupture of the bullæ. Müller very recently has described one which presented frambœsia-like growths, together with superficial ulcerations and other lesions, but none that I know of showed the peculiarities in evolution of the lesions from a papulo-pustule to a fungating and crusting excrescence. The exaggeration in character in Case I. was undoubtedly favored by the iodine compound given at first, and precisely similar eruptions have been seen by me resulting from iodide of potash. The type of eruption, however, cannot be ascribed to that fact alone, since Case II. developed the same lesions and yet had not received any iodine. In consequence I would regard these cases as representing a very unusual type, which may be described as a papulo-pustular fungoid and crusting bromide of potash eruption.

The production of cutaneous phenomena is not limited to any particular one of the compounds of bromine. Though bromide of potash usually seems to exert the strongest effect, yet the same results have been caused by the sodium or ammonium salt, by bromine vapor, and any and all of the combinations of the drug. Müller's case, referred to in my paper, was due to bromoform, a comparatively new bromine compound, and personally I have seen bromide acne arise after taking bromo-caffeine and hydrobromic acid in combination with quinia and with conium, an occurrence not mentioned in our text-books or in those treating of drug eruptions.

The diagnosis of the bromine eruptions is not always a facile one, particularly when the lesions are of an unusual type, and it has most frequently to be made by exclusion and by a careful investigation into the patient's history previous to the appearance of the cutaneous symptoms, and by an examination into the drug or drugs which have been taken. The acneic form may be mistaken for acne vulgaris, but its location on the hairy surfaces by preference, its wide distribution, and the absence of any comedones should suggest its drug origin. The macular form, owing to its coppery color, may easily be regarded as due to syphilis, but the absence of all concomitant symptoms accompanying that early syphilide should be sufficient to guard the patient against such an error. Still it has been made, and even more serious mistakes have been recorded. The prognosis is always good. As a rule the lesions disappear after cessation of the drug. Not always, however, as once produced they may persist for months and years, even without any more bromide being taken. I have had in the last winter a number of cases of folliculitis of the face, which had begun a year or more before they were seen by me, and which had appeared after taking bromide of potash for some weeks or months. The lesions had not disappeared in these cases, but had continued appearing, even though none of the salt had been taken for months and months. These cases are, however, exceptions, the opposite being the rule.

In view of this rule there is little to be said in regard to the treatment of these eruptions. Cessation of the drug is the essential and only step to be taken, though when ulcerations or bullous or other severer lesions have occurred, local antisepsis should be observed and they should receive such general care as any wound. All means should also be used to prevent scarring.

14 West Thirty-third Street

New York Obstetrical Society.—At a recent meeting of the Society Dr. Henry C. Coe was elected President.

RUPTURE OF THE TENDON OF THE QUADRICEPS EXTENSOR FEMORIS.[1]

By J. J. BUCHANAN, M.D.,

SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

RUPTURE of the tendon of the quadriceps extensor femoris appears to be a comparatively rare injury, or, at least, one rarely recorded, for a careful examination of the literature has disclosed but 120 cases. The most important papers yet published on this subject are by Karl Maydl, of Vienna, in 1883; W. T. Bull, of New York, in 1889, and T. Hafeman, of Berlin, in the same year.

Maydl collected 61 cases, all but one treated without operation. To these Bull added 23 cases,[2] of which 4 were operated. In the table appended to this paper is a record of 36 additional, making a total of 120 cases.

Statistical tables are of great value in determining the results of treatment in this injury, and the careful perusal and comparison of tabulated cases will give the inquirer a very good general idea of the value of different methods and the results to be expected from them; but the data furnished will be found insufficient for accurate conclusions. To formulate such, in cases of this kind, the following particulars are desirable: The nature of the lesion—whether only the central portion of the tendon is torn away or the lateral expansions of the vasti also are ruptured; the position of the rupture, whether close to the patella or higher; the amount of separation; the exact method of treatment, and the duration of its various stages; the length of time allowed to elapse before passive motion at the knee was employed; the result as to union of the tendon; the amount of permanent separation; the ultimate mobility of the joint; the final strength of the limbs, and the length of time which elapsed from the date of injury till the last observation of the case. An examination of the tables of Maydl, of Bull, and the one herewith appended, as well as the original report of cases, will show that all of these particulars have been furnished in such a small number of cases as to render it impossible to draw from them many general conclusions of value which can be put into numerical form. Bull, however, in his excellent paper, while realizing this difficulty, has made a careful study of the cases collected by Maydl and himself, and has arrived at the conclusion that, without operation, an imperfect result occurs in about one-half of all cases.

[1] Read before the Medical Society of the State of Pennsylvania, May 22, 1895.

[2] Bull duplicates Hulke's case, recorded by Maydl, and adds a case of fracture of the patella by Hartley.

ADDITIONAL CASES OF RUPTURE OF TENDON TO THOSE REPORTED BY MAYDL AND BULL.

No.	Reporter.	Sex and Age.	Date.	Manner of Injury.	Lesion.	Treatment.	Result
1	Spong, A., Lancet, 1835-36, i., 203.	M., 50.	1835.	Fell down stairs, striking right knee.	Rupture of middle portion only of tendon of right quadriceps.	Bandage and sitting posture for a month.	Union complete; three months later, walks nearly as well as ever.
2	Christison, Toogood, loc. cit. infra.	M.	.....	.....	.....	Confinement to bed for nine weeks.	Complete recovery without lameness.
3	Blackman, G. C., American Journal of Medical Sciences, 1847, N. S., xiii., 327.	F., 60.	.....	Fell down stairs backward.	Rupture of tendon of right quadriceps.	Local treatment at first; three months later, posterior splint for three weeks.	Ten months later, walked very little and still with a cane.
4	Brushfield, Lancet, 1847, i., 389. Under Mr. Curling.[1]	M., 37.	Aug., 1846.	Fell from a loft, causing extreme flexion of knee.	Rupture of tendon of left quadriceps about an inch above the patella.	Posterior splint for six weeks.	Flexion and extension limited; patella immovable. By aid of leather knee-cap walks, but imperfectly; no union.
5	Kübel, Zeit. für Wundärzte u. Geburtsh., 1850, p. 8.	M., 60.	March 1, 1850.	Fell on right knee.	Rupture of tendon of right quadriceps.	Bandage, splint, elevation.	In six weeks and a half walked with cane; slight stiffness.
6	Toogood, J., Reminiscences of a Medical Life, 8vo. Taunton, 1853, p. 82.	M.	.....	Fell down stairs.	Rupture of tendon of quadriceps.	None	Tendon united to femur; six years later could walk several miles daily.
7	Trent, P., Virginia Medical and Surgical Journal, 1854, iii., 9.	M., aged.	.....	Blow above knee by a heavy post.	Rupture of tendon of quadriceps; separation of two inches.	Treated as a bruise for two weeks; then elevation and bandage.	No result given.
8	Zieckers, E., Allg. Wien. Med. Ztg., 1863, 278	M., 64	Jan., 1863, and before.	Fell on ice on two different occasions.	Rupture of tendons of both quadriceps on different occasions.	Extended position, moulded splints and bandages.	In seventeen weeks could use the right limb freely, walked eighteen weeks after injury to left limb.
9	Gosselin, M., London Medical Record, March 25, 1874.	M., 62.	.....	Fell backward and pulled a piece of furniture on the limb.	Rupture of tendon of quadriceps.	Unrecognized for four months.	Treatment then ineffectual.
10	*Marguet, Cl. Inaug. Dissert. Subcut. Rupt. of Tendon of M. Ex. Quad. T. Hafeman, Berlin, 1889.	.....	1874.	.....	Rupture of tendon of quadriceps	Unrecognized for two weeks.	After long-continued treatment could walk only with difficulty, even with crutches
11	Thompson, J. F., National Medical Review, 1878, i., 1.	M., 70.	Oct. 7, 1878.	Struck above patella by tail-board of a cart.	Complete rupture of tendon of quadriceps just above patella.	Elevation of heel and gypsum bandage for five weeks.	Union seems quite close, with prospect of a perfectly good leg, though he has yet exercised it little.
12	Morton, T. G., Surgery in the Pennsylvania Hospital, Philadelphia, 1880, p. 336.	M., 55.	Jan. 12, 1879.	Fell while intoxicated	Rupture of tendon of quadriceps at its insertion; slight attachment of vastus externus unbroken	Posterior splint	Walked with crutch in three weeks, at four months and a half had almost perfect use of leg.
13	Guerin, J., Hafeman, loc. cit.	F.	1880.	.....	Partial rupture of tendon of quadriceps.	Had existed for three years.	.....
14	Weinlechner, Wien. Med. Blätt., 1881, No. 51.	M.	1880.	.....	Complete rupture four inches above patella.	No bandage.	In three months able to walk about with safety.
15	Toncker, R., Gazz. Med. di Roma, 1881, vii., p. 189.	M., 56.	Dec. 30, 1880.	Fell, forcibly flexing his right knee.	Rupture of tendon of right quadriceps, three inches separation	Gypsum splint.	Walks without interference.
16	Weinlechner, loc. cit.	M., aged.	1881.	Fell.	Complete rupture of tendon of left quadriceps one-half each and epitella.	Posterior splint and elevation.	In eight weeks could walk with crutches.
17	Gibney, Centr. f. Chir., ix., 599	M., 58.	1883.	.....	Double: six years apart	.....	Case four years old, pecuniary reasons; right patella immovable, left knee has good motion
18	Weir, R. F., New York Medical Journal, 1884, xxxix., 383, and personal comments.	72.	.....	Slipped on ice.	Rupture of tendons of both quadriceps; lateral expansions remained.	Straight splints.	Both tendons united; three months later, able to walk readily, ultimate result very good.

* Hafeman states that Marguet had two cases and gives the same particulars for both. Not having access to Marguet's original report I have entered this case only, thinking it unlikely that the two cases should be exactly similar.

ADDITIONAL CASES OF RUPTURE OF TENDON TO THOSE REPORTED BY MAYDL AND BULL—*Continued.*

No.	Reporter.	Sex and Age.	Date.	Manner of Injury.	Lesion.	Treatment.	Result.
19	Hirn, A., Dissertation: Würzburg.	M., 66.	1885.	Injured by falling tree.	Rupture of tendon of left quadriceps.	Not stated.	Complete recovery.
20	Bardeleben, Hafeman, loc. cit.	M., 63.	1886.	Fell.	Rupture of right tendon at patellar insertion.	Bandage and elevation; later, splint.	Eight weeks later, normal limb.
21	Childs, W. R., Transactions Homœopathic Medical Society, of Pennsylvania, 1886, xxii., 281.	M., 38.	March 14, 1886.	Slipped on an iron grating, striking on his right knee and extending his left leg.	Rupture of tendon of left quadriceps; right patella also broken.	Silver wire passed transversely subcutaneously through each tendon; the external ends united to form a loop, through which a loop of adhesive plaster was passed, on which traction was made and which was fastened to the sole of the foot; plaster dressing and elevation; fractured patella treated in same way.	Union; wire removed in four weeks; splints removed in two months; walked in three months; walked without cane in six months.
22	Ormsby, L., Medical Press and Circular, Dublin, 1889, N. S., xlviii., 491.	M., 30.	March 7, 1886.	Fell down stairs.	Rupture of tendon of quadriceps.	Plaster strips below patella; posterior splint; elevation.	In six weeks and a half could stand and walk with comparative ease.
23	Socin, Hafeman, loc. cit.	.....	.....	.....	Rupture of tendon of quadriceps.	.....	.....
24	Carrington, P. M., Report Supervisor Surgeon General, Marine Hospital, 1888, 243.	M., 65.	Nov. 19, 1887.	A board on which he was walking broke under him and he fell, striking fairly on his right knee.	Rupture of tendon of right quadriceps (fourteen years before sustained a rupture of left quadriceps and a secondary rupture which left him permanently lame); several inches separation.	Aspiration, bandage and posterior splint; later, gypsum dressing.	Firm union in two months; crutches then allowed; walks well with stick and can perform light work.
25	Löwenfeld, J., Münch. Med. Woch., 1887, No. 20.	M., 40.	1887.	Injured while walking on level ground.	Rupture of tendon of left quadriceps at insertion.	.....	In five months able to walk with crutches.
26	Cluness, W. R., Sacramento Medical Times, 1888, ii., 515, and Personal Comments.	M., 75.	Oct. 20, 1888.	While walking tendon ruptured without any apparent cause other than ordinary locomotion.	Rupture of tendon of quadriceps at insertion, two inches separation.	Bandage and immovable apparatus.	Limb almost or quite useless without felt splint; three or four years later, required crutches.
27	Kaufmann, Corresp. f. Schweitz. Aerzte, May 15, 1888.	M., 48.	1888.	Fell down stairs.	Tendon torn from muscle.	Sutured with catgut.	Arose in four weeks; in six months could use leg freely; in fourteen months normal.
28	Midelfast, Centralbl. f. Chirurg., Mar., 1888.	M., 12.	1888.	Fell.	Rupture of tendon at insertion; patella forced between femur condyles and tibia.	Reduction of luxation and suture.	Complete recovery.
29	Gross, F. H., Medical News, 1889, lv., 191.	.....	March 2, 1889.	.....	Rupture of tendon of left quadriceps.	.....	Three months later, a fair degree of usefulness, mainly through the accessory tendons of the vasti.
30	Chaput, Bull. et Mém. Soc. de Chir., Par., 1891, N. S., xvii., 453.	M., 60.	Aug. 16, 1889.	Fell upon his back.	Rupture of tendon of quadriceps and lateral expansions.	Open incision and catgut suture.	Three months later, perfect union; extension complete and flexion beyond right angle.
31	Bowden, J. B., Lancet, 1893, i., 277.	M., 69.	Dec. 30, 1890.	Slipped on ice and fell backward with leg under him.	Rupture of tendon of quadriceps with three inches separation.	Extension of knee; apposition of parts; plaster strips; posterior splint and swing; gypsum in five weeks, left in four weeks; leather knee-cap.	Three-fourths inch separation; able to walk eight or ten miles a day with just the slightest halt in his gait; can walk without knee-cap, but does not feel quite safe.
32	Cecaldi, Bull. et Mém. Soc. de Chir., Par., 1891 N. S., xvii., 453.	M., 60.	June, 1892.	Fell down stairs.	Rupture of tendon of quadriceps; rupture of rectus only.	Bandage; electricity; passive motion.	Walked slowly at end of a week.
33	Shepherd, Montreal Medical Journal, 1892–93, xxi., 106.	F., 41.	June 10, 1892.	Slipped and fell down a couple of steps.	Rupture of tendon of right quadriceps immediately above patella.	Figure-of-eight bandage and gypsum splint; elevation; rest in bed for six weeks; posterior leather splint and crutches.	Left hospital on 30th day, and "since then has reported herself perfectly well."
34	Koehl, E., Cor. Bl. f. Schw. Aerzte. Basel., 1893, xxiii., 454.	.....	.....	.....	Rupture of right quadriceps.	Suture.	.....
35	Owen, J. L., British Medical Journal, 1893, ii., 1425.	M., 44.	March 20, 1893.	Man ran against him and he fell.	Rupture of tendons of both quadriceps.	Inclined plane and adhesive straps for seven weeks.	Nine months later, still a separation; cannot fully extend knees; can walk fairly well on level ground with aid of a stick.
36	Buchanan, J. J., Reported herein.	F., 45.	June 24, 1894.	Slipped and fell.	Rupture of tendon of left quadriceps at its insertion.	Open incision; drilling of patella and suture with silkworm gut.	Result mechanically perfect and functionally almost so.

Of the 36 cases tabulated in the present paper, 5 were operated on by open incision (Chaput, Kaufmann, Midelfast, Koehl, and Buchanan), and one by subcutaneous wire (Childs); 2 were not recognized till too late for treatment (Gosselin and Marguet); 2 had no efficient treatment at first (Blackman and Toogood); in 3 the result is not stated (Trent, Guerin, and Socin), and in 5 the result was imperfect, but sufficient time had not elapsed to preclude further improvement (Kübel, Thompson, Weinlechner, Ormsby, and Cecaldi). This leaves 18 cases treated by external appliances, from which to draw conclusions as to results. Of these, 4 were perfect (Hirn, Bardeleben, Shepherd, and Christison); 5 were favorable (Spong, Zickero, Toncker, Weir, and Morton); 4 were unfavorable (Weinlechner, Carrington, Bowden, and Owen); and 5 were bad (Brushfield, Gibney, Löwenfeld, Cluness, and Gross). Placing the perfect and favorable results in one group and the unfavorable and bad in another, we have 9 of the former and 9 of the latter, which exactly corresponds with the conclusions of Bull.

This lesion furnishes the same indication for treatment as does fracture of the patella, but the difficulties of fulfilling the indication by external appliances are very much greater. The upper border of the upper fragment, in transverse fracture of the patella, furnishes an offset, over which can be looped the turns of muslin, plaster, leather, or other material used to make traction on the quadriceps muscle and thus approximate the fragments; but, in rupture of the quadriceps tendon, no such purchase exists, and reliance has to be placed on rest in bed, the extended position, bandage of the thigh from above downward, and of the patella from below upward, and the posterior or immovable splint. That this method of treatment is inefficient is

evident, and that its results are poor is shown by the statistics already quoted. The application of buried sutures through the open incision is the ideal method of treating this injury, but the cases so treated have yet been too few to furnish data for reliable conclusions as to the risk of the operation and the functional result. It seems reasonably certain, however, that the mortality will be found the same as in the open operation for fractured patella, which, with proper precautions, in recent cases is practically *nil*.

My attention was drawn to this subject by the following case, which came under my own care:

On June 24, 1894, Mrs. S——, a corpulent woman, about forty-five years of age, slipped and fell to the ground and found herself unable to rise. She at once summoned Dr. H. D. Rickenbach, by whose courtesy I was asked to take the case in charge. The diagnosis of rupture of the tendon of the left quadriceps femoris at its insertion into the patella was easily made. The power of extension was lost and an hiatus, about two inches in extent, was discovered between the upper border of the patella and the extremity of the tendon. The probabilities as regards usefulness of the limb without operation, based on the statistics of Bull's article, were laid before the patient, together with the slight amount of risk incurred by open incision. The patient, a woman of more than ordinary intelligence, decided to have the operation performed.

Eight days after the injury, with the usual antiseptic precautions, a free transverse incision was made at the level of the upper border of the patella, and the joint thereby freely opened. The tendon, together with its lateral expansions, was found entirely torn through, no part of it remaining attached to the patella. As before stated, there was about two inches of retraction. Two holes were drilled through the patella and the shelving extremity of the broad tendon of the quadriceps was seized with volsella forceps and drawn down into place. A double strand of heavy silk-worm-gut was passed through each hole in the patella and deeply through the tendon, tied, and cut short. The superficial parts were accurately sutured and the joint drained. An antiseptic dressing and posterior plastic splint of plaster of Paris were applied. Primary union resulted and the buried sutures yet remain in place.

The splint was left on and the patient confined to bed for four weeks, when she was allowed to rise without the splint; at the end of five weeks she was allowed to walk with crutches, which she discarded about three weeks later. She now, at the end of ten months, walks with the least perceptible halt and the anatomical conditions appear normal. She considers the limb as good as the other.

The following is a list of all the cases operated on by open incision of which record can be found: 1. Lister (1878) (Roxburgh's case), by a complicated plastic operation, repaired an old rupture of the tendon with buried catgut sutures, with a very good result. 2. Lüning (1880) sutured the tendon with catgut, as a part of the repair of an open wound, made by a butcher's cleaver, with result of a freely movable joint. 3. McBurney (1885) sutured the tendon with catgut and a wire retention stitch, with a perfect result. 4. Wilkin (1887) sutured the tendon with silk-worm-gut as part of the repair of an incised wound of the thigh, with good function and almost perfect flexion. 5. Kaufmann (1888) sutured the tendon to the muscle, from which it had been torn. Complete recovery. 6. Midelfast (1888) operated on a case in which the patella was found driven between the femur and tibia. He sutured the tendon and secured primary union. 7. Bull (1888) sutured the tendon with catgut, with good result. 8. Chaput (1889) sutured the tendon with catgut, with perfect result. 9. Koehl[1] (1893) sutured the tendon. 10. Buchanan (1894) drilled the patella and sutured the tendon to it with silk-worm-gut, with perfect result.

In view of the favorable results in these operated cases, the extremely unfavorable statistics of cases trusted to external appliances, and the safety of the operation, I think we are fully justified in recommending this procedure to our patients, laying before them the advantages of the treatment, and not failing to state the possibilities, however remote we may consider them, of failure in our antiseptic efforts, failure which, in such case as this, may carry with it loss of limb or loss of life.

[1] I have not been able to secure the full record of this case.

Progress of Medical Science.

Experimental Appendicitis.—Dr. Roux says that the mechanism of perforation of the appendix is little known; it has been attributed to an ulceration caused by the presence of a calculus, to an ulcerative lesion caused by compression of the vessels, to a dilatation of the appendix from retention of mucus, and, finally, to an infective process. M. Roux has studied the question experimentally, and chose swine as suitable subjects. The colon was drawn out, the cæcum isolated, and an artificial appendix made by passing a row of parallel silk-threads around it just beneath the serous coat, and drawing them moderately tight. Farther up in the cæcum an incision was made, and through this foreign bodies were introduced. Sixty-seven swine and two dogs were thus operated upon; the two dogs died in twenty-four hours from gangrenous peritonitis. Two swine also died from faulty technique; the others bore the operation with scarcely any reaction. The results as to a formation of an artificial appendix were good. The silk cut through, and was passed from the anus, the pocket persisted. At the end of some months the foreign body had disappeared, the mucous membrane was found to be intact. In a single case a suppurating appendicitis was produced. The presence of a foreign body alone, therefore, was not sufficient to cause perforation; some other factor must be added. Roux thinks that upon the occurrence of a traumatism or a chill the mucosa becomes turgid, presses firmly upon the foreign body, and the circulatory disturbances which result ultimately lead to gangrene and perforation.—*Annals of Surgery.*

The Mortality from Tuberculosis in German Cities.—Dr. Bollinger has succeeded in procuring the mortality tables of various German cities, extending over long periods, with the special intention of inquiring into the mortality from tuberculosis. From a comparison of the tables, it is certain that, as regards the large cities, such as Vienna, Berlin, and Hamburg, a distinct diminution in the death-rate from tuberculosis is taking place. In the city of Munich, for instance, a diminution of 18 per 10,000 has taken place during the last twenty-six years. In correspondence with this, the tuberculous material in the Pathological Institute has diminished, so that in the space of five years eight per cent. fewer cases of tubercle are met with on the post-mortem table. Formerly one-third of all post-mortem examinations were on subjects that had died from tuberculosis in some form, where they now number only one-fourth. As regards the prevalence of tuberculosis in cattle the doctor states that in one year 21,000 cattle, found to be suffering from tuberculosis, were slaughtered in the Berlin slaughter-houses, and that in the kingdom of Saxony one ox in seven and one cow in four were affected with tubercle. In the years 1893 and 1894 a remarkable increase in tuberculosis in cattle took place in Schwerin, and this increase corresponded with a dearth of fodder for cattle. Dr. Bollinger mentions this fact as a wholesale experiment illustrating the effects of deficient nutrition in predisposing to disease.—*Munchener Medizinische Wochenschrift.*

The Management of the Pregnant, Parturient, and Lying-in Woman Suffering from Cardiac Disease.—Dr. Phillips does not believe that during pregnancy the left ventricle is hypertrophied, as is often taught. During pregnancy the work of the heart is greatly increased, owing to the larger quantity of blood and the resistance to the circulation caused by the enlarged uterus. During labor the greatest strain comes upon the heart, the blood pressing strongly upon the ventricular walls with the contraction of the uterus, while the right heart does not receive venous blood as usual, and hence the partial cyanosis which is so often observed. After the birth of the child the abdominal pressure sinks, while the right heart becomes overfilled. To obviate the disturbances caused by this change of pressure a large sand-bag may be placed upon the abdomen so soon as the presenting part passes through the vulvar orifice; the bag should be retained for at least an hour. Several forms of cardiac disease are found during pregnancy: adhesion from pericarditis, degeneration of the heart muscle, valvular heart disease, and endocarditis grafted upon a chronic form may be present. In the treatment of these cases, if the patient passes through pregnancy without bad symptoms, treatment should be confined to keeping the bowels open and avoiding fatigue and climbing of stairs. Compensatory disturbances may appear as early as the ninth week, although usually not until the fifth month. Albuminuria is a serious complication.

These cases are best treated by arsenic, iron, and strychnia, while ether and ammonia should be given for attacks of syncope; if serous effusion with dyspnœa be present digitalis or strophanthus may be employed. Over-exertion and straining during defecation should be carefully avoided. During labor the patient will be better in a sitting posture if severe dyspnœa develops; ether and brandy must be given by injection. The patient should be delivered so soon as dilatation will permit. If dilatation is not complete, incision may be practised; ether should be used as an anæsthetic. After the birth of a child a twelve-pound sand-bag should be laid over the fundus of the uterus to counteract the rapid fall from abdominal pressure. The greatest danger to the mother, however, lies in the first few days of the puerperal state. Post-partum bleeding should not be prevented; but, if anything, a moderate loss of blood will relieve the patient. Ergot is often followed by good results. In cases of great dyspnœa and cough, nitrite of amyl should be inhaled; better results are obtained from this agent than from venesection. Phillips reports four cases, one of aortic stenosis, two of mitral disease, while the fourth was a case of chronic mitral disease in which labor was followed by acute endocarditis with regurgitation. In one of his cases of chronic mitral disease the patient was not seriously ill until the third day after delivery, when she was suddenly attacked by profound syncope; three of his cases recovered from labor, while the fourth perished from endocarditis. In studying the literature of the subject Phillips finds that labor should not be induced. Two-thirds of the cases which he collected perished during the puerperal state. These patients are especially liable to septic infection.—*The American Journal of the Medical Sciences.*

Suturing the Pericardium.—The following case was recently observed by Dr. Dalton (*St. Louis Medical Journal*): A man in a fight was stabbed over the left breast; the wound was an inch in length and an inch and a half above the left nipple. There was little hemorrhage from the wound, and normal cardiac dulness was found on percussion. The percussion of the chest showed absence of dulness. The wound was closed and antiseptic dressings applied. Ten hours after admission to the hospital, percussion revealed dulness over the entire left side, and much pain was complained of. The patient was removed to the operating theatre, and the dressings taken off, when it was found that blood and air gushed from the wound with each inspiration. An incision was accordingly made, eight inches in length, over and parallel to the fourth rib, and six inches of the rib resected. The intercostal artery having been tied, the pleural cavity was found full of clotted and fluid blood, which, with each inspiration, poured from the wound with great force. The patient was turned on his left side, and with a long pair of forceps armed with a sponge the pleural cavity was cleansed of blood. Subsequently it was discovered that a transverse wound of the pericardium existed to the extent of two inches, and steps were taken to suture the lesion. In carrying out this procedure great difficulty was experienced owing to the pulsation—at the rate of 140 per minute—of the heart. The pericardium with each pulsation of the heart rose and fell, and in order to carry into effect that which was being attempted it was necessary to follow the movements of the organ. Ultimately, a continuous suture of catgut was satisfactorily inserted in the wounded pericardium, the pleural cavity was then thoroughly irrigated with hot sterilized water, the external wound closed, without a drainage-tube, and antiseptic dressings applied. It may be noted that at several stages of the operation, which lasted an hour, the patient seemed to be dying, and in order to avert collapse hypodermic injections of whiskey and strychnine were resorted to. Before the pericardial wound was sutured, examination of the heart was made with a view to the discovery of a wound in the organ, but no lesion was found. The patient made an uninterrupted recovery.

Jacksonian Epilepsy from Old Cerebral Abscess.—Dr. Lépine reports the case of a woman, aged sixty-two, who ten years before her admission to hospital had had a series of convulsions with loss of consciousness, and these were succeeded by left hemiplegia, which lasted fifteen days. Since then she had had frequent attacks, which had been regarded sometimes as Jacksonian attacks, sometimes as hysterical. In December last she had several attacks in one day, and these continued to recur day after day. There was loss of consciousness in the severe ones, but there were also slighter ones in which there were jerkings of the fingers and forearm, but no loss of consciousness. On the day after her admission, following a severe attack, left hemiplegia was noted, affecting both arm and leg, but sparing the face. The attacks came on more frequently, and although bromides lessened their severity it did not control them, and the patient gradually sunk and died. At the autopsy it was found that in the right frontal lobe, rather nearer to the anterior border of the hemisphere than to the fissure of Rolando, there was a cyst two to three centimetres in diameter, with caseous contents. It was, in fact, apparently a cold abscess, and there seems every reason for believing that it must have existed for the ten years during which symptoms, only explicable on the hypothesis of such a lesion, had been present.—*Revue de Médecine.*

A Suit for Contracting Typhoid Fever.—The widow of a man who died of typhoid fever in Ashland, Wis., has brought suit against the Ashland Water Company for $5,000 damages, alleging that the corporation permitted the water to become polluted by typhoid germs, and that her husband's death was due to this pollution. There is no doubt, as our contemporary, *The Times*, states, that suits of this kind will in the future increase, and that damages will sometimes be obtained. At present, however, it is asking a good deal of corporations to keep germs out of the aqueducts and reservoirs, especially where these latter are large and drain a wide area of ground.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 2, 1895.

THE NERVOUS SEQUELÆ OF INFECTIOUS DISEASE.

THE above was the title of a subject chosen for discussion before the Section on Children's Diseases of the British Association for the Advancement of Science. The discussion was opened by Dr. Henry Hanford, of Nottingham, who read a lengthy paper. Taking up the subject of the brain first, Dr. Hanford presented statistics regarding the percentage of post-febrile insanity. Out of 229 cases of typhoid fever, reported by Osler, there were 3 cases of melancholia arising during convalescence. Clouston found that among 1,000 cases of insanity, 10 followed an attack of fever. Epilepsy, according to Dr. Hanford's figures, and according to common observation, follows, especially, scarlet fever, next measles, and least after typhoid fever. Meningitis occasionally follows the acute fevers, but it is usually a complication rather than a sequel, and is of septic origin. Taking up next the spinal cord, Dr. Hanford found that acute myelitis sometimes follows smallpox, measles, and scarlet fever, but were very rare sequelæ. It seems to be more particularly the venereal diseases which are followed by inflammatory disturbances of the spinal cord. Attention is called to the curious fact that after an attack of acute infectious fever certain degenerative diseases, such as progressive muscular atrophy, sometimes develop in families predisposed to this disorder. It is under the head of neuritis that we find the largest number of nerve disorders following infectious disease, especially those of an acute and febrile type. Dr. Hanford gives briefly the history of the discovery and description of the various types of neuritis following typhoid fever, scarlet fever, measles and influenza. The conclusion is that, excluding diphtheria and influenza, more cases of peripheral neuritis follow typhoid fever than all of the other acute infectious diseases put together. It is a somewhat curious fact that while diphtheria is not infrequently followed by neuritis, scarlet fever is never followed by it, or, if so, the neuritis is due to some other than the specific poison of the scarlatina. Dr. Hanford's paper was discussed by eleven other gentlemen whose experience, on the whole, confirmed that given by the first speaker. Dr. Fletcher Beach spoke especially regarding the question of idiocy, and stated that among 2,000 histories of idiots which he had collected, he found only 37 in which the trouble seemed to follow some acute infectious disease. The disease which caused it oftenest was measles, then came scarlet fever, whooping-cough, and typhoid fever. Dr. Cheadle, physician to St. Mary's Hospital, observed that, with the exception of diphtheritic paralysis, nervous sequelæ in children were exceedingly rare, and this opinion was apparently the common one. It is a matter of importance to bring this matter into prominence, because the too assiduous investigation of rare morbid conditions sometimes brings them into disproportionate relation. We must not forget the fact that although the acute infectious fevers of childhood do leave some nervous wrecks, the vast majority pass through the trouble without the slightest apparent after-effect.

MEDICAL REFORM IN OUR CITY HOSPITALS.

IN an editorial which appeared in our last issue we predicted that the high-handed action of the Commissioners of Charities and Correction would not fail to call forth a vigorous protest from the members of the profession who are not "in the ring." Our prediction was verified at the annual meeting of the County Medical Society, held last Monday evening, when a resolution condemnatory of the "deal" was unanimously adopted, and was forwarded to the Mayor and Commissioners. The following is the text of the resolution:

Resolved, That we, the Medical Society of the County of New York, protest against this outrage upon the medical profession of the county of New York, and condemn the action of the Commissioners of Charities and Correction in delivering to these incorporated colleges three-fourths of the appointments upon the consulting and medical boards of these hospitals, to whose support the profession at large, as taxpayers, contribute.

In the preamble attention is called to the fact that under the new arrangement "three thousand physicians are excluded from positions upon the medical boards of the city hospitals, except by courtesy of the faculties of the incorporated colleges and the Fourth Division of Bellevue Hospital," which "are composed of less than one hundred physicians."

This is certainly a fair and temperate presentation of the question from the stand-point of the general profession, though, of course, it will not produce any impression upon those who do not recognize the rights of any except the oligarchy, which has arrogated to itself the right to dictate the future policy of the Commissioners. But, while there is a general disposition to blame the Commissioners for the wholesale degradation of faithful medical officers, without the bare courtesy of an explanation, we should not lose sight of the fact that the politicians were merely tools in the hands of their medical advisers, and doubtless accepted the suggestions of the latter without thinking of the injustice which they were doing to worthy members of the profession.

We are accustomed to regard the system of political patronage as the most pernicious feature of organized tyranny. But what is the present spasm of reform in its recent application to the city institutions but an organized scheme on the part of the colleges to control

political patronage, and thus to increase their power and influence?

The situation is not without its humorous side even to those who are smarting under the sense of injustice. As the late Mr. McAllister defined the numerical limits of our best society, so in the future the *élite* of the profession may come to be known as the one hundred, outside of whose mystic circle are only the "riff-raff," as one of the Commissioners is reported to have designated the members of the abolished medical boards. The sharp distinction will naturally appeal to the laity, who are prone to judge of professional ability by the possession of high-sounding titles. Granted that the faculties of the three undergraduate schools include in their ranks a fair proportion of the ability and learning of the profession. Do they include all? Are there no flowers that "blush unseen?" But we are assured that under the new arrangement not only will better men be secured on the attending staffs of the various city hospitals, but those institutions will be utilized for the purpose of clinical teaching. Oh! Come now, gentlemen of the new *régime*, be honest. You know how little the institutions on the island are available for this purpose, and that you have more clinical material than you can utilize in close proximity to your schools. Why not admit that you simply saw a favorable opportunity to utilize the present reform movement to your own advantage, with a cold-blooded disregard of the rights of your *confrères*, many of whom had served the city faithfully for years?

However cute this "deal" may appear as a political trick, there is a general feeling among the medical profession of New York, as expressed in the resolution quoted, that the victors are more deserving of sympathy than the vanquished.

THE CASE OF MEDICAL INSPECTOR KERSHNER.

The case of Medical Inspector Kershner, of the navy, to which reference has been previously made in these columns, now awaits the action of the President of the United States, who may or may not approve the finding of the recent court-martial for dismissal from the service. As the proper discharge of such a responsibility on the part of the chief executive necessarily involves many weighty considerations bearing on the character of an efficient officer of the service, and indirectly upon the medical corps of the navy, it is to be hoped that no pains will be spared in arriving at a calm and necessarily just decision regarding the facts as brought out in the aforesaid trial.

With every incentive on our part to view the situation from a strictly impartial stand-point, it must not be forgotten that from time immemorial there has been a bitter and unreasonable jealousy between the line and staff concerning the very matters of medical authority upon which the questions of prerogative in the trial appear to hinge.

Whatever else may be said there can be no doubt in the mind of anyone who studies the record of the court-martial that the defendant was in any way lacking in the proper motives for the discharge of his duties as he understood them; in fact as everyone else must understand them who is acquainted with the regulations defining them. These regulations direct that the medical officer shall keep the commanding officer informed in regard to all diseases that may appear on board ship, invade the ship, or directly, or indirectly, endanger the crew. Too frequently, however, this provision becomes a dead letter unless the superior authority of the captain sees fit to enforce it. It will be recollected that the present unfortunate misunderstanding of relative obligations grew from an unreasonable, injudicious, and unjust charge of inhumanity against the ship surgeon, who, having the medical safety of the crew at heart and in fear of yellow fever, then prevailing, protested against the visiting of a patient on a suspected merchant ship that was nearer help from the shore than from the war vessel. For calling attention to such danger the captain of the ship reported the fact to the admiral, who sent to the Navy Department the infamous charges against the humanity, the moral character and professional ability of said surgeon of the fleet. In natural distress of mind Surgeon Kershner forwarded a verbatim copy of the charges to Surgeon-General Tryon, who was asked to lay the case before the Secretary of the Navy. He also wrote to several of his personal friends and to the members of his family in a general way to the same effect. Accounts of the difficulty then found their way to a daily paper, but whether these were obtained from the official reports or indirectly through some of Dr. Kershner's friends, does not appear. It was charged, on general principles, however, that the defendant was the guilty party, thus violating navy regulations and wilfully subverting discipline. In a court-martial at Kingston, Jamaica, an attempt was made to prove that a verbatim copy of the so-called charges was sent directly or indirectly to the daily press by the defendant, and resulted in the inspiration of a widely published criticism. The witness admitted writing the substance of the charges to friends, but being informed that an explicit answer was requested only in connection with a verbatim copy to the newspapers, formally and explicitly denied the latter charge. The report of the trial at Jamaica formed the basis of a second trial at the Brooklyn Navy Yard, in which it was charged that the witness had sworn falsely on the previous trial, to the effect of denying that he not only did not send any verbatim reports to the papers but that no reports were sent at all by him. The omission in the imperfectly reported proceedings of the first court-martial, accidentally or purposely, of the word *verbatim*, on the use of which the only denial of the defendant was based, made it appear that no answers whatever were offered or no testimony given as to the written reports to friends or even a verbatim copy to Surgeon-General Tryon. Nor was it possible, in spite of the efforts of the learned counsel for the defence, to refresh the minds of the first jury concerning such essential points. Not even the benefit of a reasonable doubt as to motive or intent by defendant was allowed, the jury simply voting to dismiss the officer from the navy on the charge of "making false statements wilfully, knowingly, and with intention to deceive."

It certainly appears quite remarkable that on such quibbling charges, based on incomplete and inaccurate reports, a faithful officer, a thoroughly competent sur-

geon, and an honorable gentleman should, from the spite of any one—admiral, captain, or commander—be the victim of such a dreadful conspiracy of adverse circumstances. There is yet one chance for justice, in an impartial review of the whole case by the President himself.

News of the Week.

The Reorganization of the City Hospitals—Another Protest.—The following resolutions were adopted at a meeting of the New York County Medical Association, held October 21, 1895:

Whereas, Information comes to us from reliable sources that the Medical Boards of the Gouverneur, Fordham, City, Maternity, Nervous Diseases, Workhouse and Almshouse, and Randall's Island Hospitals have been abolished, to take place November 1st, and that the members composing said boards are to be removed without cause; and

Whereas, In the case of the Harlem Hospital the Committee of the New York County Medical Association appointed to consider matters of interest to the medical profession, asked for a hearing before the Commissioners of Public Charities and Correction, in the interest of the medical men who had been unjustly deposed, and urged upon the appointing boards of the medical colleges that they defer action until charges had been preferred, or that, in the absence of charges, they be reappointed; and

Whereas, The medical colleges and the Commissioners ignored the communications, and thereby expressed their apparent contempt for your representatives, and their indifference to any wrong done to the profession; therefore, be it

Resolved, That this Association condemns the wholesale dismissal of medical men from hospital positions without cause or hearing.

Resolved, That we express our disapproval of the action of the Faculties of the four divisions of Bellevue Hospital and Commissioners of Public Charities and Correction in ignoring the communications of your Committee.

Resolved, That copies of the preamble and resolutions be forwarded to the Faculties of the Medical Department of the University of the City of New York, the Bellevue Hospital Medical College, and the College of Physicians and Surgeons, to the Commissioners of Public Charities and Correction, and to the medical press.

The Regents' Preliminary Examinations for Medical Students.—The following is a copy of a notice just issued by the Examination Department of the University of the State of New York to all medical schools in the United States and Canada:

"Will you kindly call the attention of students to the following amended New York statute relative to degrees in medicine, which took effect May 13, 1895:

"The degree of Bachelor or Doctor of Medicine shall not be conferred in this State before the candidate has filed with the institution conferring it the certificate of the Regents that, three years before the date of the degree, he has either graduated from a registered college or satisfactorily completed a full course in a registered academy or high school, or had a preliminary education considered and accepted by the Regents as fully equivalent; or had passed Regents' examinations representing for degrees conferred in 1898, one year of academic work, for degrees conferred in 1899, two years of academic work, and for degrees conferred in 1900, a full high-school course."

"This law prohibits us from admitting to the New York licensing examination any applicant on any lower requirement than that exacted for M.D. degrees, and for admission to the licensing examination in the case of graduates of New York schools. Hereafter no applicant not matriculated in a registered medical school before May 1, 1895, will be eligible for a card of admission to the New York licensing examinations, unless he met the standard in point of preliminary education three years before the date of his medical degree. According to an opinion of the Attorney-General the Regents should not discriminate against the New York medical schools and New York medical students by registering any medical school out of the State whose minimum graduation standard is less than that fixed by statute for New York medical schools."

Health Board of the City of New York.—The Board of Estimate and Apportionment have appropriated $40,000 for a new Ambulance Station and Vaccine Laboratory. The Health Department this year receives $498,918, which is an increase of nearly forty thousand dollars over last year.

Obituary Notes.—Dr. Frank E. Barrington, late house surgeon, Hartford Hospital, Hartford, Conn., died at Windsor, Vt., October 16, 1895, of acute tuberculosis. He was graduated from the University of New York, Medical Department, in 1883, with honor. Dr. Barrington was a young man of rare talent, not only in his chosen profession, but also in music, having composed many sweet songs. He was twenty-eight years of age and unmarried.—Dr. George A. Mursick, of Nyack, died at his home in that city on October 17th. He was born in New York City on February 26, 1834, and was graduated from the New York College of Physicians and Surgeons in 1860. In January, 1863, he entered the Union Army as assistant surgeon, and was assigned to hospital service. Later he was surgeon in charge of the army general hospital at Duvall's Cliff, Ark., and became medical purveyor of the Department of Arkansas in April, 1865. Dr. Mursick went to Nyack in 1869, where he has since practised. His wife and two sons survive him.—Dr. Timothy B. Cox, of Frankfort, Ind., died at his home in that city on Wednesday, October 16th, aged seventy-eight years.—Dr. John S. Young, of Brooklyn, died on September 24th, at his home in that city, aged sixty-two years. He was a graduate of St. John's College, Fordham, and of the College of Physicians and Surgeons of New York, in 1854. He served as Secretary of the Health Department in Brooklyn from 1886 to 1888, and for the five years following as Deputy Commissioner.—Dr. Francesco Vallardi, the well-known medical publisher, died in Milan, on September 18th, after a brief illness. He was born in that city in 1809, and obtained his medical degree in 1833. He

practised for a short time only and then became a publisher, first of ethical and religious, and later of medical works.—Dr. Abbie J. Seymour, of Buffalo, was found dead on October 17th, her body lying on the track of the New York Central Railroad. Her skull was crushed, and one of her hands and both feet were cut off. It is supposed that she was struck by a West Shore train which passed shortly before she was found. Dr. Seymour was the most prominent professional woman in Buffalo. She was born in Batavia forty-two years ago, and was a graduate of Rush Medical College, Chicago. Of late she had been in bad health, and only returned from a sanitarium on the morning of the day of her death. In the afternoon she left her home, and was not seen again until her dead body was found.—Thomas Keith, M.D., LL.D., the well-known surgeon, died on October 9th, aged sixty-eight. He has long been known as being one of the early ovariotomists, and as being one of the most successful of gynecological surgeons. Dr. Keith performed his first ovariotomy in 1862. Before many years he had become renowned for his successful work in this line, and he did a great deal to increase the fame of the Edinburgh Hospital and School. In 1888 he went to London, and practised in that city until about three years ago. In 1894 he published the results of some of his experiences in the work entitled "A Text-Book of Surgery," which was written, however, for the most part, by his sons.—Baron Larrey died recently at his home near Paris. He was the son of the celebrated surgeon to the great Napoleon, and was born in 1808. He was at one time surgeon to the Emperor Napoleon III., and was Surgeon-General of the Army in Italy. He was for a short time a member of the Chamber of Deputies. Baron Larrey was a man of considerable ability, but he owed a good deal to his father's fame.

Surgeoncy of Police.—Dr. Marvin R. Palmer, of this city, reached the highest grade in the recent competitive examination for the vacancy in the surgical staff of the police force, and was appointed to the position accordingly. This is a becoming recognition of fair play against the political pull which has in times gone by so strongly actuated the department. We congratulate the Commissioners on this new evidence of their determination to do the right thing in the right way.

French Centenarians.—At the date of the last French census there were 213 genuine centenarians, of whom 147 were women and 66 men; 33 of the women were old maids and 11 of the men bachelors.

Tea and Indigestion.—Dr. McKechnie reports in the *Medical News* some experiments to determine the influence of tea upon digestion. The experiments were carried on by himself by means of test-tubes and of a gastric fistula formed in a monkey's stomach. Dr. McKechnie finds that tea infusions retard digestion somewhat, but is of the opinion that it is not the tannic acid that is the injurious agent, but some of the less soluble extractive matters. Tea is not, however, very indigestible, especially teas that are freshly made.

The Late Dr. W. B. Conrad.—At a special meeting of the London Medical and Surgical Society, held October 21, 1895, the following preamble and resolutions were adopted:

Whereas, In the death of Dr. H. B. Conrad the Society has lost one of its earliest and most zealous supporters, and its members a genial and generous friend;

Resolved, That we deplore his sudden and untimely end, and offer to his bereaved family our most heartfelt sympathy; and

Resolved, That these resolutions be entered upon the minutes of the society, published in the Medical Record and *Medical Journal*, and a copy sent to the family of our late member.

J. Blake White,
Frederic S. Sellew,
H. H. Seabrook,
Committee.

The New York Obstetrical Society Officers for the Year 1895–96.—*President*, Henry C. Coe, M.D.; *First Vice-President*, J. Riddle Goffe, M.D.; *Second Vice-President*, A. Palmer Dudley, M.D.; *Recording Secretary*, Arthur M. Jacobus, M.D.; *Assistant Recording Secretary*, George W. Jarman, M.D.; *Corresponding Secretary*, Robert L. Dickinson, M.D.; *Treasurer*, J. Lee Morrill, M.D.; *Pathologist*, George C. Freeborn, M.D.

A Brave Doctor.—Our English contemporaries are sounding the praise of Dr. Charles Toller, of Ilfracombe. Dr. Toller allowed himself to be lowered over a perpendicular cliff, one hundred and fifty feet high, in a strong gale of wind, so that he could reach and give assistance to a shipwrecked sailor who lay on the rocks below. Dr. Toller's act was one requiring great courage and nerve, and he justly deserves the encomiums of his brethren. It looks as though he would, for the time, become almost as famous as Mr. Grace, who made one hundred runs at cricket.

Homicidal Mania.—A case of homicidal mania has recently developed in Italy which resembles very much that of "Jack the Ripper" in London. The criminal in this case, however, chose for his victims babies. After having strangled five of these, he was discovered, tried, and sentenced to twenty years' imprisonment—a rather mild punishment for so many murders.

Sensitive Ethics.—A correspondent of *The Lancet* writes a most indignant letter, complaining that he has seen in the daily papers the statement that "Dr. —— and Dr. —— have returned to their respective homes after a holiday." This, as it seems to the correspondent, is a most unwarrantable breach of ethics; and the correspondent has taken the pains to place a large black mark against the names of the criminals. The world is a silly place, but there seems to be no place quite so supremely silly as the head of the average London doctor when he gets on the subject of medical ethics. Why the daily press should not state that Sir William Broadbent has returned from his vacation, if this is a matter of interest to its readers, we do not see. The daily press is full of the comings and goings of lawyers, clergymen, and business men, of far less worth than he.

Philadelphia has 2,610 medical students this year, as against 2,345 last year; 285 are homœopathic and 200 are women.

Reviews and Notices.

THE DISEASES OF THE LIVER: JAUNDICE. GALL-STONES. ENLARGEMENTS. TUMORS, AND CANCER, AND THEIR TREATMENT. By J. COMPTON BURNETT, M.D. Second revised and enlarged edition. Boericke & Tafel. 1895.

THE author of this homœopathic treatise is evidently one of the minority who still adhere to the original doctrines propounded by Hahneman. He prescribes chelidonium for jaundice and enlargement of the liver, because the plant has a yellow juice. But this remedy must be used only when the enlargement is in a perpendicular direction. If pain starts on the right side and goes toward the left, one remedy is to be given; another if the pain has a contrary direction.

The most remarkable statement in the book is that several cases of carcinoma of the liver, which have been diagnosed as such by several reputable physicians, have been thoroughly and permanently cured by the administration of cholesterine in small doses.

It would require many grains of sodium chloride to make this statement digestible, and we are forced to the conclusion that the reputable physicians made a mistake in diagnosis.

THE POCKET MATERIA MEDICA AND THERAPEUTICS. A *résumé* of the Action and Doses of all Official and Non-officinal Drugs now in Common Use. By C. HENRI LEONARD, A.M., M.D., Professor of Medical and Surgical Diseases of Women and Clinical Gynecology, Detroit College of Medicine. Second edition, enlarged and revised. The Illustrated Medical Journal Co., Detroit, Mich. 1895.

IT would require a much larger pocket than is usually found in the modern style of dress to carry this volume. Nevertheless, it contains a great deal in a compact form, making it useful to the student and busy practitioner as a book of ready reference. While undoubtedly most physicians are inclined to diminish rather than increase the number of drugs used in daily practice, yet it is perhaps well to have some knowledge of all. The author claims that the arrangement of the various drugs is original; and this part of the work especially commends itself.

EXERCISE AND FOOD FOR PULMONARY INVALIDS. By CHARLES DENISON, A.M., M.D., Professor of Diseases of the Chest, University of Denver. Denver: The Chapin & Hardy Co. 1895.

THIS little manual should be in the hands of every physician for distribution to his patients suffering from pulmonary tuberculosis. Its principle of treatment in this disease is the correct one, viz., the preservation of the vitality of the living cell in its battle with the tubercle bacillus. The vitality of the cell depending upon the nutrition which it receives, nutrition must be carried to the highest point by rational exercise and proper diet.

The rules laid down for the guidance of patients in these respects are practical; they are the result both of personal experience and extended observation, are simple, easily carried out, and if followed in detail will do much to restore to health many who are in the early stages of phthisis.

THE URINE IN HEALTH AND DISEASE, AND URINARY ANALYSIS PHYSIOLOGICALLY AND PATHOLOGICALLY CONSIDERED. By D. CAMPBELL BLACK, L.R.C.S. Edin., F.F.P. and S. Glas.; Professor of Physiology in Anderson's College Medical School; Physician to the Glasgow Public Dispensary. Philadelphia: Lea Brothers & Co. 1895.

THIS new work on a very important subject can be recommended to the profession. The author first takes up the anatomy and physiology of the kidney. This portion of the work is condensed, but is complete and clear. A consideration of the normal elements of the urine follows, and the tests for each given. The most important are treated quite exhaustively, and the methods of quantitative analysis given, which can be carried out by the general practitioner. All of the latest tests for the abnormal constituents of the urine are presented, and a comparison of their delicacy and value made.

The details of the experiments are clearly stated, so that the book is an excellent working manual of urinary analysis. The author has omitted a great deal of the purely speculative work found in larger text-books, and has included only that which is of importance from a clinical stand-point.

MODERN MEDICINE AND HOMŒOPATHY. By JOHN B. ROBERTS, A.M., M.D. Philadelphia: The Edwards & Docker Co. 1895.

THE author of this little work, comprising two addresses delivered before the Philadelphia County Medical Society, has written in a liberal spirit.

He shows that the instruction given in the homœopathic medical colleges to-day differs very little from that of the other schools, and that the doctrines of similars and the potency of infinitesimal doses have been abandoned by the majority of the best educated members of the so-called "new school." On the other hand, it is just as evident that many of their prominent writers and teachers adhere firmly to these doctrines. In the minds of the people they are still closely associated with the name homœopathy. Therefore, as the author states, harmony of action and true fellowship among those who tacitly or openly accept the doctrines of Hahneman, and those members of the profession who endeavor to practise upon broad scientific principles, is impossible.

CLINICAL LECTURES ON DISEASES OF THE NERVOUS SYSTEM. Delivered at the National Hospital for the Paralyzed and Epileptic, London. By W. R. GOWERS, M.D., F.R.S., Physician to the Hospital, etc. Philadelphia: P. Blakiston, Son & Co. 1895.

THESE are reprints from various English journals, with the exception of two that now appear by permission of an American publisher. Originally delivered at the National Hospital, they cover an instructive set of abnormal conditions. Two chapters of the twenty are devoted to locomotor ataxia, two others to the infantile causes of epilepsy, and two to the exposition of optic neuritis. Lead palsy, saturnine tabes, neuralgia, syringomyelia, acute ascending myelitis, bulbar paralysis, syphilitic hemiplegia, facial paralysis, argyria and syphilis, facial contraction after palsy, the treatment of muscular contraction, mistaken diagnosis and the principles of diagnosis of diseases of the nervous system complete the list of subjects. The style is clear, forceful, and insinuating, which adds greatly to the valuable information that the book contains.

LECTURES ON APPENDICITIS, AND NOTES ON OTHER SUBJECTS. By ROBERT T. MORRIS, A.M., M.D. G. P. Putnam's Sons. 1895.

THE large number of cases of appendicitis which are seen every year, the importance of early diagnosis and prompt treatment, make any contribution to this subject by one who has had considerable experience in it of decided value to the profession. The author of this book has devoted most of his time to surgical work, has decided opinions, and is not afraid to express them, though they may run counter to the general opinion. Though one may not altogether agree with the theories expressed, yet it must be acknowledged that the author has reached his conclusions through practical study of the subject.

No exception can be taken to that part of the work relating to the preparation of the surgeon and the patient for all operations. It contains the principles of modern aseptic surgery, and the minute details, so often omitted, are given with a clearness and precision which their importance warrants. The results obtained under their guidance, not only by the author but others, are a guarantee of their efficiency.

Bacteria invading the tissues of the appendix through some injury to its wall is believed to be the true cause of all cases of appendicitis. When once this infection has taken place, though nature may be able in the first attack to limit the action of the bacteria, yet some will remain ready to start the destructive process afresh. Therefore, the only safe plan when an appendix has been infected is to remove it at once. Probably the severest criticism will be made in regard to the technique of the operation advised. The author claims that a long incision through the abdominal wall heals more slowly than a short one, necessarily keeps the patient in bed longer, and is more apt to be followed by hernia. Therefore he advises the shortest incision possible compatible with easy removal of the appendix, and fixes the limit at one and one-half inch. He claims that through this opening, in uncomplicated cases, the appendix can be safely removed by an operator expert in abdominal surgery, and that the average time in bed required will be only nine days.

The statistics of one hundred consecutive operations are given. In forty of these the one and one-half inch incision was used, and all recovered. Of these forty, in five there was suppuration in the wound coming on after union, and one developed a hernia. Of the sixty operated upon by a long incision there was suppuration or sloughing in five, and only one hernia is reported. That occurred where for some reason the wound had to be kept open. The number of days spent in bed by each patient is not given.

From these statistics it would seem that, so far as healing of the wound and hernia is concerned, the short incision has not much in its favor. The question of its advantages can only be settled by a large number of cases extending over a considerable period of time. The notes on other subjects included in this volume are mostly papers which have appeared from time to time in various medical journals.

Some Physiological Factors of the Neuroses of Childhood. By B. K. Rachford, M.D., Professor of Physiology and Clinician to Children's Clinic, Medical College of Ohio. The Robert Clarke Co. 1895.

This book is an important contribution to a subject which has been almost entirely neglected by writers on diseases of children. The author uses the term neuroses to cover all local and general nervous disorders which do not depend on known local pathological lesions of the nervous system. To these disorders belong what are commonly, but incorrectly, called functional nervous diseases. No one who has looked into the subject can deny that troubles of this sort are very prevalent among the children of the present generation. Therefore anything which throws light upon the causes which produce them, and the means for their prevention, is distinctly of value. While these neuroses may not be dangerous to the life of a child, yet they exert a tremendous influence upon its future.

The opening chapters deal with the physiology of the nerve-cell. Its functions are three: First, the generation of energy, and the amount of energy generated depends upon the degree of its functional development and the amount of healthy metabolism. Second, to discharge energy. Third, to inhibit energy. Both of these functions may be voluntary, involuntary, or reflex.

The brain of the normal healthy child is morphologically and functionally immature, and during childhood it develops much more slowly in function than in size and weight. The inhibitory function is naturally more feeble and slower in development than the other functions; and unfavorable conditions of food, heredity, and environment may produce abnormally feeble inhibition. According to the author, it is the higher degree of excitability of the nerve-cell in a child, due to the functional immaturity, plus the feeble inhibitory power, which causes most of the nervous diseases in childhood.

The variable temperatures of infancy and childhood are explained by the activity of the thermogenic centre at the base of the brain and the feeble inhibitory centre in the cortex. The exciting causes of fever are bacterial products of insolation, which the author considers the etiological factor of cholera infantum, muscular action, and reflex irritation.

The chapters on auto-intoxication and reflex irritation as causes of the neuroses are worthy of close attention. Auto-intoxication may occur through the urine, not by urea and uric acid, as Haig believes, but by the presence in the blood of the leucomains, paraxanthin and xanthin, and other unnamed poisons. Certain forms of epilepsy, with migraine, gastric neuroses, neurasthenia, etc., are probably dependent upon this form of auto-intoxication. Such neuroses as chorea, hysteria, nocturnal nacentium, and convulsions, may be due to bacterial toxines produced by the organisms of tuberculosis, malaria, or intestinal fermentation. Finally, the author shows what powerful factors excessive brain work and nerve excitement are in the production of neurotic disease, especially in delicate children.

He deprecates the modern social life of children and the forcing process of education, which are adding thousands each year to the vast army of neurasthenics and hysterics which inhabit our cities. Parents, nurses, and teachers should be taught that precocity is frequently an evidence of physical weakness, and should be discouraged rather than fostered. No child should be advanced in its studies until its physical development is up to the standard. Vegetation is the ideal life for infancy and childhood. The individuality of the child is frequently destroyed by nurses and governesses. He should be allowed some solitude each day, and companionship with his intellectual equals. Numerous playgrounds in our cities are of more value to the community than hospitals and monuments.

We recommend the book to all who are interested in the treatment of children.

Atlas of Clinical Medicine. By Byrom Bramwell, M.D., F.R.C.P. Edinburgh, Assistant Physician to the Royal Infirmary, etc. Vol. III., Part II. Edinburgh: Printed by T. & A. Constable, at the University Press. 1895.

This number contains the following: A consideration of hereditary syphilis; a description of plates illustrating progressive muscular atrophy; a chapter devoted to progressive muscular dystrophies, viz., pseudo-hypertrophic paralysis, the juvenile form of myopathic muscular atrophy of Erb, the pseudo-scapulo-humeral form of Landouzy and Déjerine, the hereditary form of progressive muscular atrophy of Leyden, the (purely) atrophic form of myopathic muscular atrophy, generalized progressive muscular atrophy of early childhood, and the peroneal type of progressive muscular atrophy; points to be observed in the clinical examination of cases of pseudo-hypertrophic paralysis and other forms of progressive muscular dystrophy; notes of cases of pseudo-hypertrophic paralysis and other forms of muscular dystrophy (to be continued in Part III.). There are also ten large plates, illustrating ichthyosis, multiple cancer of the breasts and other organs, congenital syphilis, progressive muscular atrophy, and cyanosis. The atlas continues to be a model of style in medical literature and book-making, and is also the embodiment of much practical and well-selected knowledge. Undertaken at great expense, each new fasciculus keeps to the original standard of excellence and interest. This atlas is one of the many important works that the Edinburgh school is constantly giving to the widely scattered English-speaking medical public. It deserves ample recognition everywhere.

Diseases of the Female Bladder and Urethra. By Howard A. Kelly, M.D., Baltimore, Md.

Dr. Kelly's pamphlet, beginning at p. 664 and ending at p. 726, suggests that it is part of a book that is to be. It contains a description of methods, posture, and instruments used in the investigation of diseases of the urethra, bladder, and ureters in women. Up to the present time this class of disease has been the most neglected field in the whole range of scientific medicine. There is a groundwork of reason in this neglect, for the commoner urinary diseases of men are far more apt to prove dangerous to life. Then, too, diseases of the lower urinary tract in women have not been made the subject of exclusive study by specialists. Gynecologists, to whom they have been referred by common consent, have too often slighted them as difficult or impossible to diagnosticate and intractable to treatment. The whole urinary tract in women may now be examined without pain or injury, and its disorders successfully treated. Dr. Kelly is one of perhaps half a dozen gynecological surgeons who have given special attention to a neglected source of pain, discomfort, expense, and disablement. There are over twenty illustrations, a careful explanation of methods, interesting references, and histories of cases relieved and cured.

A Clinical Manual. A Guide to the Practical Examination of the Excretions, Secretions, and the Blood, for the Use of Physicians and Students. By Andrew MacFarlane, A.B., M.D., Instructor in Neurology and Diseases of the Chest in the Albany Medical College, etc. New York and London: G. P. Putnam's Sons. 1894.

Written for the purpose of giving in a concise manner methods employed to utilize the marvellous advances of the past ten years in physiological chemistry and in clinical microscopy, the author acknowledges his indebtedness to Jaksch, Vierodt, Ewald, Leube, Eichhorst, Fraenkel, Berheim, Osler, Councilman and Lafleur, Delafield and Prudden, and others, and especially to Tappeiner's "Anleitung zu Chemisch Diagnostischen Untersuchungen am Krankenbetta," after which this clinical manual has been to some extent modelled, and from which certain procedures have been directly translated. There are thirty-nine wood-cuts and several colored plates. The work described can be carried on by any physician in his own office, with a suitable microscope and a small amount of apparatus. The directions are plain and precise, embodying all that a physician need know of chemistry, and not more than is necessary for successful practice. It is a very useful manual.

THE THEORY AND PRACTICE OF COUNTER-IRRITATION. By H. CAMERON GILLIES, M.D. London: Macmillan & Co. 1895.

THE author states that he likes the plan of this essay very much; so does the critic. First comes a complete history of the subject, then a new theory is formulated and discussed, and the whole second part devoted to a consideration of the uses of counter-irritants generally. The new theory is not absolutely startling in its novelty, since it is to the effect that every process of inflammation is a natural effort toward cure, and that the beneficial effects of counter-irritations always result from their facilitating or accelerating that process. The term counter-irritation is a misnomer, since it does not in any sense check or divert or act counter to the processes of inflammation. The expression external stimulant or irritant application is better. It does not counter-irritate when it serves any good purpose. The best known and most useful irritant applications are the actual cautery, the Spanish fly, mustard, turpentine, iodine, and a few others. They are so carefully described and discussed by the author that it is impossible to imagine anything further being said upon the subject.

A MANUAL OF ORGANIC MATERIA MEDICA. Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms, for the Use of Students, Druggists, Pharmacists, and Physicians. By JOHN M. MAISCH, Ph.M., Phar.D., late Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Sixth edition. Revised by HENRY C. C. MAISCH, Ph.G., Ph.D. With two hundred and eighty-five Illustrations. Philadelphia: Lea Bros. & Co. 1895.

THE sixth edition of any manual speaks for itself. Although the last edition was issued in the autumn of 1892, the subsequent publication of the Pharmacopœia of the United States has necessitated some additions and alterations. Where necessary, specific names have been changed to correspond with those officially recognized. Articles that have received official recognition now appear in large type. The text has received careful revision, and the results of recent investigations and observations have been incorporated in the present edition, which is somewhat reduced in size through condensation, though the matter contained has been increased.

Clinical Department.

THE USE OF THE CURETTE IN OPERATIONS FOR EMPYEMA.

BY J. A. FULTON, M.D.,

SURGEON TO ST. MARY'S HOSPITAL, ASTORIA, ORE.

IN the treatment of a number of cases of empyema by resection of the rib, followed by drainage, experience has shown that a majority of the cases so treated terminate in a way which is entirely satisfactory to all concerned, while a small percentage of the cases, instead of going on to recovery, require further operative treatment or terminate fatally. The reason for the very different results thus obtained from practically the same treatment, no doubt, may be due to some differences in the constitution, temperament, previous condition, or the present conditions surrounding the patient. These differences, of course, include those cases of tuberculous origin as well as those which have acquired the tuberculous disease as a sequela to the empyema.

How to reduce the already small percentage of failures from the operation is now the important question to consider. To the writer it seems that often the cause of failure to secure the desired results from operation may be due to the incompleteness of the operation. In operating on these cases we may find anyone of two or three different conditions to be present. In the first, we may find only pus in the pleural cavity; in the second, we may find also large masses of coagulated lymph; and in the third we find, in addition to the former conditions, that the wall of the pleural cavity is lined with a deposit of lymph varying in thickness from a mere coating to a deposit several lines in thickness. In the first of these conditions free drainage, under aseptic precautions, will result in a cure; in the second, drainage alone will not remove the large coagula, they must be removed with a scoop or the finger of the operator, if a cure is to be expected. The third condition is the one to which the writer desires to draw attention. In this variety the finger of the operator and the scoop may remove the floating lymph, but it requires something more to detach the deposit from the walls of the chest. It has been the writer's custom to look upon empyema as he looks upon pus elsewhere, or as a large pus cavity which should be treated as any other large pus cavity is treated.

To open and drain an ordinary abscess, if of large size, is barely sufficient; it is necessary to curette thoroughly, wash thoroughly, and pack carefully under the strictest aseptic precautions. This is the method adopted by the writer in the treatment of those cases of empyema where the wall of the cavity is lined with the lymph deposit. After resection and thorough douching with plain hot water, the entire cavity is gone over carefully with the curette; the douche is kept going all the time, and as fast as the deposit is loosened it floats away. Care is used to avoid wounding the pleura, and curettes with flexible handles are needed, so the entire surface may be reached. After the entire cavity has been thoroughly gone over and everything washed away, it is dried and carefully packed, and from that time on treated very much as if it were a large abscess cavity elsewhere.

The experience of the writer, with this method of treating empyema, while not extensive, has proven so satisfactory that he feels justified in the continuance of the same; and, furthermore, it has encouraged him to report it to the profession. It has not been deemed necessary to report cases, or to enter into a long description of an operation, which has only to be mentioned by name to be clearly understood by the surgeon. The object of the writer in this paper is simply to draw attention to the indications for the use of the curette in the treatment of certain cases of empyema. It is possible that the method practised by the writer in these cases is not new to others, but after a rather extensive experience with the works and writings of others he can find no reference to this practice; in fact, the authors accessible to the writer seem to be more or less opposed to doing anything more in these cases than to furnish an outlet for the pus. The fact that something more than drainage is indicated in many cases is apparent to anyone with experience, and any method which holds a promise for a better and more perfect and certain result is certainly worthy of consideration.

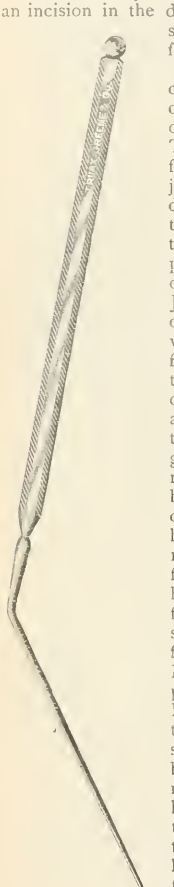
The Late Dr. Charles F. J. Lehlbach.—At a meeting of the Practitioners' Club of Newark, N. J., held September 2, 1895, the following minute was adopted: "Charles F. J. Lehlbach, M.D., died August 14, 1895. Dr. Lehlbach was one of the founders of the Practitioners' Club, and by voice and pen contributed largely to its successful establishment. He possessed a scholarly mind richly stored by extensive reading and observation. His keen logic, brought to bear upon the varied abstruse points in our discussions, readily separated the wheat from the chaff and made his presence among us invaluable. Admirably gifted with genial social traits, he embodied within himself those qualifications which it is the chief aim and design of the Practitioners' Club to promote. With profound sorrow for the loss of our late associate, and grateful remembrance of his valuable labors among us, the Practitioners' Club affectionately directs this minute to be recorded."

A NEW OPERATION FOR CHRONIC CATARRHAL AND CHRONIC SUPPURATIVE DEAFNESS.

By THOMAS H. SHASTID, A.B., M.D.,

GALESBURG, ILL.

In several cases of deafness, of the kinds mentioned above, I have noted the results of traction on the handle of the malleus by means of a blunt hook carried through an incision in the drum-membrane. This procedure, so far as I know, has not been performed or proposed before.



It was suggested to me by an accident, which, in the course of an operation, occurred in consequence of the unruliness of the patient. This patient had long been a sufferer from catarrhal deafness with subjective noises, for which all the ordinary means of treatment had been tried in vain. I was therefore attempting, by an original method, to produce a permanent perforation of one of her tympanic membranes. Just at a moment when, as a part of the technique of my method, I was introducing through the perforation an angular spatula, the patient suddenly, and without a word of warning, jerked her head away, and the spatula, engaging in the tympanum, was pulled from my fingers. When I recovered the instrument she declared that she heard better. A moment later she declared also that her "head noises" had almost ceased. The assertion regarding the hearing I verified, finding that the hearing-distance had increased for the acoumeter from 4 feet to 25 feet, for loud speech from 8 feet to 30 feet, and for whispers from 0 inch to 8 feet.[1] Exactly what it was that had taken place to produce the improvement I could not determine; but from the position in which I had held the spatula I thought that it must have been a traction made by the instrument upon the handle of the malleus. Whether or not this explanation was right, the procedure of traction on the handle of the malleus applied intentionally I have frequently found to give good results.

The way in which I do the operation is this: The auditory canal having been thoroughly cleansed and antisepticized, a slight scratch is made with the lance-knife on the anterior portion of the drum-membrane and a twenty per cent. solution of cocaine instilled into the ear and allowed to remain for five minutes. This not only produces perfect anæsthesia for the incision, but also decidedly lessens the unpleasant sensations that accompany the tractions. These sensations, it may be as well to remark, are usually whistling, ringing, or roaring sounds, together with dizziness and sometimes actual pain. The incision is made with the lance-knife just anterior to the handle of the malleus, parallel with it, and from two and a half to three millimetres in length. It is made in front of the handle rather than behind it, since in the former place the hemorrhage is less—though in neither place is it of much consequence. The first instrument that I used for applying the traction was the angular spatula; but I have since had made a blunt hook which I find far easier to introduce through the simple slit. This hook (shown in the illustration a trifle too heavy and too long) is 1½ mm. in length, slightly enlarged and rounded at the extremity, very slightly curved toward the operator, and mounted on a shaft at an angle of one hundred degrees. It is introduced through the incision and rotated in such manner that it comes to lie directly across the handle of the malleus, when with it are made three or four rather quick, but of course perfectly gentle, tractions. It is then turned and withdrawn. If, upon test, no improvement be found, the instrument may be again introduced and the tractions repeated with a little more force. This technique has been employed, practically without variation, in all the cases whose record follows, the single modification having been the substitution in the last four cases of the blunt hook, or tractor, for the spatula. The incision, it is true, instead of being made parallel with the handle of the malleus, might be made at right angles to it, when the necessity for rotating the hook would be obviated; but since I have observed that now and then during the performance of the tractions the hook slips along the handle of the malleus, I have thought that if the incision were at right angles the hook in slipping might possibly tear the membrane and thus inflict upon it an unnecessary traumatism.

Case I.—A woman, thirty-two years of age, complained of bilateral deafness with loud subjective noises. The noises she had had for many years, the deafness she had noticed for only two years. The drum-membranes exhibited no changes, except slight retraction. The tuning-fork, however, localized the trouble in the middle ear. The hearing distance of the right ear was, for the acoumeter, 1½ foot; for loud speech, 12 feet; of the left ear, for the acoumeter, 2 feet; for loud speech, 10 feet. Politzerization and massage of the ossicles for six weeks produced no improvement. Traction was performed on both sides, and the hearing distance of the right ear was found to be, for the acoumeter, 18 feet; for loud speech, 20 feet; for whispers, 5 feet. Of the left ear, for the acoumeter, 20 feet; for loud speech, 20 feet; for whispers, 5 feet. At the end of a week this improvement had almost subsided. Traction was applied a second time with a quicker, sharper touch, and the hearing distance of the right ear found to be, for the acoumeter, 25 feet; for loud speech, 25 feet; for whispers, 5 feet; of the left ear, for the acoumeter, 25 feet; for loud speech, 25 feet; for whispers, 5 feet. These distances, at the end of six months, were found to have remained unaltered.

Case II.—A man, thirty years of age, had had suppurative otitis media for twelve years, during the last six of which he had noticed a gradually increasing deafness. Both ears, at the time he came to me, were discharging. The drum-membranes presented, each, a large perforation, through which could be seen a mass of granulations. The granulations were removed and the tympana treated to a cure. The hearing distance of the right ear was then found to be, for the acoumeter, 5 feet; for loud speech, 5 feet; of the left ear, for the acoumeter, 15 feet; for loud speech, 20 feet. Politzerization and catheterization had frequently been applied during the treatment of the otitis, and hence were not further indicated. Traction was tried, but gave no results. At the end of a week it was tried again, and at the end of another week a third time, but each time without results. The reason why traction was not serviceable in this case was, I thought, that here there was no restricting tissue to be loosened or torn; on the contrary, the ossicular ligaments were relaxed and the ossicles themselves already too mobile.

[1] The first figures in these comparisons represent the hearing distance as it was after having been improved by the artificial perforation. It is an interesting fact in this case that when the artificial perforation closed no diminution in the hearing occurred. This can be explained by supposing that the hindrance to sound-conduction having been removed by the accident, the perforation was no longer advantageous.

Case III.—A woman, aged thirty-five, had had deafness and tinnitus aurium for five years. The pharynx was covered with granulations. The drum-membranes were opaque and moderately retracted. The hearing distance of the right ear was, for the acoumeter, 15 feet; for loud speech, 20 feet: of the left ear, for the acoumeter, 10 inches; for loud speech, 12 inches. Politzerization and massage of the ossicles for four weeks increased the hearing distance of both ears, for the acoumeter, by 3 feet, but the hearing for speech it did not improve. Traction was applied, and increased the hearing-distance of the right ear, for the acoumeter, to 25 feet; for loud speech, to 28 feet; but the hearing of the left ear it did not improve. At the end of four weeks the increase in the distances of the right ear had totally subsided. Traction was not re-performed, as the patient was shortly to pass from observation.

Case IV.—A girl, aged sixteen, had been deaf from catarrh for one year. She had been treated by Politzerization and catheterization with the result, she said, that she got worse. The pharynx was covered with granulations, and the mucous membrane covering the inferior turbinated bones was hypertrophied. The drum-membranes were opaque and moderately retracted. The hearing distance of the right ear was, for the acoumeter, 9 inches; for loud speech, 5 feet; of the left ear, for the acoumeter, 5 feet; for loud speech, 10 feet. Under three weeks' treatment of the nose and pharynx the hearing of both ears increased, for the acoumeter, 3 feet, but for speech not at all. Traction was applied, and the hearing of the right ear increased, for the acoumeter, to 15 feet; for loud speech, to 20 feet: of the left ear, for the acoumeter, to 20 feet; for loud speech, to 35 feet. The treatment of the catarrh was continued to a cure, and the results are now, six months after traction, practically unaltered.

Case V.—A girl, aged ten, had been deaf from catarrh since the age of six. She had repeatedly been treated, with but slight and temporary results. The Politzer air-bag had, by her last physician, been placed in the hands of her parents with instructions to "use it." It had been used vigorously and frequently, often several times a day. The membranes were atrophic and flaccid, and the one on the right side was ruptured. The hearing-distance of the right ear was, for the acoumeter, 4 inches; for loud speech, 2 feet; of the left ear, for the acoumeter, 6 inches; for loud speech, 2 feet. The air-douche was discontinued, and the pharynx was treated for four weeks. At the end of this time no improvement could be found in the hearing. Traction was applied, and the hearing-distance of the right ear found to be, for the acoumeter, 30 feet; for loud speech, 35 feet; for whispers, 12 feet: of the left ear, for the acoumeter, 35 feet; for loud speech, 35 feet; for whispers, 15 feet. These distances, five months afterward, were found to be unaltered.

Case VI.—A woman, aged thirty, had been deaf since the age of four. At the latter age she had got a suppurative otitis media from an attack of measles. The discharge had persisted till the age of ten or twelve. For the last eight or ten years the deafness had steadily grown worse. The drum-membranes were white, perfectly opaque, and slightly retracted, the left one presenting a small perforation. The acoumeter could be heard by the left ear only at 4 inches; by the right ear, not at all. Speech could be heard only when very loud and very near. Under Politzerization with treatment of the naso-pharynx the hearing did not improve. Traction was applied, and the hearing-distance of the right ear increased, for the acoumeter, to 2 feet; of the left ear, to 4 feet. The gain in hearing for speech, however, was much more remarkable, moderately loud speech being distinctly heard by either ear at 16 feet. This, in effect, restored to the patient her power to converse. It is now three months since the results were secured.

To sum up the report: Of the six cases four were of catarrhal, two of suppurative origin. Of the four cases of catarrhal origin traction was found useless in one, decidedly beneficial in three. Of the two cases of suppurative origin traction was found useless in one, decidedly beneficial in one. All the cases had previously been treated by ordinary methods, either entirely without benefit or with benefit of only a slight or only a temporary character.

How can we explain the fact that in some of these cases traction succeeded when the usual methods had failed? In this way: By traction the force was applied to the ossicles directly; by the usual methods it was applied to them indirectly—that is, through the medium of the drum-membrane. This structure, in many cases of middle-ear deafness, is so thickened and stiffened that when the blast of air strikes upon it it either entirely refuses to draw the handle of the malleus outward, or draws it outward to only a very slight extent. Even when the membrane willingly stretches till the umbo has described as great an outward arc as it could possibly do under the influence of traction—even then, by its very stretching, the membrane lessens the suddenness with which the force acts upon the ossicles. But it is precisely suddenness of action that we want. The truth of this last assertion we may know not only from the supposition that, in these cases, the good that is done is accomplished by the rupturing of limiting adhesive bands, and hence is accomplished in greater degree the greater the rupturing power or suddenness with which the force acts, but also from the well-known clinical fact that frequently when inflation, by means of a slow, gradually increased blast, has been tried in vain, a quick, sharp, sudden blast opens the gates of sound like magic.

In conclusion, I desire that in laying before the profession the facts concerning this operation I be not misunderstood. As a measure for routine I do not think the procedure worth the slightest attention. Politzerization, catheterization, and massage, in the kinds of cases we have been considering, have long been, and are likely long to remain, our chief reliance, to the almost total exclusion of intra-tympanic operations. All that I wish to claim for traction on the handle of the malleus is that it is simple and safe, and that, judging from the results in the few cases in which I have tried it, it is likely to prove of real and decided service in some of the many cases in which ordinary treatment is ineffective.

REPORT OF TWO TRACHEOTOMIES FOR LARYNGEAL CELLULITIS.[1]

By T. C. EVANS, M.D.,

LOUISVILLE, KY.

LECTURER ON OPHTHALMOLOGY AND LARYNGOLOGY IN THE KENTUCKY SCHOOL OF MEDICINE; MEMBER OF THE LOUISVILLE CLINICAL SOCIETY, ETC.

Case I.—On March 11, 1895, I was called to attend a man who was said to be choking to death. I found the patient, aged twenty-nine years, in the throes of a most urgent and agonizing inspiratory dyspnœa. Notwithstanding the extreme dyspnœa, his voice was but little impaired except from exhaustion. From his friends I learned that on the afternoon of Saturday, the 9th, he complained of chilly sensations and some discomfort on swallowing. The indisposition was not of sufficient importance to cause any alarm, as he went to the theatre in the evening, and after that slept well during the night, and went to church on Sunday morning. After this he had paroxysmal attacks of coughing and dyspnœa. His family physician was called, and remained with him until early on Monday morning, the 11th, when I was called to do an intubation.

On laryngoscopic examination I found the epiglottis

[1] Read before the Louisville Clinical Society.

enormously swollen, and of a deep red color, the free margin forming apparently a complete ring with a small central aperture about the size of a crow's quill, the swelling being more pronounced on the right side. Of course the condition of the epiglottis made an examination of the cavity of the larynx impossible, but the fact that the voice remained good made it clear to my mind that the swelling was confined to the epiglottis. An intubation being neither possible nor practicable, I advised a tracheotomy, to which the patient readily consented. Dr. Ap Morgan Vance was called, and performed the low operation under cocaine anæsthesia. Owing to the unusual depth of the trachea it was found impossible to keep the tube in position, so a stout ligature was passed through the lip of the tracheal wound and the two ligatures tied around the neck, keeping the wound open by tension. These ligatures came away on the fourth day. The swelling of the epiglottis reached its climax forty-eight hours after the operation. At the time of the operation the patient had a temperature of 103° F., and it ranged from this to 105° F. for four or five days after the operation. On the second day after the operation the patient developed considerable cellulitis of the neck above and to the right of the tracheotomy wound, but apparently having no connection with the wound. The swelling subsided without the formation of pus, as did also the swelling of the epiglottis. Eight days after the operation he was able to breathe comfortably through the larynx. The tracheal wound was allowed to heal by granulation, and the patient discharged on March 27th, sixteen days after the operation. Several times since his recovery I have made laryngoscopic examination and found nothing abnormal or pathological. If he has any constitutional disorder, he has up to this time (six months after the operation) failed to develop any symptoms.

Case II.—April 28, 1895, I was called to see Sallie L——, colored, aged twenty-two years. Found her suffering with marked dyspnœa; she could speak only in a faint whisper. From her mother I learned that she had been hoarse for three or four days, and had been attended by a general practitioner until within a few hours of the time that I was called, when he retired from the case, advising them to call a specialist. With the laryngoscope I found the obstruction in the arytenoid and inter-arytenoid region. I thought it would be possible to introduce an intubation tube. Trying first the medium-sized rubber tube, and finding it impossible to introduce this, I next tried the small adult tube, and was able to engage the point of the tube in the chink, but could not, with all the force that I felt at liberty to use, introduce the tube into the trachea. She readily consented to a tracheotomy. Dr. W. C. Dugan was called. In the few minutes that elapsed between the time he was called and his arrival, the patient became unconscious. The conditions were now so serious as to demand an immediate operation. Without waiting for cocaine I made extension of the head, and Dr. Dugan fixed the trachea with his left hand and plunged the knife into the tube. Withdrawing the knife the wound was kept open by a pair of artery forceps. The tracheotomy tube was introduced between the blades and the forceps. The patient's head was then lowered to prevent the blood from flowing into the trachea. The hemorrhage was inconsiderable, and stopped of its own accord. The incision was through the first or second ring of the trachea, and evidently severed the thyroid isthmus. After a few full inspirations the patient regained consciousness, and passed a fairly comfortable night. An examination of the larynx twelve hours after the operation showed the œdema involved, also the ventricular bands. This swelling did not perceptibly diminish until the fourth day, when it began slowly to diminish. On the eighth day the tube was removed. There was no return of the dyspnœa, though the hoarseness continued for nearly six weeks. After the swelling subsided it was plainly evident that the antero-posterior diameter of the larynx was abnormally short, and the arytenoids actually or apparently taller than usual. The site of the tracheal wound was plainly visible with the laryngoscope for several months after the operation.

Up to this time, five months after the operation, she has developed no symptoms of any constitutional disease.

A few words in regard to the anatomy of the parts involved and the pathological conditions present in the acute obstructive diseases of the larynx will, I hope, be sufficient apology and explanation for having reported the foregoing cases under the above title.

The mucous membrane of the larynx, as all well know, is more or less intimately attached to the underlying structures by a layer of connective tissue varying in thickness and density in different regions of the larynx. This connective tissue is especially abundant and lax in the ary-epiglottic folds, the ventricular bands, and posterior surface of the epiglottis. These areas of connective tissue are of course subject to the same diseases as the connective tissue in other parts of the body, and under certain conditions become the seat of an inflammatory infiltration or serous transudation sufficient in extent or quantity to lessen or altogether occlude the lumen of the larynx, and produce death by mechanical interference with respiration. Much confusion, in the nomenclature as well as in the treatment of the acute obstructive diseases of the larynx, has been caused by grouping together the several different pathological conditions of the connective tissue of the larynx under the general term "Œdema of the Glottis," or "Œdema of the Larynx," the first of which is not only a misnomer, but an anatomical impossibility, from the fact that in the true vocal cord the mucous membrane is firmly adherent to the underlying structures. The last is, to say the least, ill-chosen, or should be used in a restricted sense to apply to the non-inflammatory cases: for this reason I have presumed to say a few words in regard to the nosology of this particular branch of laryngology.

In enumerating the pathological conditions of the laryngeal connective tissue we have left, after eliminating those infiltrations and exudations which form a part of the clinical history of perichondritis, tubercular and syphilitic laryngitis, two distinct affections, one an inflammatory infiltration due to some form of sepsis, and which may terminate in resolution (as in the two cases reported), or in suppuration, either circumscribed or diffuse; the other a non-inflammatory serous transudation, due to some renal or hepatic disease, some blood dyscrasia, or circulatory disturbance. Now, in order to describe the conditions more explicitly to avoid confusion, and at the same time to conform to the nomenclature of general medicine and surgery, I would designate the former affection as laryngeal cellulitis, the latter as laryngeal anasarca. As to what proportion of the cases are inflammatory, and what are dropsical, I have no means of knowing, but am inclined to think that by far the larger proportion of cases are inflammatory, as localized anasarcas are rather rare in any part of the body.

I have purposely laid considerable stress upon the fact that in the so-called œdema the lesion is in the sub-mucous connective tissue and not in the mucous membrane, for the reason that the opinion seems to be more or less prevalent that œdema is a sequela or complication of catarrhal laryngitis, an opinion which seems to me to be entirely erroneous.

A marked impairment of the voice may follow an acute catarrhal laryngitis, but an obstruction sufficient to interfere to any considerable extent with respiration is always due to some involvement of the connective tissue. The literature on "Œdema of the Larynx" is rather voluminous, but confusing, ambiguous,

and unsatisfactory. Most of the authors that I have consulted quote largely from the statistics and conclusions of Sesteir, of Paris, who collected and tabulated two hundred and forty-five cases of œdema of the larynx, and wrote a monograph on the subject in 1852. You will remember that this was before the day of the laryngoscope, and that four-fifths of these cases were gleaned from medical literature of that day when it was customary to call all forms of laryngeal obstruction "Œdema Glottitis." Again, several authors quote from the statistics of Peltesohn, who in 3,887 autopsies found œdema of the larynx 210 times, or 1 in 18, while Hoffman, in the same city, in 6,062 autopsies found only 33, or 1 in 183. The divisions that these statisticians make of their cases into primary and secondary œdemas fail to convey to me any definite impression either of the pathology or etiology of the affection. Owing to the faulty classification, and the fact that the statistics are made almost entirely from post-mortem examinations, it is impossible to form an intelligent estimate of the mortality.

As to the treatment, the text-books recommend hypodermatic injections of pilocarpine, steam inhalations, and especially scarification. As to scarification I wish to demur; I can see how in cases of anasarca it would lessen the effusion, or in slight inflammatory affections the local depletion might be beneficial, but when the case has become at all urgent, scarification would add a serious complication in the way of hemorrhage, which would be sufficient to excite paroxysms of coughing, which may at any time prove fatal. Aside from this, we know that the swelling due to cellulitis in other parts of the body is not readily controlled by incisions. Most of the cases will require the more radical measure of tracheotomy, which should be performed early without subjecting the patient to hours and days of danger and distress. Intubation is not suited to these cases.

A PIECE OF BONE IN THE APPENDIX VERMIFORMIS.

By WARREN COLEMAN, M.D.,

NEW YORK.

INSTRUCTOR IN PATHOLOGY AT THE LOOMIS LABORATORY.

THE piece of bone shown in Fig. 1 was found in a man, aged sixty-seven, who died at the Metropolitan Hospital. Death occurred from chronic diffuse nephritis and a complicating broncho-pneumonia.

On opening the abdominal cavity the tip of the appendix, uncovered by the small intestine, was found enlarged and lying on the sacral promontory. The appendix itself arose from the lower end of the cæcum, and curved inward and upward. As a whole it was longer and larger than normal. It had a mesentery for more than half its length, but was not bound down, nor was there any evidence, old or recent, of inflammation. When the appendix was slit open a foreign body, which upon examination proved to be a piece of bone, was found at the point of enlargement. From the shape and appearance of the piece I should say it is a fragment of a large bone. It is rounded at one end, while the other presents four projecting points. It seems probable that any one of the points would have penetrated the intestinal or appendicular wall during a strong contraction. The bone measures five-eighths of an inch in its long diameter and one-fourth of an inch in its broadest transverse diameter. It entered the appendix, blunt end foremost, and travelled as far as it could go (Fig. 2). The wall of the appendix encircled it so closely that the point of the scissors was introduced with difficulty. The piece of bone was enveloped in mucus, which filled the lumen of the appendix throughout its whole length. A localized thickening of the wall of the appendix had taken place at the site of the bone. Microscopically the thickening was found to be due to a local hyperplasia of the submucous coat, and the mucous membrane had been denuded of its epithelium. From the localized thickening of the wall it may be assumed that this body has been in the appendix for a long time.

FIG. 1.

A complete history would add much interest to the case. The bone is larger than the lumen of the appendix, and must have caused marked distention as it travelled along. The length of time occupied in the passage would be an interesting point. Reasoning from analogous conditions in the ureters and bile-ducts, the man probably had a protracted attack of sharp colic, the pain having its centre, at least, in the neighborhood of the right iliac fossa.

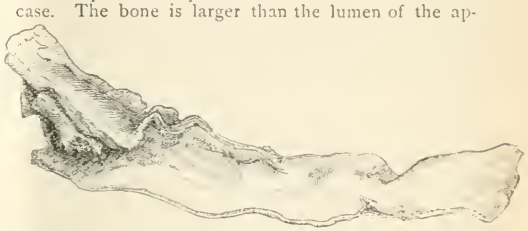


FIG. 2.

In a valuable contribution to the pathology of the vermiform appendix[1] we find the following statements with reference to foreign bodies:

"The literature of the subject reveals a most extraordinary collection of substances which are stated to have been found within the cavity of the appendix. Thus fruit-seeds, cherry-stones, hairs, bristles, shot, pins, gall-stones, lumbricoids, pills, teeth, peanuts, shells, and bones have at all times been recorded as having been found within the appendix. I venture to assert that many of them are inaccurate. From their similarity in size, shape, and appearance, so-called fecal concretions have frequently been mistaken for foreign bodies. It may be said that the occurrence of foreign bodies, properly so called, within the cavity of the appendix, is exceedingly rare, and probably much more so than has been usually believed; in proof of this statement there are the following facts: That in my series of anatomical cases in no single instance did I find a foreign body of any description. Concretions were found in several instances, but these are not included under the present term."

In further proof of the above statements the claim is made that "the anatomical position of the appendix renders it a physical improbability that any foreign body, particularly one the size of a cherry-stone, or even a shot, could enter the organ." Without wishing to discredit the author's observations, I should like to say that my own are not in accord with this statement. While it must be admitted as true of a large number of cases, it is not true of all. The point of origin of the appendix is variable. In the majority of cases which I have examined it has arisen from the wall of the cæcum a little above its lower extremity, and in a recent autopsy as much as four inches above, though in others it has arisen directly from the lower end. Moreover, the direction of the appendix is not always the same. It may pass upward or downward, and in almost all cases where it has come off from the blind extremity of the cæcum it has passed over the pelvic brim and downward into the pelvic cavity. Such a point of origin and such a direction, instead of rendering it physically improbable, renders it probable that a foreign body would enter the appendix. The action of gravity would tend to carry it into the neighborhood of the opening with the individual in the upright position. In the case under consideration the point of

[1] Pathology of the Vermiform Appendix, by Richard J. A. Berry, M.D., Journal of Pathology and Bacteriology, April, 1895.

origin was at the blind extremity, but the appendix curved upon itself so that its tip lay upon the promontory of the sacrum.

In the absence of any evidence as to the direction of the peristaltic wave in the human appendix, no positive statements can be made as to the assistance it would lend in carrying a body onward. While in the intestine, as a whole, the peristaltic wave is, for the most part, in one direction, it does, under certain conditions, travel in the other. Dr. W. Gilman Thompson tells me that in the appendix of the rabbit the wave travels in both directions, and this must be true of all animals in whom the appendix has a digestive function to perform. After the partially digested food has entered that organ, the refuse must find exit, and that only by reversed peristalsis.

In the present case the foreign body is too large to have moved along the lumen of the appendix without the aid of muscular contraction, and its expulsion would have been prevented by the sharp, projecting points. The fact that the so-called fecal concretions (appendicular calculi) remain in the appendix, at least long enough for their formation, would make it appear probable that the reverse peristaltic wave is feeble, if it occurs at all.

A CASE OF ACUTE THYROIDITIS.

By JOHN H. BRADSHAW, M.D.,

ORANGE, N. J.

EARLY in December, 1894, I was consulted by a young married lady for a sore neck and throat. A history of exposure to cold was given, the lady having taken the day previous a five hours' drive in an open carriage with insufficient clothing. During this ride she had repeatedly expressed herself as being very chilly. Soreness of the neck was felt the same night. Upon examination of the neck and throat nothing abnormal was seen or felt. No redness of the pharynx, no laryngitis, no swelling of the tonsils or cervical glands could be found to account for the dysphagia, which was, when seen by me, the principal symptom complained of by the patjent.

The patient was told she suffered from muscular rheumatism, and was put on fair doses of salicylate of soda without relief. Even phenacetine, which was afterward added, gave but little intermission to the pain. The dysphagia increased, even talking caused the patient to clutch at her throat with every evidence of acute suffering. I confess I was puzzled; but in the absence of any sore throat, properly speaking: in the absence of any elevation of temperature; in the absence of any physical signs, I confidently told the patient she undoubtedly had one of those obscure forms of that strange and erratic complaint called the grip. This seemed to satisfy her completely, for the early diagnosis of rheumatism of the throat the patient herself had scouted.

But I watched the case rather carefully. There was so much prostration on the fifth day of the attack that the patient took to her bed. Eating was now almost an impossibility; she looked badly and felt very weak. It was only toward the end of the first week that any enlargement of the neck was to be seen. By the tenth day there was a typical enlargement of the thyroid gland, as one sees it in true goitre. As the gland enlarged, the pain in deglutition diminished, and the patient was able to go about the house and attend to her duties. During the next ten days the gland grew smaller and smaller, and at the end of the third week from the attack the swelling and soreness disappeared entirely.

I report this case of acute thyroiditis because it is the first I have met with in my practice, and because I do not think the affection receives much notice in our text-books or literature.

The disease is an acute disease, running a regular course, having a tendency to spontaneous cure, like so many acute infectious glandular affections. The cause in my case was exposure to cold. The first and principal symptom throughout the attack was pain located in the thyroid region, with intense dysphagia, some expectoration of mucus, and afterward enlargement of the thyroid gland. The pain is greatest during the first of the disease, while the gland is enlarging. The disease ran its course without fever. Whether the natural tendency of the disease without treatment is to the formation of pus, from the experience of one case I should think such not to be the case. Local and internal medication did not prevent the attack lasting three weeks.

Should I meet with another case, and early recognize its nature, I would keep hot anodyne fomentations over the thyroid gland; and I would administer aconite, small doses of quinine, and enough of the analgesics to keep the patient from acute suffering.

ATROPHY OF THE UTERUS.

By HILBERT B. TINGLEY, M.D.,

ROCKAWAY BEACH, N. Y.

I REPORT the following case as one of more than ordinary interest, especially as to the result:

I was called on Saturday morning, August 12, 1893, at about nine o'clock, to attend Mrs. C——, aged twenty-two, and found her just entering upon the second stage of labor. She gave the following history: Some two years before she was delivered of a large child, which "could not be born alive," and she had some trouble afterward which left her with a "sore spot" in the right side. She had been told that she could not be delivered of a living child, consequently she expected trouble and was very nervous. Upon examination I found a narrow pelvis, but not abnormally so. The head was engaged, but movable. About 11 A.M. the pains became weak and the head was found to be impacted. I then gave an anæsthetic, and after some trouble succeeded in delivering the woman of a fine, big boy. In a few minutes I attempted to remove the placenta by the combined method, but it refused to come. After a short wait I attempted to remove it by the hand within the vagina, but found it adherent to almost the whole uterine wall, but principally upon the right side and the fundus, so firmly that I could not remove it. In a few minutes hemorrhage began. I then sent for Dr. Van Valzah, and upon consultation we decided that the only thing to do was to empty the uterus as quickly as possible, and we then began to remove the placenta piecemeal, and by seven o'clock had removed it as thoroughly as possible in the weakened condition of the patient; we then irrigated and packed the uterus with iodoform gauze, ten per cent.

August 13th.—Temperature normal; patient doing well.

August 14th.—Removed gauze, irrigated, and repacked.

August 16th.—Removed the gauze and irrigated each day until 25th, when she was able to sit up in bed.

August 26th.—About midnight she had a severe hemorrhage, which was checked with some difficulty. I then kept the patient in bed until September 2d, when I gave an anæsthetic and curetted, removing a large handful of fragments of placenta, etc., after which the uterus was kept packed for about one week, being irrigated at intervals. The patient made an uninterrupted and perfect recovery.

In October, 1894, she weaned the baby, and as she had not menstruated by July, 1895, she came to me for consultation, although she felt perfectly well. Upon examination I found the cervix gone, the os appearing like a small hole in the vault of the vagina, the ovaries and tubes almost obliterated and the uterus in normal position, but about one and one-half inch long and about as thick as a man's thumb. Upon attempting to pass a sound I could not get above the internal os—in fact the uterus and appendages were almost entirely atrophied. What was the cause of the atrophy? The sexual function and desire was unimpaired.

REMOVAL OF AN INTUBATION-TUBE FROM THE BRONCHUS BY TRACHEOTOMY—RECOVERY.

By CHARLES H. MAYO, M.D.,

SURGEON TO ST. MARY'S HOSPITAL, ROCHESTER, MINN.

On July 6, 1895, I was called, in consultation, by Dr. F. R. Mosse, to make an immediate intubation upon H. F——, a boy five years old. He had been sick four days with an increasing croup cough and fever, was cyanotic and struggling for air, and although a bacteriological examination was not made, the case was one which, in practice, is considered and treated as membranous croup. The third in the series of O'Dwyer's intubation-tubes (the one directed to be used in children from four to six years of age) was inserted, the result being complete relief of the dyspnœa. The head of the tube rested well above the vocal cords, easy to reach with the finger. The condition of the child improved, and the tube was removed at the end of the third day. The breathing was comparatively easy, and after watching the patient half an hour it was considered safe to leave the house. Three hours later I was hurriedly called to reinsert the tube for rapidly developing dyspnœa. The tube was allowed to remain two days this time, when it was removed without difficulty; but, as before, it became necessary to reinsert it six hours later for impending suffocation. Shreds of membrane with tenacious mucus were loosened and thrown out by the manipulation of finger and tube. The tube was left, head well up and fitting snugly in the swollen tissues of the larynx. After remaining forty-two hours this third time, it was noticeable that the breathing was more difficult and noisy. On examining with the finger I was surprised not to feel the head of the tube, and to find that the swelling and œdema of the larynx and immediate structures had disappeared. Reaching further over into the œsophagus, the head of the tube could now be felt in the trachea, just below the vocal cords. The trachea was compressed about the tube and forced up, while the extractor was introduced into the larynx, the finger behind the larynx holding the tube forward. The difficulties will be readily understood by those accustomed to intubating. During the third attempt at extraction the tube was felt to slip down into the bronchus. Efforts at respiration became furious, cyanosis coming on rapidly, and it was evident that the tube must be removed at once. Immediate and rapid preparations for tracheotomy were made. The child's condition had grown worse, and respiration had entirely ceased just before the first incision of a low tracheotomy. The operation was pushed rapidly until the trachea was opened and caught by two artery clamps at the sides of the incision. My assistant grasped the child by the feet and held him head downward. Efforts at artificial respiration were now commenced. A probe was inserted through the incision into the left bronchus, but coming in contact with nothing metallic, it was passed into the right where it clicked the lost tube. It loosened it and occasioned a slight cough when the tube slipped down to, and was withdrawn through, the incision. After fifteen minutes longer of forced respiration it became natural and the child soon regained consciousness. A tracheotomy tube was procured and inserted in the wound, where it was allowed to remain six days. In spite of a septic broncho-pneumonia the patient made a perfect recovery. The particular tube was one which had been used by me in three previous cases.

With a considerable experience in intubation and knowledge of its literature I have heretofore had no fear of this most rare accident.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

PASTEUR—LARREY.

Paris, October 12, 1895.

Two great losses have just befallen the scientific world—Pasteur, the illustrious *savant*, was buried on Saturday, a national funeral having been accorded him by the Government, and Baron Larrey, the eminent military surgeon, has since passed away. A brief review of their remarkable careers well merits the earnest attention of all interested in science and military surgery.

Pasteur was a quiet, laborious student from his youth up, and after having gone through all the grades except that of Doctor, taught chemistry; he soon began to turn his attention more especially to the study of fermentation and contagion, it being from this that his grand discoveries came. We arrange them in the following order: 1. Pasteur saw that contagion, like fermentation, was always the function of a living organism—a microbe. 2. In his experiments with pébrine, a parasitic disease of the silkworm, he demonstrated conclusively the modes of contagion or penetration of microbes into the economy by alimentation, by contact, as well as by atmospheric dust. 3. Charbon-pustule maligne, or anthrax, and afterward chicken cholera, led him to his greatest discovery, viz., the attenuation of virus and the fixity of the different classes of attenuated virus, proceeding all from a fixed virus. 4. Finally, the treatment of hydrophobia learned us, among other things, that a virus can be successfully neutralized even after penetration into our tissues.

Every discovery of Pasteur's was a struggle—for each discovery raised him determined adversaries. The biologists and physicians resented that a chemist should dare infringe upon their territory, and one of them declared, at the Academy of Medicine, "Yes, microbiology constitutes for medicine at once a social and intellectual peril, for it leads to homicide and infatuation." Pasteur lived, however, to see his most violent opposers become his most ardent supporters. Professor Grancher tells us how his labors in the treatment of hydrophobia began. He says: "I had been working for some months in Pasteur's laboratory when he did me the honor to consult me in the case of little Meister. He was a boy that had come from Alsace, upon the advice of Dr. Weber, to be treated by Pasteur. Meister had been seriously bitten in fourteen different places by a mad dog. But Pasteur, in spite of his scientific faith in experimental pathology, in spite of his belief in the identity of human and animal physiology and pathology, hesitated to inoculate Meister; he therefore asked Vulpian and myself to give him our opinions. It appeared to us that the experiments of Pasteur authorized him to obey a natural sentiment of humanity and inoculate Meister. He then delegated

me to make the inoculations, which I did, with more concentrated virus each day, under the skin of the abdomen. This was in the month of July, 1885, and the 26th of October of the same year Pasteur communicated the facts to the Academy of Medicine. A cloud of distrust followed the burst of enthusiasm. Then came the case of Jupille, who was bitten in the same month of the same year in the Jura, while rescuing from a mad dog some school children at play, and of whom a statue now stands in front of the Institute Pasteur. Jupille was entirely cured, and is still an attendant in the Institute. In 1887 there was still some distrust of the method upon the part of the medical profession, but the day soon came when it triumphed; people belonging to all nations came for the prophylactic or curative treatment, and Pasteur Institutes were established in different parts of the world. Pasteur's most brilliant experiment was with the sheep that were being decimated by charbon. His work for the prevention and cure of Asiatic cholera was not entirely concluded when death put an end to his labors. In speaking to his class and co-workers, Pasteur had that simple but powerful eloquence that goes to the soul by sure and comforting truths; his expressions were always noble because he had noble ideas. He died having faith in a better humanity. He said: "I believe invincibly that science and peace will triumph over ignorance and war; that peoples will be of accord not to destroy but to edify, and that the future will belong to those who have done most for suffering humanity." What more fitting epitaph for the world's greatest scientist?

Baron Larrey, father and son, whose names have been identified with the Napoleonic dynasty for nearly a hundred years, was the student of Dupuytren and of his father, the great surgeon of the armies of Napoleon I.

Professor Agrégé of Surgery at the Faculty of Medicine of Paris, of External Pathology at Val-de-Grace, and Surgeon-in-chief of the Military Hospital of Gros-Caillou, he subsequently became the physician of Napoleon III., Surgeon-in-Chief of the Army of Italy, President of the Society of Surgery and of the Academy of Medicine, also Member of the Academy of Sciences, where he occupied Civiale's chair. He was a grand officer of the Legion of Honor and attained to numerous other positions of honor, including that of deputy as well. From the double point of view of professional courage and military virtue he was a brave man; at twenty-four years of age he took service in the Picpus Hospital at the height of the terrible epidemic of Asiatic cholera in 1832; he had a horse killed under him at the battle of Solferino; during the siege of Paris in 1871 he was Surgeon-in-chief of the besieged armies, when he was more prodigal of his services than his rank demanded.

Baron Larrey was a man of science of high value, and although he does not leave behind him any resounding discoveries yet he has written voluminously, as his father before him had done, on military surgery, of which he had become the apostle and oracle. He was very proud of having seen the Emperor Napoleon I. at a review, to which his father took him in 1815. He was then only six years of age. After passing along the front line of troops, he recounts, "the emperor came toward us. My sister, who was with me, made a gracious courtesy, while I inclined my head respectfully. Napoleon I., who was accompanied by my father, addressed him: 'Are those your children, Larrey,' and tapping me on the cheek with his right hand he added, 'we will try and make something of him, won't we? As for the rest, he has only to resemble you.'" This he did.

"How is Practice, John?"
"All gone! She died last week!"

CHLOROFORM WITH OXYGEN.

To the Editor of the Medical Record.

Sir: The valuable and instructive paper of my friend Dr. Cole, in your issue of the 12th ultimo, will doubtless set many other surgeons to experimenting with oxygen combined with ether, and probably other anæsthetics, and it is to be hoped that their results will be recorded as accurately and carefully as Dr. Cole's seem to have been. The matter is a vital one. My only excuse for trespassing upon your valuable space is that I have heard of a case which ought to be reported, if it has not been, in which oxygen was combined with chloroform with the happiest results.

The operator, whose name I do not know, is said to have produced complete anæsthesia in a feeble old man with senile gangrene with a few drachms of chloroform combined with oxygen, so that he was able to amputate the leg at the knee-joint, the patient standing the operation well and making a good recovery, although the case was so unpromising that a number of other surgeons had declined to operate.

If oxygen will sustain the heart and respiration, and keep up the anæsthesia in feeble and unpromising cases when combined with ether, as it surely seemed to do in the cases reported by Dr. Cole, is it unreasonable to hope that its combination with chloroform may obviate the dangers attendant upon the use of that more elegant and efficient anæsthetic?

Very truly yours,
Richard C. Newton, M.D.

Montclair, N. J., October 21, 1895.

THE QUESTION OF AN INTERNATIONAL LANGUAGE.

To the Editor of the Medical Record.

Sir: I am interested and amused by the letters on this subject appearing in your columns, and would not for the world say a word in disparagement of either Greek or Latin. I love the former, it is our *lingua sancta*, and am moderately pleased with the latter language, but when I see a correspondent recommending the adoption of a barbarous dialect of the grand old Latin tongue, I must confess my blood begins to boil. French is bad enough, but Spanish is worse, and practically unintelligible to any person unacquainted with Latin or French. How many of your readers, who know nothing of the language of old Rome, or of that of modern Paris, could make out a word of the paragraph given by your correspondent in what he fondly assumes to be Spanish? Not one, I venture to say, bar the word "gonorrea," which, of course, is Greek pure and simple. Is it not a fact that considerably over one hundred millions of people to-day speak and write English, and its use is spreading daily and hourly; there is a ready-made international language for you, and what more can anybody want?

I dare say the Frenchman and the German would squirm at the idea—let them—their fancies do not alter facts; both nations have annexed many of our words, and now that the United States are increasing their population by leaps and bounds; that a great English-speaking nation is springing up in South and Central Africa and another in Australia; that Russia has made the teaching of English obligatory in her schools; that the Japanese have done the same, and almost adopted it as their national tongue; that it is daily becoming more familiar to the millions of India, I consider it is very bad taste and shows a great deal of ignorance on the part of any English-speaking person to stand

up and advocate its being forsaken by those whose language it is in favor of any other, new or old.

Even in diplomatic circles English is gaining ground, and I venture to predict that before the end of the next century English will be the language of the world.

It is nor a perfect language, perhaps, but it is a good, practical one. I remember when I was in Australia a French blacksmith on the diggings (a Parisian by the way) once said to me: "Without English the work of the mines could not be got through. A Frenchman comes into my forge and he says to me, 'Bonjour, monsieur, voulez-vous me faire une pointe à ciseau (ou aigüe), à ce pic?' What circumlocution! An Englishman comes, holds up his pick, and says, 'Square' (or 'round'), et tout est dit!"

Perhaps your readers can apply the moral, but for goodness' sake let us hear no more about the want of an international language; we have one—English—and so much the worse for those who are too proud or too stupid to use it. Yours, etc.,

W. T. GREENE, M.D.

BELVEDERE, KENT, ENGLAND, October 10, 1895.

THE CURVED CAPSULE KNIFE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The undersigned has an especial reason to feel flattered by the distinguished mark of appreciation bestowed upon an instrument designed by him several years ago, and described in the MEDICAL RECORD of September 28, 1895, in that Dr. John E. Weeks, of New York, has concluded to appropriate (by inference) the paternity of the design, under the name of "A Knife-needle," etc., in the MEDICAL RECORD of September 28th. This knife was made for me by Tiemann four or five years ago, and has been used by me ever since as a better instrument for its purpose than the straight capsule knife, commended by H. Knopp. To save space, I described the knife, together with a slight modification of it designed for operations on the membrana tympani, well knowing that any instruction to those competent to use such a knife, as to the method of use, would be entirely unnecessary. Mr. E. B. Meyrowitz, who obtained from me the model after which the instrument delineated on page 467 of the MEDICAL RECORD has been constructed, in asking me to describe the two instruments, *i.e.*, capsule knife and tympanic knife, furnished me with only one cut, and that is how I came to speak of both knives under one caption. The ophthalmic surgeon will find the use of the curved capsule knife to be attended with fewer difficulties than that of the straight knife. In certain cases a knife with a very much greater curvature to its blade than that shown in the cut of my capsule knife, might be used to great advantage, and the principle of the inclined plane be still further produced in the knife; the mechanism through which curved blades cut being well known to all surgeons.

The discission knife devised by me, and which Meyrowitz himself saw me operate with more than two years ago, at which time I explained to him its advantages over Knopp's knife and also the technique of its use, has not a two-edged point. The two-edged point exploited by Dr. Weeks, in his description, is not an advantage but the contrary. The back of the knife must be closely applied to the corresponding angle of the corneal wound, and the whole thickness of the cornea is the pivot along which the blade glides as it enters the anterior chamber, there being just sufficient division of tissue effected by the cutting edge to provide space for the entrance of the blade. The triangular wound is exactly filled by the blade and subsequently by the shank. Now, if the initial puncture has any other shape than that of the blade of the knife, there will result a minute, in this case triangular, space between the back of the knife and the corresponding angle of the wound. Again, the sweep of the handle, made necessary to maintain the tangent as between the blade and the plane of the cornea, as the anterior chamber is entered, will inevitably cause the edged back of the knife to cut, which is not desired.

The increased intra-ocular tension induced by the pressure of the fixation forceps, and the pressure of the point of the knife, together with a faulty incision, will result often in escape of aqueous. This in turn embarrasses the surgeon, increases the difficulties of the operation and the danger to the patient, and may necessitate the abandonment of the operation for the time. It may be claimed that the double-edged knife is easier of introduction than the one properly made, and this claim is too puerile to discuss.

CORNELIUS WILLIAMS, M.D.

ST. PAUL, MINN., October 1, 1895.

REQUIREMENTS FOR INSANE ASYLUM PHYSICIANS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After reading Dr. McClain's article I would suggest the following notice for insertion in the medical journals when a vacancy occurs in any insane hospital:

Vacancy.—The position of Junior Assistant at the Blank Asylum is vacant. Applications will be received by the Superintendent for the next six months. Applicants must be expert surgeons, specialists in eye and ear, nose and throat, brain, lungs and heart, liver and stomach, diseases of women, etc. Applicants must not be identified with any political party or have any views on the political questions of the day, and must not be under forty-five years of age. The salary is six hundred dollars a year, including board and washing.

Respectfully,

F. M. WILES, M.D.

INDIANAPOLIS, IND.

ALKALINE INJECTIONS IN GONORRHŒA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of September 7th there appears an article on gonorrhœa by Dr. Philip Jaisohn. In speaking of the mixed infection in this form of urethritis he writes: "There is nothing which will destroy these pyogenic cocci more effectually than the solution of bichloride of mercury." "For this purpose," he says, "I use the mercurial solution at the strength of one to ten thousand, making this alkaline by adding liquor potassii at the proportion of one-half drachm to the ounce."

I wish to call his attention to the fact that his injection contains no bichloride of mercury whatever. The mixture consists of a solution of chloride and hydrate of potassium, with a precipitate of the yellow oxide of mercury. The last salt may be a good application in gonorrhœa, but if it is desired, in this case, a "shake" label must be put on the bottle. When solutions of the caustic alkalies are mixed with solutions of salts of mercury, the oxide of mercury is formed, which, being insoluble, is thrown down in the form of a precipitate thus: $HgCl_2 + 2KHO = HgO + 2KCl + H_2O$. This is not written with a desire to be over-critical; chemical incompatibilities in prescriptions may be allowable, or even sometimes desirable. Long experience in compounding prescriptions has led me to believe that doctors are very prone to lose sight of the fact that chemical compounds may not partake of any of the properties

of their factors. If good results are obtained from any treatment, it is desirable that we trace the results to the real cause. A physician once came into a drug store and asked me to compound, quickly, a prescription containing ammonium carbonate. As I rubbed up the salt with the menstruum in the mortar, he became impatient and said: "Now, I'll give you a pointer; just add a little acetic acid to that and it will dissolve without trouble." To my protest that the therapeutic effect might not be the same he replied: "You put the carbonate of ammonia in, it must be there, so what's the difference? A little acetic acid will do no harm." Yours very truly,

D. H. Galloway, Ph.G., M.D.

Chicago, October 13, 1895.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 28, 1895.

Egbert H. Grandin, M.D., President, in the Chair.

The meeting was devoted to the reading of reports, election of officers, and executive and new business. The Treasurer's report showed a smaller balance than at the close of last year. The Committee on Hygiene made no report. The report of the Board of Censors consisted of the report of the Counsel of the Society, Mr. Taylor. Only five hundred dollars had been collected as fines against illegal practitioners during the year, but the way had been made easier for the enforcement of the law in the future. It would, however, involve much work, no less work, indeed, than in the past.

Action of Commissioners of Public Charities and Correction Condemned.—By unanimous consent Dr. N. E. Brill was permitted to offer a resolution out of the regular order of business.

Whereas, The Commissioners of Public Charities and Correction have, without preferring charges against them, abolished the consulting and medical boards of certain hospitals (named); and,

Whereas, These Commissioners have conferred upon the College of Physicians and Surgeons, University Medical College, Bellevue Medical College, and Fourth Division of Bellevue Hospital the power to fill all vacancies upon the medical boards of these hospitals, and to appoint all internes in these hospitals; and,

Whereas, The colleges named are incorporated institutions, and their faculties with the Fourth Division of Bellevue Hospital are composed of less than one hundred physicians; and,

Whereas, There are in the county of New York about three thousand physicians; and,

Whereas, These three thousand physicians are excluded from positions upon the medical boards of the hospitals mentioned, as well as of Bellevue and Harlem Hospitals, except by courtesy of the faculties of the incorporated colleges and the Fourth Division of Bellevue Hospital; and,

Whereas, These hospitals are county hospitals, supported by the tax-payers of the county; be it

Resolved, That we, the Medical Society of the County of New York, protest against this outrage upon the medical profession of the county of New York, and condemn this action of the Commissioners in delivering to these incorporated colleges three-fourths of the appointments upon the consulting and medical boards of those hospitals to whose support the profession at large, as tax-payers, contribute.

The resolution was adopted with scarcely a dissenting voice, and the President was given power to appoint a committee of five, himself a member of it, to carry the resolution at once to the Commissioners and the Mayor.

Rights of Free Speech to be Defended.—The Society in executive session decided to defend Dr. Van Fleet in the suit brought against him by a refracting optician for some remarks made in relation to the latter's advertisement in the *Medical Directory*.

Officers.—The following were elected to office: *President*, E. D. Fisher; *First Vice-President*, Frederic Peterson; *Second Vice-President*, J. H. Fruitnight; *Secretary*, C. H. Avery; *Assistant Secretary*, W. E. Bullard; *Treasurer*, John S. Warren; *Censors*, B. F. Curtis, E. H. Grandin, S. D. Powell, A. M. Jacobus, C. L. Gibson. Thirty-five delegates were elected to the State Medical Society.

Dr. R. A. Murray, of the Committee on Prize Essays, stated that no essay had been received deemed worthy of the prize.

Dr. E. B. Bronson read the report of the Committee on Ethics. Charges had been brought against several members for violating Chapter XVI. of the By-Laws, relating to affixing one's certificate to proprietary articles, etc. Little could be done except call the attention of the offenders to the by-laws, and receive their apologies.

New Instruments.

A NEW NASAL SEPTUM KNIFE.[1]

By SAMUEL GOLDSTEIN, M.D.,

New York.

Attending Surgeon, New York Throat and Nose Hospital; Assistant Visiting Surgeon, Infants' and Children's Hospital, Randall's Island, Nose, Throat, and Ear Division, etc.

This instrument, that I with pleasure place before you, will, I hope, receive the benefit of your favorable attention. The simplicity of construction, ease, and expedition with which it can be manipulated, and facility in taking it apart for cleaning, will at once be manifest to you. The knife consists of a staff, at the proximal end of which is a ring for the thumb; near its distal extremity the staff is made wider and perforated. The perforation is of such size and shape as to allow it to pass over growths of any kind usually seen on the septum. Below this perforation is a slit, to allow the passage of the blade of the knife, which has perfect freedom of motion in two grooves, one on each side of the staff.

The cutting edge of the staff is convex, very sharp, and so curved as to fit around the growth, before it is pushed home in the act of cutting; the two ends of the knife are blunt, in order the more surely to avoid any damage to the mucous membrane of the parts not included in the growth. There are two rings on the staff, one on each side, for the index and middle fingers: these rings allow the operator to keep a firm hold of the instrument, when in position over the growth that is to be removed.

The thumb-ring at the proximal end of the staff is fastened by a screw, so that it can be removed when taking the instrument apart. The purpose of making this ring detachable is to allow the blade of the knife to be easily pushed forward.

[1] Presented before the Metropolitan Medical Society, September 24, 1895.

and removed from the staff of the instrument for cleansing.

The method of using the instrument is as follows: The nose is examined, the growth located; the knife is placed in position, completely surrounding the growth; the thumb, in the ring at the end of the staff, is pushed forward from the operator (the index and middle fingers in the rings on each side of the staff, pressing the instrument tightly against the septum), and the growth is cut through, and may then be removed with any nasal forceps.

To me, this septum knife has made the operation simplicity itself; there need be no scraping, or curetting, or boring, or mangling of the mucous membrane, or fear of the danger of perforating the septum.

The operation is done with ease and rapidity, and is consequently painless under the usual cocaine anæsthesia, as it consumes so little time.

The septum knife is adjustable for growths of any size or consistency, and may be employed equally well on either side of the septum. My plans have been very accurately carried out by Messrs. George Tiemann & Co.

166 East Ninety-third Street.

A NEW NASAL SAW.

By H. DUDLEY YOUNG, M.D.,

Boston, Mass.

Accompanying is a diagram of a nasal saw. I recently designed for the removal of small cartilaginous and osseous outgrowths. The blade is less than a millimetre thick, three millimetres wide, and about one inch and one-quarter in length, probe-pointed, and attached to a straight handle, which is of metal, nickel-plated. In

the experience of the writer the obtuse-angle handled instruments, while allowing a better view during an operative procedure, are not so easily controlled.

The advantages claimed for this saw are its short, narrow blade, with probe-point, and long straight handle, all of which make it a convenient instrument for the removal of outgrowths from any portion of the nares. The cut represents the saw at about one-half its actual size.

Acknowledgment is tendered Messrs. Feick Brothers, Pittsburg, Pa., whose superior workmanship has enabled me to place this little instrument in the hands of the profession.

Free Medical Treatment and Tea.—A Liverpool grocer has issued a circular to his hoped-for customers agreeing to provide them with free medical attendance whenever they may fall ill, the only condition being that they purchase a quarter of a pound of tea each week. The intending patient must have bought a quarter of a pound a week for at least four weeks before he can avail himself of the free treatment, and if he fails to buy his tea for two weeks in succession he will forfeit all right to the services of the grocer's medical assistant. In the circular announcing this wonderful scheme are the names and addresses of the medical men who are ready to further the enterprising grocer's advertising dodge by contracting with him to treat his customers.

Professor Schede. Director of the Surgical Department of the Hamburg General Hospital, has been appointed to the Chair of Surgery in the University of Bonn, in succession to Professor Trendelenburg.

Surgical Suggestions.

Malignant Disease of the Rectum.—In choosing between extirpation and colotomy, it is necessary to consider the compass of the disease, hence the extent of the operation and the ability of the patient to go safely through with it. When the neoplasm is of limited extent, movable, and easily approached by the dorsal incision, and the patient is a fair general condition, extirpation is to be preferred; in other cases, colotomy. It must be remembered that a rectum after the operation of extirpation is seldom a perfect one in function, and that we often pay a high price in the way of risk for the choice between incontinence in the perineum and incontinence in the groin. I think it safe to say that in the near future colotomy will be made oftener and earlier the world over.—Evans.

Dr. A Leveran, who was an army surgeon at Algiers, was the first to observe in blood taken from malarious soldiers, pigmented discoid bodies, and also spherical pigmented bodies possessing flagella, whose extremely rapid and varied movements left no doubt as to their nature; this was on November 6, 1880.

The Treatment of Chancroids in Women.—After an extensive trial of other remedies, Dr. Herff expresses a preference for liquefied carbolic acid, which he has successfully employed in over one hundred cases. His manner of procedure is as follows: After careful disinfection of the genitals, with sublimate solution, the ulcers are dried with cotton, and then lightly touched with carbolic acid, any excess being wiped off with cotton. If the ulcers are very large and situated in the vicinity of the clitoris or urethra, previous cocaining is advisable. The after-treatment consists of sitz-baths, and irrigation of carbolic acid or permanganate of potash solutions. At the end of four or five days, the majority of the ulcers have begun to cicatrize, although it may be necessary to cauterize one or more which refuses to heal. If the adjacent lymphatic glands are already affected, this usually subsides spontaneously in a short time. Occasionally rest in bed may be required.—*Monatschr. f. Geburtsh. und Gynäkol.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 26, 1895.

	Cases.	Deaths
Tuberculosis	122	113
Typhoid fever	67	9
Scarlet fever	45	2
Cerebro-spinal meningitis	2	6
Measles	51	7
Diphtheria	175	28
Small-pox	1	1

The Dispensary—A Disease of the Body Politic.—Julius Weiss, M.D., New York, writes:

Synonyms.—Out-door department, ante and post-graduate's reservoir, embryonic specialists' and writers' Eldorado, etc.

Definition.—A chronic contagious disease, manifested by degeneration and atrophy of the pocket-books of the bulk of physicians and druggists, and by peculiar cerebral developments in patients, as, hallucinations of poverty and delusions of getting something for nothing.

Pathogenesis and Etiology.—The chief factor in causation is the desire of building up a reputation as a

specialist by increased opportunities for observation and experience and the naturally accompanying financial gain.

About twelve years ago, after a meeting of the German Medical Association on Second Avenue, a few of us retired to a cosey refreshment place, and the scheme of launching the German Polyclinic was hatched. Each colleague that joined the corporation thought it expedient to contribute $100.00 C. O. D. Since that time the usual Board of Directors and other paraphernalia have appeared and tertiary symptoms developed in the shape of St. Mark's Hospital. Six years ago a colleague called on me to assist him in starting the East-side Dispensary, 327 East Third Street. He was shocked to learn that foreign doctors were reducing medical fees to twenty-five cents. How much better to treat people free of charge! A faculty was gathered, per capita tax of $35.00 was imposed, and another successful institution is the result. The inevitable tertiary symptoms will follow, as a hospital is threatened. On the West Side we had considerable trouble. We had about $25,000 (collected from philanthropic citizens). But business in the old building of the German West-side Dispensary was bad. A new set of doctors took hold of the matter, and erected a beautiful centre for pauperization in Forty-second Street, between Eighth and Ninth Avenues. From last reports business has improved considerably. These few instances will suffice to illustrate the contagiousness of the disease, and the nature of the disease germ, viz., competition and gain.

Symptoms.—These vary according to the severity of the ailment. In some dispensaries as the East Side, Good Samaritan, Bellevue, Centre Street, Grove Street, Northwestern, the deserving poor form ninety-five per cent. of the number of patients treated. In others, as the New York Hospital, Vanderbilt Clinic, Manhattan Eye and Throat, Presbyterian, New York Polyclinic, the number of deserving poor is probably only twenty per cent. The Mt. Sinai and German Dispensaries also treat a large number of undeserving people. In the New York Hospital, out-door patients pay one dollar initiation fee. But practically, since such patients seldom return a second time, this so-called charitable institution charges as much as the ordinary practitioner. The Vanderbilt Clinic has injured the West-side practitioner very noticeably. While the purses of the attending staff undergo a peculiar fatty infiltration, those of the majority of doctors suffer fibroid changes and consequent atrophy and shrinkage.

Therapeusis.—A committee might be appointed by our medical societies to investigate the true state of affairs in various dispensaries, and prepare a full report upon the same. Some practical remedy may possibly be suggested by such a body. The Charity Organization Society will be of great aid in such an investigation. Prophylaxis in the way of discouraging future unnecessary institutions may be tried. Above all, physicians ought to insist upon getting paid for their work, and not allow a false sense of pride and dignity to breed among the people an habitual misconception that the service of doctors are not to be paid like those of the lawyer, engineer, or mechanic. Loose business methods among physicians, more than dispensaries, create a sentiment of financial valuelessness of medical work. The very men who shout against dispensaries send well-to-do patients there for treatment by specialists. In brief, reform must come from harmonious co-operation among practitioners themselves.

The Beginning of Structural Disease.—In the treatment of organic or structural diseases, as of the nervous system, the blood-vessels, and various vital organs, the fact is quite generally overlooked that the structural change is a consequence, and not an actual disease. The real disease is the morbid process which has resulted in the tissue-change. Nothing could be more unphilosophical than the limitation of the therapeutic efforts to such measures as may be supposed to be calculated to affect favorably the morbid structures. A rational mode of treatment must be based upon a recognition of the producing cause of the morbid changes which have taken place. The researches of Bouchard and other modern investigators have thrown great light upon this subject, and have placed upon more than probable grounds the theory that the presence in the blood and tissues of various morbid substances of a toxic character, such as uric acid, and various leucomaines and ptomaines, originating in the tissues as the result of imperfect oxidation or absorbed from the alimentary canal wherein they are produced by microbic action and morbid digestive processes, constitutes the real morbid entity in a large number of organic or structural maladies, especially those of the nervous system and kidneys. In the treatment of these affections, it is, then, of the utmost importance that the physician should look carefully after the processes of digestion and respiration. These are the two great means by which the blood is to be purified. The exclusion from the dietary of poisonous substances, and of such food substances as readily undergo putrefactive processes in the alimentary canal, and the introduction of an increased quantity of oxygen whereby the poisons resulting from morbid tissue-changes may be destroyed by oxidation, constitute the most important measures for combating the onward march of an organic affection. Remedies of any sort, if aimed directly at the morbid tissue itself, will fail to accomplish anything more than temporary palliation, unless combined with measures which strike at the root of the disease. An ideal mode of treatment will necessarily include both classes of remedies. Bacteriology and physiological chemistry are opening up for us, almost daily, new lines of thought, new methods of treatment, and new possibilities of cure.—*Modern Medicine.*

The Last Illness of Pasteur.—Pasteur was a striking example of the fact that sometimes a person may have a cerebral hemorrhage and live many years, thereafter doing the very best work of his life. Pasteur was first attacked with a hemorrhage in 1868, twenty-seven years ago. But it left scarcely any traces, and he continued in good health until 1888, when his health began to decline. It was about this time that he was made the object of the most violent attacks from many members of the medical profession and the scientific world, on account of his claims regarding the prevention of rabies. In 1892 he had several attacks of uræmia, and at that time he was found to have some cardiac lesion. His last illness was due to a sudden accession of uræmia, with very intense dyspnœa, and a feeble and irregular pulse. He succumbed within a few hours after the attack came on.

The Late Dr. Henry W. Rand.—At a meeting of the College Faculty of the Long Island College Hospital, held October 8, 1895, the following report was unanimously adopted: "The Committee appointed at the last meeting of the Faculty to take action in regard to the death of Professor Henry W. Rand, submits the following: The pain at parting from our beloved associate, Professor Rand, cannot be expressed in words. We can only say that his loss is deeply felt, and that our sorrow is as profound as was our love for him. Our admiration for the man was the highest and most enduring, and was inspired by his many noble qualities of head and heart. In all his relations to us, the teaching Faculty of this institution, he was always honest, honorable, earnest, and competent. He was securely established upon the highest plane of professional success, and while we were rejoicing in the hope that he would continue his good work for many years, he was suddenly called hence. We all feel that his devotion to his profession, his interest in his brethren, and his ceaseless services to those committed to his care, were instrumental in taking him from us at the noon-time of

his noble life. While this thought adds greatly to the burden of our grief, it magnifies the greatness and goodness of the man. There was no shadow of selfishness in the heart of this man, who gave all for the welfare of others. Feeling keenly our own loss, we naturally think of his family, and our sympathy is extended to them in all kindness and sincerity. The Committee suggests that this all too meagre tribute to the memory of our deceased associate be spread in full upon the minutes, and be published in the medical press and in the daily press of Brooklyn; and that a copy be transmitted to his family.

"JARVIS S. WIGHT,
"FRANK E. WEST,
"*Committee.*"

The Annual Meeting of the Association of German Naturalists and Medical Men was held at Lubeck, from September 15th to 21st, the President being Professor Wislicenus, of Leipsic. Professor Klebs read a paper of a theoretical character on some problems concerning the physiology of generation. Professor Behring made a speech on the results and objects of serotherapy. Behring stated that the time had passed when medical men should use expressions like "genus epidemicus," in order to explain the degree of mortality. He stated that vaccination had succeeded in compelling this genus to withdraw; this had been done in the case of malaria by quinine and in smallpox by vaccination. He believed that the same effect on the "genus epidemicus" of diphtheria was produced by antitoxin. Professor Behring then went on to give a large number of statistics in rebuttal of criticisms that had been made upon his method, and expressed the opinion that the mortality from diphtheria could be made to fall to five per cent. Even if something less than this were done, forty-five thousand lives would be yearly saved in Germany. At present mortality rates the lives of fifteen thousand people had already been saved. The protecting or immunizing effect, he added, was not yet so obvious as the curative, because the number of cases reported was still too small. Professor Ridle, of Vienna, read a paper on surgical operations on the skull. He stated that of one hundred brain tumors, six only are found and operated on; in three of these death occurs from the operation, and that three per cent. only have a favorable issue.

The Late Dr. Frederick M. Warner.—At a special meeting of the Medical Board of the City Hospital, held at the Academy of Medicine on October 21, 1895, the following resolutions were adopted by the Board:

"*Whereas*, It has pleased God to remove our late colleague, Frederick M. Warner, M.D., from his field of labor in the City Hospital: and

"*Whereas*, He was by temperament, experience, and education thoroughly equipped for the alleviation of human suffering in the City Hospital, where he labored zealously and conscientiously for several years;

"*Resolved*, That we, his late colleagues, express our sincere admiration of him as an associate, and our profound regret that his future—so full of brightness and promise—should be lost by death.

"*Resolved*, That we tender his family our deep sympathy with them in their bereavement, and that a memorial page be set aside in our book of minutes.

"*Resolved*, That an engrossed copy of these resolutions be sent his family.

"J. BLAKE WHITE,
"THOMAS H. ALLEN,
"J. R. HAYDEN, "SIMON J. WALSH,
Secretary. "*Committee.*"

The Slowness of our System of Advancement.—The slowness with which promotion sometimes arrives in our system of advancement by seniority is illustrated by the recent "elevation" of Dr. Lauder Brunton to a full physicianship at Bartholomew's. The name of Lauder Brunton is certainly anything but unknown, yet for twenty-five years his field of energy has been limited by the walls of the out-patient room. Indeed, this promotion has only occurred through the institution of an extra post, and it has been calculated that but for its creation Dr. Brunton might have reached the limit of age before he had been relieved from the drudgery of the ambulatorium.—London Correspondent of the *Therapeutic Gazette*.

New Anatomy Law in Wisconsin.—Section 1437, of chapter 58, of the annotated statutes of Wisconsin, was amended by the last legislature so that every public officer having charge of the body of any deceased person, required to be buried at the public expense, not merely "may," but "shall, without charge," deliver such body to that member or agent of the State or any county medical society, or of any legally organized medical college, who shall first present to him an order therefor, signed by the president or secretary thereof, "stating" that such body will be used only for the promotion of anatomic science within the State, and that the remains shall be afterward decently buried without public charge. But, as heretofore, no body of any person who in his last sickness requests to be buried, or of any stranger or traveller who shall have suddenly died, shall be so disposed of. And no person so having charge of any such body, it is added, shall sell or deliver the same to anyone to be used for scientific or any other purposes outside of the State of Wisconsin. Any officer or other person violating any of the provisions of this act shall be liable to the person, society, or corporation aggrieved in the sum of $50 damages, to be recovered in an action therefor.

Subcutaneous Emphysema caused by Straining during Parturition.—Dr. Ulrik was called in to see a primipara, aged twenty-eight, who, after having been delivered of a stillborn twin, had suddenly become incapable of further assisting the progress of the labor, (*British Medical Journal*). An hour and a half after the birth of the twin the woman's strength seemed almost gone, but on some strong pains again commencing she was told by the midwife to attempt further straining efforts, during one of which a sudden swelling of the face and neck was produced, coincident with a complete cessation of the pains, which did not again return. The second twin was easily delivered by the forceps. The face had the appearance of pronounced œdema; the deformity was considerable, the skin pale and tightly stretched, especially over the cheeks and under the eyes, which the patient could scarcely open. Downward the swelling extended over the whole neck region and the upper part of the chest, and also into the axillæ, and behind as far as the scapular spines. Everywhere the characteristic crepitant sensation was experienced. The breathing was unimpaired, and there were no signs of lung disease. The emphysema began to disappear after a couple of days, and was quite gone in a fortnight. The patient had not subsequently developed any lung affection. The author believes that the air after the rupture of the air-cells must have found its way to the hilum, and thence along the great vessels and trachea through the mediastinum to the loose tissues of the neck and face; the nervous shock produced by the accident evidently caused the sudden cessation of the pains. He considers the accident so natural that it seems strange that it should not occur more often.

Surgery of Contusions of the Abdomen.—The Paris correspondent of the *Medical Press* writes that M. Michaux spoke at great length recently on the results of surgical intervention in cases of contusion of the abdomen. He said that all authors were agreed on the subject of early interference, but the greater number advised that the surgeon should wait at least for

the symptoms of peritonitis, while he considered that the best treatment of grave contusions of the abdomen consisted in an immediate operation, for, if no visceral lesion were discovered no harm would have been done to the patient. He had occasion to operate eleven times in the last four years for contusions of the abdomen, the history of which he would not give in detail, but would mention some particulars of a few of the cases. The first was that of a drayman who was knocked down by a large barrel of wine, and was carried to the hospital with all the signs of rupture of the intestines. Laparotomy was performed, but the patient succumbed the following day. A second was operated on for a tear in the transverse colon and made a rapid recovery, in spite of a considerable effusion of blood into the abdominal cavity. Another case was operated on with success on the third day after the accident, while a similar result was obtained in a fourth laparotomy performed on the seventeenth day for rupture of the biliary ducts. In April, last year, M. Michaux operated, ten hours after the accident, on a railway employee caught between the buffers of two wagons on a level with the epigastrium. About three quarts of blood were found in the abdomen and a rent in the mesentery of six inches in length ; this tear was sutured and the man recovered. A short time afterward he was called to operate on a mason, aged thirty-nine, who had fallen from the second story of a house on the angle of a marble table. By this accident some of the lower ribs on the left side were broken and a rent on the under surface of the left lobe of the liver, with a small effusion of blood, was produced. The man got well without much trouble. In an anatomical point of view, the eleven cases might be classed as follows : Three ruptures of the intestines ; one of the biliary ducts, two of the liver (slight), three of the mesentery, one of probable rupture of the kidney, and one (double) rupture of the bladder, with fracture of the bones. His friend, M. Gross, in a recent publication, mentions seven similar cases, so that of the total eighteen cases, twelve were exceedingly grave, and all were accompanied with considerable effusion of blood. In a clinical point of view, these contusions of the abdomen submitted to his observation, presented the two characters : 1. Period traumatic, collapse more or less prolonged. 2. Reaction, characterized by high temperature, delirium, and the premonitory symptoms of peritonitis. The shock was always intense and more marked in slight contusions than in the graver cases. At the end of from two to seven hours the patient enters the second stage. In this first period, also, the abdomen is retracted, the muscles strongly contracted over the seat of the lesion, and great pain is experienced to the touch. As soon as the temperature rises the patient must be closely watched, as the time for interfering is at hand. However, during the first twenty-four hours, no certain sign denoting a lesion of the viscera, such as a rupture of the intestine, is manifest. But experience having shown that in three-fifths of the cases grave lesions do exist, and that death is almost always the consequence, it can easily be understood that laparotomy, for the purpose of exploring the region, imposes itself as an absolute necessity, as alone it permits us to recognize with certainty the nature and extent of the evil and the application of the treatment. It should be practised within the first twenty hours after the accident, and as rapidly as possible, care being taken to remove the blood and any other liquid.

A Death from Nitrous Oxide.—Mrs. Flora Joseph, forty-two years of age, died on October 5th, under the influence of nitrous-oxide gas, in a dentist's chair in East Eighty-sixth Street. Artificial respiration, the hypodermic use of whiskey and strychnia, and other appropriate measures were promptly resorted to, but without result.

BOOKS RECEIVED.

SOME CONSIDERATIONS WITH REGARD TO THE SENILE HEART.[1]

BY ROBERT H. BABCOCK, A.M., M.D.,

CHICAGO, ILL.

PROFESSOR OF CLINICAL MEDICINE AND DISEASES OF THE CHEST AT COLLEGE OF PHYSICIANS AND SURGEONS, ATTENDING PHYSICIAN TO COOK COUNTY HOSPITAL, CHICAGO.

THE term "Senile Heart" is an unfortunate one, since it implies that the disease thus characterized exists only in the aged. Degenerative changes in the myocardium and in the arteries underlie the group of symptoms that constitute the clinical history of this affection, and yet these degenerative changes are by no means limited to persons of advanced age. Balfour, although fully acquainted with this myocardial degeneration, repeats all through his book that the senile heart is a weak heart, which having become hypertrophied as years advanced, is deprived at length of sufficient nutrition, either through anæmia or through vascular changes in the organ itself, and thus weakened, becomes incapable any longer of carrying on the circulation against the peripheral resistance set up by the arterial rigidity incident to senility. This is undoubtedly true; but it seems to me that greater stress should be laid on degeneration of the myocardium in considering the etiology and pathology of the senile heart.

The man who, at forty-seven, perchance, with rigid arteries, succumbs to ingravescent cardiac asthenia—to use Balfour's favorite expression—"dies because disease of the heart muscle has paved the way for gradual heart failure." This degeneration may not be fatty, and may not be apparent after death to the unaided eye. It is more often what is known as "chronic myocarditis," or "hyperplasia of the interstitial connective tissue," and requires the microscope for its detection. Even then its real extent may not be discovered, because of faulty methods or of inadequate search. We have been accustomed to think of degeneration of the myocardium as affecting generally the ventricles, and of these, particularly the left; whereas recent observations indicate that the auricles may be more frequently and extensively degenerated than appears microscopically, or than are the ventricles.

Radazewsky[2] has published an account of his painstaking investigations into the condition of the myocardium in six cases of heart disease. Two were chronic valvulitis, two chronic myocarditis, one was cardiac debility and dilatation of the right ventricle with pulmonary emphysema, and one a hypertrophied and dilated heart in an old man of seventy-two. The author's object was to determine the extent and location of fibroid, not fatty, degeneration, with special reference to its bearing on the clinical characters of the pulse. Numerous small pieces, amounting in some instances to as many as one hundred and five, were taken from the auricles and ventricles, and after being appropriately prepared, were studied microscopically and compared with similar fragments taken from a young and healthy heart. In four of the six, the connective-tissue changes were most marked in the auricles—sometimes the right, sometimes the left—but involving both. In these four, arrhythmia of the pulse had been a marked clinical feature, whereas regularity of the pulse had been noted in the two cases in which fibroid degeneration of the ventricles exceeded the changes in the auricles. With reference to the conjunction of a regular pulse with degeneration of the left ventricle, Radazewsky cites the conclusion of Hampeln, who, in a study of five cases of myocarditis that had manifested regularity of the pulse, says essentially that the character of the pulse, as to regularity or irregularity, affords no basis for conclusion concerning the condition of the heart muscle. In other words, perfect regularity of the pulse does not exclude the existence of degeneration of the myocardium.

On the other hand, although Radazewsky recognizes his material as too meagre to establish his conclusions, he nevertheless thinks it sufficient to justify the deduction that arrhythmia indicates a preponderating degeneration of the auricles. Furthermore, this assumption accords with the discoveries of Romberg, Krehl, and others, who have shown that the automatic and rhythmic action of the heart originates in the muscle-fibres themselves, and not in the cardiac ganglia as formerly supposed, and that the primary impulse to contraction starts in the walls of the auricles near the openings of the great venous trunks. To us Radazewsky's studies are valuable by teaching that degeneration of the auricles may exist even when the myocardium of the ventricles is comparatively healthy. But they are not alone valuable from the stand-point of morbid anatomy; they may aid us in forming our diagnosis and prognosis. If Hampeln is right, that regularity of the pulse may coexist with dangerous degeneration of the ventricles, and if it shall be proved that degeneration of the auricles causes cardiac arrhythmia, then, in any given case, the character of the heart's action may aid us in locating the chief seat of myocardial sclerosis. Moreover, as it seems to me, the prognosis as to life may depend somewhat upon the seat of this change. As the walls of the left ventricle are subjected to the greatest strain, so preponderating degeneration of these is the most serious and likely to prove the most rapidly fatal. On the other hand, disease of the auricles, unless having caused destruction of the individual muscle-fibres, may give rise to an irregular pulse without seriously threatening life. Radazewsky's observations help me to understand some cases that at the time were rather puzzling. For instance, I can recall an elderly man who was suffering from cardiac feebleness, with so irregular and intermittent a pulse that it seemed to me the poor overstrained and dilated organ was likely to give up the struggle at any moment; and yet this heart went on beating for more than a year and a half before it succumbed.

I have under occasional observation a gentleman of seventy-one who, a year ago this time suffered with cardiac asthma of such severity that he thinks he was snatched from the grave, and who is now able to attend to business in a moderate fashion. Yet this patient's pulse is at times too irregular to be counted, and according to his statement has been so for several years. On the other hand, I have known patients with dilated and degenerated hearts who seemed in no im-

[1] Read at the Mississippi Valley Medical Association's Twenty-first Annual Meeting, held at Detroit, September 3, 1895.

[2] Zeitschrift f. klin. Med., Band 27, S. 381.

minent danger, and yet died suddenly a short time afterward, or failed steadily and rapidly in spite of treatment; and in these cases the pulse, though more or less rapid and weak, presented little, if any, irregularity.

Although recognizing the folly of attempting to base prognosis in these cases on the rhythm of the pulse alone, I have come to dread the weak accelerated, but regular, pulse sometimes observed in connection with dilatation of the heart in elderly men, and to regard a pulse irregular in force, volume, and rhythm, apart from other grave symptoms, as much less serious than I formerly did. It is quite otherwise with intermittence of the heart's action, if the intermissions set in unexpectedly after a period of rapid regular action. There is positive danger in such cases of the inhibition resulting in permanent asystole. Furthermore, valuable prognostic data are furnished by the effect of exercise on the character of the pulse. If gentle walking cause a weak, irregular pulse to become fuller, stronger, and more regular, it is a favorable indication. If, on the contrary, it occasions greater feebleness and rapidity, with irregularity, perchance intermittence, it portends evil, and indicates physical rest. It is a sure sign that the heart muscle is unequal to the strain.

Another symptom common to senile hearts, although of very variable severity, is dyspnœa. We have been taught to believe this due to pulmonary engorgement, together with accumulation of carbonic acid. But recent experiments and observations by Zerner[1] have shown that two other factors are concerned in its production, namely, increased volume or swelling, together with lessened elasticity, that is, rigidity or stiffness of the lungs. This enables us to understand the striking difference in the degree of dyspnœa displayed by patients, who otherwise manifest on examination no great dissimilarity in the dilatation of their hearts or the rigidity of their arteries. During the past few months I have attended two men—one aged forty-seven, the other aged fifty-three—in whom this sympton was a most distressing feature. The former used to say he could breathe only about an inch deep, while the latter suffered from paroxysms of such frightful dyspnœa that he seemed in imminent danger of strangulation. Indeed, during the last few weeks of life his want of breath was so extreme and constant and the veins of the neck were so turgid as to resemble pressure from a mediastinal tumor, and to necessitate frequent resort to large doses of morphine hypodermatically. Yet the post-mortem examination in this case revealed nothing to explain the dyspnœa aside from the usual changes in the lungs, heart, and kidneys, depending upon sclerosis of the coronary arteries and of the general aortic system. A peculiar characteristic of breathlessness due to coronary sclerosis is its occurrence during the act of dressing, as in raising the arms to comb the hair or fasten the necktie. Stooping to tie the shoes also occasions dyspnœa in these cases. Yet this is much less trustworthy as an indication of coronary sclerosis, since individuals with abdominal corpulence are often unable to stoop without shortness of breath, probably from pressure of the abdominal on the thoracic viscera. In such I have often found more relief to follow a brisk purge than is the case in coronary sclerosis.

Another manifestation of dyspnœa of quite a different sort is that paroxysmal exacerbation which comes on at night most commonly, and is called cardiac asthma. Conheim has shown its dependence on inequality in the strength of the two ventricles, whereby the right forces more blood into the lungs than the left can forward into the aorta. This results in acute hyperæmia and œdema of the lungs, with the sense of suffocation, the copious râles, cough, muco-serous expectoration, and small feeble pulse, which constitute the chief phenomena of these attacks. Balfour speaks of them as *angina sine dolore*, adopting the term invented by Gairdner. They are truly paroxysms of suffering akin to agony, but I am not convinced of their possessing sufficient etiological relationship to angina pectoris to like the term *angina sine dolore*. Since disproportionate feebleness of the left ventricle is present in these attacks, it has always seemed to me that the use of nitre fumes, asthma pastilles, etc., might be dangerous. Cardio-vascular depressants, which assuredly nitre fumes are, are contra-indicated, unless arterial spasm be clearly determined, to precipitate or maintain the attacks. By all odds the best treatment for such a paroxysm is the hypodermic administration of an eighth of a grain of morphine with a two-hundredth of atropine. Relief afforded is generally prompt and complete, the patient soon falling into quiet sleep, from which he wakes next morning refreshed and apparently none the worse.

Finally, there is a form of dyspnœa which is generally thought to usher in the last stage of the struggle; this is the Cheyne-Stokes respiration. It is very rightly regarded as a very grave prognostic omen, but that it may appear for a time and then vanish completely *pari passu*, with improvement in other symptoms, is borne out by the case of an old gentleman, aged eighty, whom I now have under observation. Last April this patient manifested this type of breathing in a typical manner—so much so, that a physician who saw him in consultation assured the family that the end could not be far distant, as he had never known Cheyne-Stokes respiration to last for longer than about three weeks. Nevertheless, this symptom has now been absent for three months or more, and the old gentleman declares he is better now than he was a year ago. In his case the respiration assumed the Cheyne-Stokes type chiefly when he was asleep, although it was not always absent during waking hours. The patient of seventy-one years of age, previously referred to in this paper, exhibited this type of breathing only when unconscious in sleep; and it has seemed to me that when such is the case, Cheyne-Stokes respiration may be regarded as of less evil portent than when it is constant both waking and sleeping. Of course, I do not refer to that physiological form of Cheyne-Stokes respiration which Murri has shown may sometimes be observed during profound sleep, even when the heart is healthy. In the case just cited there was a pathological condition to account for the occurrence of this type of breathing.

The treatment of this form of dyspnœa has been the subject of considerable contention in Germany. At the meeting of the Congress for Internal Medicine in Wiesbaden, in 1892, Unverricht read a paper in which he expressed the decided opinion that morphine and atropine exert no antagonistic influence upon Cheyne-Stokes respiration. Indeed, some observers have even gone so far as to assert that morphine intensifies this phenomenon. Stadelmann[1] has published the results of something like twenty-five observations of the effect of morphine and atropine, alone and combined, upon this type of breathing. The observations were made on two patients, and the doses were 0.01 to 0.02 of morphine, and 0.001 to 0.0015 of atropine. The effect was neither uniform nor constant; sometimes shortening a period of apnœa, sometimes that of dyspnœa, and then again at other times lengthening one or the other, or both. In five experiments Cheyne-Stokes breathing was lessened or removed by the morphine, as against four trials in which it was aggravated. Although Stadelmann's observations showed so inconstant and unreliable an effect on the part of morphine as to appear to confirm Unverricht's assertions, he nevertheless concluded that the effect of this agent on the whole was to mitigate the severity of the attacks. There certainly seemed to be no injurious effect exerted

[1] Zeitschrift f. klin. Med., Band 27, S. 529.

[1] Zeitschrift f. klin. Med., Band 26, S. 267.

by the morphine, and since it undoubtedly blunts the patient's sensibility and induces sleep, I can see no contraindication to its employment, even if it seems occasionally to change an irregular, unperiodic form of dyspnœa into the periodic type characteristic of Cheyne-Stokes respiration. Its beneficial action was so marked in the case of the gentleman, aged seventy-one, already cited, that I think it best to append a brief description of its effects in this case. The night before I was called to see this patient had been one of intolerable suffering; so soon as he dozed off, if but for a moment, he would wake up with a start, clutching his throat and declaring he was going to be suffocated. Nitro-glycerine and other cardiac stimulants had been administered freely without relief. His dread of the forthcoming night was so great that it was decided I should remain with him. I resolved to try morphine, but notwithstanding my assurance that he would certainly experience relief and pass a comfortable night in sleep, I could not obtain his consent to its use before midnight. At length, after his suffering of the night previous had begun to be repeated, he yielded. One-eighth grain of morphine with one two-hundredth grain of atropine was injected, and in a few minutes he was sleeping peacefully, although exhibiting Cheyne-Stokes respiration. From that time forward, for two months, he received his nightly injection of morphine, which never lost its effect and never had to be increased. When, at last, in response to treatment, his heart had regained something of its former vigor, chloralamid and bromide of potash were substituted as a hypnotic. Depression following the withdrawal of the morphine was trifling, and lasted but for a day. At the present writing, this patient considers himself in pretty fair health, although still under occasional observation.

It may be that this was an example of irregular dyspnœa having been changed by the morphine into the Cheyne-Stokes type of breathing. Yet, if my memory is not at fault, this character of respiration did not wholly disappear with the withdrawal of the morphine. The two-hundredth grain of atropine was not sufficient to antagonize the influence of the morphine. Nevertheless, I shall hereafter employ morphine alone, using as small a dose as will suffice. The remedy should always be administered hypodermically, not only because more prompt than by the mouth, but because more efficient. Another reason for its use in this manner is its action as a cardiac stimulant.

Conclusions.—1. The term senile heart is unfortunate, because the degenerative changes underlying the disease are not limited to the aged.

2. The changes in the heart muscle are generally those of chronic myocarditis, and their real extent and location often escape recognition.

3. Radazewsky's investigations indicate that the connective-tissue changes affect the auricles more often than is generally supposed, and often exceed degeneration of the ventricles.

4. Fibrosis of the auricles causes cardiac arrhythmia, whereas fibroid degeneration of the ventricles does not produce irregularity of the pulse.

5. Cardiac dyspnœa has been shown by Zerner to depend upon swelling and rigidity of the lungs, in addition to pulmonary engorgement and accumulation of carbonic acid in the blood; and this probably explains the striking difference in the degree of dyspnœa displayed by patients with similar cardiac lesions.

6. That paroxysmal exacerbation of dyspnœa, called cardiac asthma, is due to disproportionate weakness of the left ventricle, and is most promptly and efficiently relieved by the hypodermic injection of morphine, one-eighth, and atropine, one two-hundredth of a grain.

7. Stadelmann's experiments appear to confirm Unverricht's assertion, that morphine and atropine exert no antagonistic influence over attacks of Cheyne-Stokes respiration.

8. Nevertheless, since morphine hypodermically was shown to sometimes modify in a favorable manner the severity of the attacks, and since it blunts the patient's sense of dyspnœa and induces sleep, its employment hypodermically is justified in these cases.

9. Morphine should be administered in cardiac cases hypodermically, and in as small a dose as will accomplish the result desired; and given in this manner it acts as a powerful cardiac stimulant.

VENETIAN BUILDING.

WHAT SHOULD BE THE POLICY OF THE STATE TOWARD PROSTITUTION?[1]

By DENSLOW LEWIS, M.D.,

OBSTETRICIAN AND GYNECOLOGIST TO COOK COUNTY HOSPITAL CHICAGO, ILL.

A DISCUSSION of this trite subject would be useless to-day, were there not a possibility that the time had come when an enlightened public sentiment might effect something of real value. This discussion of the subject of prostitution must be based upon facts. History must be recognized, efforts already made toward the restriction of the vice and the results obtained must be appreciated at their true value. It is the truth that in all large cities the habitat of the prostitute is to most people of respectability as much an undiscovered country as the interior of Africa; it is truly as much a *terra incognita* as the island of Tierra del Fuego.

Indeed, there is an involuntary feeling of disgust and abhorrence when prostitution is mentioned. The whole matter is to most people so loathsome that they cannot even speak of it without horror. However, it is needless to say to medical men that the importance of the subject justifies its scientific study and its very serious consideration. It is said one cannot touch pitch without being defiled; nevertheless, the annals of medicine show many instances of martyrdom to the cause of science. The deaths due to sucking of the tracheotomy wound in diphtheria, and the many deaths that have occurred throughout the world due to scientific effort made in the study of disease, suffice to demonstrate the courage of the medical man and the sociologist in the discharge of what they believe to be their duties.

In reference to the study of prostitution, moreover, the effects of this vice must be judged by the truth as demonstrated by actual observation and experience. Inherent notions of right and wrong are out of place, for they are at best but relative—often geographical. Preconceived ideas, founded on religion, are inconsistent with the spirit of the times and incompatible with the scientific methods of a liberal profession.

Let us, then, very briefly study this matter, let us know what it is, why it persists, how it thrives, and as we take cognizance of the etiological factors incident to its existence and perpetuation, let us endeavor, if we cannot do away with it entirely, at least to suggest some remedial measures tending to diminish its extent, to control its objectionable features, and to eliminate its pernicious effects. Some people object to this, as I have already said. They claim the whole subject of prostitution is so degrading that its very mention is contaminating. I need not stop here to demonstrate to medical men the absurdity of this position. Nor do I need to insist further upon the importance of its consideration. As a matter of fact history shows that it has always existed. We certainly know its prevalence everywhere to-day. I for one cannot see how, for many generations to come at least, we can expect to eradicate it. As a matter of fact, next to the instinct of self-preservation the instinct which dictates the perpetuation of the species is dominant in all animals. Fortunately, in the genus *homo* this instinct does not exist

[1] Remarks made at the September Meeting of the Doctors' Club of Chicago.

in the female to the extent that it is found in the male, otherwise there would be no such thing as virtue or morality. There are philosophers—master minds—who after conscientious and critical study of the subject in all its relationships do not hesitate to assert that prostitution is desirable. Be this as it may, it is certain it is less objectionable than certain other evils. The great historian Lecky characterizes the prostitute as the eternal priestess of humanity, blasted for the sins of the entire people. There is no doubt that she is of value as a safeguard to the virtue of the family. If, in a word, our religion, our education, and our civilization cannot teach our young men to refrain from the sexual act until such time as it may legitimately be indulged in, it is decidedly better for us to have these young men cohabit with women of the town rather than with the wives and daughters of their neighbors. It is better for them to do this rather than indulge in the disgraceful practices and degrading crimes against nature, which prevail even in our midst to-day.

When we consider what shall be done with the prostitute, certain persons in the community, dominated by a sense of disgust, which all must entertain for her if they had not thought in a sense of justice regarding the causes that have made her what she is, cry out: "Away with her. Prostitution is so baneful, let us stamp it out, let us have none of it." How little such persons know of history or of human nature. The most stringent measures have at different times been adopted. Invariably they have proven ineffectual. Prostitutes have been publicly horsewhipped; their noses and ears have been cut; they have been ordered thrown in the river; they have suffered every degradation, but they still exist. Indeed, St. Louis, in 1254, was forced to the conclusion that suppression was worse than useless, and I think I may safely say that a consistent study of the facts will reveal that since that time all efforts at restricting the vice by summary legislation have ignominiously failed. If prostitution has not been allowed to exist publicly, it has existed clandestinely, and its evils have been greater because no longer under supervision or control.

I will not go into the history of prostitution. The recent edition of Sanger's work and the comprehensive treatises of Jeannel and Parent du Chatelet give full details of a most interesting character. My own observation teaches me that women, as a rule, become prostitutes not from passion but from necessity. With imperfect and insufficient education, with degrading environments, without the fostering care of family, young women only too often, dominated by love and vanity, which Chesterfield has described as the two universal characteristics of women, fall ready victims to the lust of man. Then, again, the insufficient wages paid by many of our leading merchants to young women in their employ is unquestionably an etiological factor in the development of prostitution. Illegitimate pregnancy, as I have abundant opportunity of noting, causes many a woman to adopt a life of shame. She does this not because she wishes it, but because in the present state of our society in all large cities there is no place for the illegitimate infant—no helping hand for the erring woman. Many women through force of circumstances find themselves burdened with an illegitimate child which perhaps they desert. Ignorant of all reputable means of maintaining life, realizing after a few days of effort the impossibility of finding employment adequate for her maintenance, let me ask you, as matter of fact, "what is there for such a woman to do?" There is but really and actually one method by which she can live. She becomes a prostitute rather than starve.

I will not attempt to describe her daily life. In the works I have referred to you may read all details if you choose. As a matter of fact, in this country when a woman enters a house of prostitution, she too often enters what is practically a prison, from which escape is impossible. The methods of the proprietors of these houses are generally known. The young woman is furnished with clothing and anything else she may desire, so that she may remain constantly in the debt of the proprietor. As long as her attractions make her capable of adding to the revenue of the house, she remains there. When disease or debauchery shall have degraded her to such an extent that she is no longer sought by the patrons of the house, she is thrown out as a worthless piece of merchandise. Then comes further degradation, still more debauchery, from which transient relief is obtained only by the use of opium. Finally, and in a very few years, death closes the scene. One more woman has run her course, one more victim has met her fate, that is all.

Prostitution is not attractive. Pope's lines, where he speaks of vice and says:

> "But seen too oft, familiar with her face,
> We first endure, then pity, then embrace,"

do not apply here. To many an unfortunate woman the prospect of proper clothing, three meals a day, and no work, is undoubtedly preferable to starvation on the public streets or a sojourn in the bridewell. The hideousness of her calling, the revolting characteristics of her occupation are soon revealed to her oftentimes when no turning back is possible, when she has become in effect a slave of lust for life.

Few women become votaries of the vice from choice. In the great majority of cases the prostitute is what she is because man has in one way or another made her so. Under these circumstances, however disgusting and degrading may be her calling, I cannot in justice bring myself to look upon her with abhorrence, for I appreciate the circumstances that have made her what she is.

Now if we are to consider calmly and dispassionately the remedy of prostitution, we must take cognizance of its etiological factors and our remedy must be largely sociological. We cannot eradicate one of the great instincts of human nature, but we can and should teach its control. We should improve the economic conditions under which dependent women live, and we should open up all possible avenues of honest industry where women can find means of support. We can teach our young girls the perils that beset them. This may be immodest, but in certain States of the Union where the age of consent occurs before the girl has menstruated, or very soon afterward, it is only just to teach the child that knowledge which may enable her in a small degree to realize the dangers against which she is called upon to protect herself.

With these remarks upon the subject of prostitution in general, the causes which determine its existence and are instrumental in its maintenance, and with this reference to the prophylaxis of the condition, a prophylaxis based on facts, attested by history and by every-day observation, I proceed to the consideration of the policy of the State toward what is called the social evil.

As a matter of fact, in Illinois we are permitted to take no official cognizance of prostitution, nor to pass laws regulating it in any way. There is a State law against such action, just as I am informed there is a State law against keeping saloons open on Sunday. I hold this law to be wrong in principle and ineffectual in practice. I believe in the supremacy of the individual, and while I do not regard license as liberty, I think prostitution, which exists everywhere, can best be controlled by municipal rather than State legislation, for its evils vary in accordance with local rather than general conditions.

If this is true, the State law must first be repealed before we can take action of any sort. For the purpose of discussion, assuming this to have been done, assuming the possibility of doing what we think best in the matter, let us now determine if we wish to do

anything and to what extent, without infringing on the constitutional prerogative of every individual not a criminal, we are capable of limiting the extent or controlling the ill effects of prostitution. This brings us to the consideration of another matter of vital importance in this connection. I refer, of course, to venereal disease, which is chiefly disseminated by promiscuous sexual intercourse. Right here we are again met by objectors—not bigots or fanatics alone, but medical men of sincerity and honesty, whose motives cannot be gainsaid. They say: "If a man does such things let him take the consequences. He ought to know better." Armstrong, of New York, says that *caveat emptor* is the maxim of the market-place. I am glad to reply to him that it is not the maxim of the sanitarian, whose duty consists in doing more than crying "Beware," otherwise we had better abolish all our Boards of Health. As a matter of fact, there is no thought of guaranteeing the health of an individual any more than there is thought of a government pledging itself to guarantee immunity from epidemics.

Venereal disease is recognized, by those who know about it, as wide-spreading in its effects. The position has been taken that any attempt at controlling disease results in the extension of prostitution. It is said that if men knew they were safe, they would gratify their sexual passion more freely than they do now. In other words, men are said to be restrained by the fear of disease more than anything else. And then some persons say it serves them right if they are wicked enough to consort with prostitutes. They get only what they deserve. The wages of sin is death. The absurdity of this statement, as White has pointed out, is seen if it is followed to its logical conclusion. If it is right for every man who has intercourse with a prostitute to become diseased as a divine retribution for his indiscretion, we must encourage disease in each prostitute to make sure that no transgressor fails to receive his just punishment for his sin. Moreover, the man is often not the only victim. His wife, his children, his neighbors, all persons he comes in contact with, may fall innocent victims to the disease that he disseminates.

For this reason, if for no other, medical men must consider the prophylaxis of venereal disease in its relations to prostitution. All will agree, I am sure, that there is a possibility of improving the present conditions; all will acknowledge that something should be done rather than persist in the "let-alone" policy now in existence.

This thought leads to the consideration of the method called regulation, which means usually a systematic registration of all prostitutes and periodical inspection by deputized medical men. It means in some countries many things besides, dependent on local conditions. I will not detail the varied statistics that have been compiled in attempts at determining the value or worthlessness of regulation. It is easy to prove almost anything by statistics. I will simply say now that in every instance where regulation has been persisted in for any considerable length of time under proper supervision by qualified officials, the result has been in the main satisfactory. It has not always been as satisfactory as we would wish, but it has accomplished something. It has diminished venereal disease among soldiers and civilians, and brought more cases to the proper hospitals where the disease could be most satisfactorily treated. It has decreased the number of public women and produced a marked disappearance of young prostitutes. It has lessened the number and improved the character of the public houses. It has made segregation a possibility, so that police surveillance and supervision have been more systematic. It has restricted debauchery and prevented the use of these houses as the harborers of thieves and other criminals. Can it truthfully be said that the "let-alone" policy has accomplished even one of these results? The proper policy of the political body, be it State or municipality, that has jurisdiction over prostitution, should be not to close the eyes and say nothing exists because nothing is seen. Much less should the presence of prostitution be disregarded on account of its loathsomeness or its contaminating influence. By education, by religious instruction, by the judicious inculcation of adequate knowledge, by proper environment, and above all by a radical improvement in the economic conditions of our dependent young women, by teaching our young men principles of honor, of justice, of chivalry, and of charity for those who in pity should be able to look to them for protection and support—by these means we shall tend to restrict prostitution by preventing its increase through the agency of rational measures consistently applied.

As for the prostitute of to-day, let us grant her that liberty to which she is entitled; let us realize why she is what she is, and be just to her. At the same time, when we are permitted by the repeal of the State law to act in her case as we act toward every other source of infection, we will take all proper measures to diminish the extension of the disease to which she is specially liable, and in our endeavor to act in this manner for the welfare of the public, history shows we may count on her active co-operation.

I have made my answer to the question of the evening. You will pardon me if I add a thought as to immediate action. There are matters of importance that can receive attention at once. They pertain not to prostitution as such, nor to its regulation nor restriction, except incidentally. They concern medical men especially, for they relate to a medical matter worthy of very serious consideration.

Something can be done now to lessen the extent of venereal disease. In corporate institutions where large bodies of men are congregated, there can be proper inspection and suitable treatment which will diminish the spread of disease. In our houses of correction, our prisons, our asylums, our refuges, free treatment can be offered, and in most cases it will be gladly accepted. Our dispensary and hospital facilities for the care of venereal diseases are singularly inadequate for a metropolis like Chicago. Hospitals should be built and maintained exclusively for the treatment of this class of cases. The interests of the community demand that if we must have the prostitute, we shall do our best to have her free from disease. Our treatment may not be all we would desire. It is, however, better to have a certain amount of treatment than to have none at all. If we cannot take a woman with gonorrhœa and cart her off to a hospital to be kept locked up there until she is well, as is done in Berlin and Paris, we can treat her as much as she will allow and instruct her in the use of antiseptic douches, for by that means some man may escape infection. If we cannot detain a woman with chancroid, we can destroy the virulence of the disease as far as possible, for it is better to do that than to do nothing. If we cannot keep a syphilitic woman under observation for two years, as I believe should invariably be done, we can treat her as long as she will permit, for incomplete treatment is better than none at all.

In a word, let us do all we can to treat disease, for that is the main object of our existence. Let us do the best we can in these cases, for there is much left undone that, with proper facilities, might be done to-day.

While awaiting the time when prophylactic measures shall diminish prostitution, let us for the present devote our energies toward the institution and perfection of such means as in our judgment will best tend to minimize its pernicious effects.

The Insane in Scotland.—On January 1st, in the present year, there were 13,852 insane persons under official cognizance in Scotland.

DIET AND SYSTEMATIC MUSCULAR EXERCISE IN THE TREATMENT OF TUBERCULOSIS.[1]

By T. J. McGILLICUDDY, A.M., M.D.,

NEW YORK.

SURGEON TO THE MOTHERS' HOME MATERNITY HOSPITAL; CONSULTING PHYSICIAN TO THE ITALIAN HOSPITAL, ETC.

Up to about twelve years ago the treatment of tuberculosis was entirely empirical. In 1882 Robert Koch, of Berlin, for the first time proved beyond a doubt that this disease was caused by bacilli which, on account of their peculiar behavior toward strong acid, could be positively diagnosed in every case of tuberculosis. All subsequent experiments have shown that Koch's statements were perfectly correct, and to-day we can say that there is no tuberculosis without the presence of these characteristic tubercle bacilli. It is true that at the commencement of the affection it is not always easy to find the bacilli, but careful examination of the sputa at different times will invariably show their presence in a greater or less degree.

Tuberculosis may start very slowly and gradually; so much so that, physically, no characteristic symptoms of the disease may be found, but examination of the sputa will already, at this early period, demonstrate the presence of the bacilli. In every case of cough which has lasted for some time the physician should invariably make it the rule to examine the sputum, whether he suspects tuberculosis or not. If this is done, and only then, can we expect better results from our treatment than we have heretofore achieved.

In a large number of cases bacilli may be found in the sputa long before there are any well-marked physical signs, so that their detection will afford the first clue to the patient's malady. Even at the present day some physicians claim that there are cases of phthisis without the presence of tubercle bacilli. The trouble with them will, however, simply lie in the meaning of the word "Phthisis," as some will call a chronic catarrhal pneumonia fibroid phthisis. That this is not tuberculosis need hardly be mentioned.

Another mistake which is often made is to call tubercle bacilli the sole cause of tubercular infection, since tuberculosis will never affect people with good constitutions, but only those with poor, broken-down constitutions. People with good constitutions may continually inhale the bacilli without any bad effects whatever. The human body may be in a condition that is termed health, and still pathogenic bacteria may be present; these are kept in abeyance by the defensive action of the blood-serum and leucocytes. It is this repressive power of the blood that keeps them from propagating and doing injury to the economy.

Bacteria often seem to be destroyed by phagocytosis. There is an antibacterial property in the tissues, fluids, and secretions of the body, and these are natural defences against the growth of micro-organisms. The contact of germs does not lead to infection unless the material is present to favor their development. One of these causes is a poor or broken-down constitution. When this is present any existing bacteria will multiply and thrive. Another cause is the presence of the products of fermentation, inflammatory exudates, and diminished blood-supply. If the constitution is improved, and the pabulum upon which the bacteria thrive removed or its formation stopped, their development is hindered or entirely checked, and thus the severer forms of inflammation are obviated. A plant cannot grow upon a rock or thrive upon barren soil, and so it is with all forms of life, even the minute organisms. The substances upon the surfaces of wounds which cause the development of micro-organisms and thus produce infection, are readily removed by the most important and chief means for all sterilization, that is, the mechanical purification by washing and cleansing with water. Why should not the substances in the interior of the organism, which are the pabulum for bacterial development, also be removed, at least to a great extent, through the channels of the body which terminate directly in the emunctory organs. It is quite possible that the sewage system of the tissues, when properly stimulated in the work of elimination, will carry along in its circulation much of the material which causes infection, and thus produce what might be termed an internal sterilization or asepsis. Many seem to think that because a germ once entered the body, it cannot be removed until it is thoroughly digested; but why should not cleanliness, applied to the internal organs whenever possible, aid in the elimination of the micro-organisms? If we cleanse the oral cavity daily, we may just as well go farther and cleanse the stomach and intestines. Tubercle and other bacilli usually enter the organism by the canals and ducts which communicate with the outside of the body. The alimentary canal in many cases is the primary means of entrance. The infection then extends by following various routes. The bacilli are carried along the lymphatic channels into the tissues or lymphatic glands. These glands appear to have the power of arresting the infection for a time at least, before it finally passes into the blood, and this would seem to be the critical period in the treatment. Pure or sterilized granite or trap-rock waters, taken hot in sufficient quantities and at proper times, combined with systematic muscular exercise, hot baths, and massage, will certainly help to cleanse out the tissues of the body.

We may furthermore take advantage of the bactericidal properties of the blood-serum. This protective property of nature is best enhanced by enriching the blood by the various means within our power, one of the most important of which is scientific dieting. The ordinary diet of individuals is often extremely bad, the place of wholesome food being taken by sweets and stimulants, such as sugar, pastry, tea, coffee, and alcoholic drinks, so that not infrequently patients will grow weak and the constitution will suffer simply on account of the deprivation of proper nourishment.

The plan of treatment which I have already described in the *New York Medical Journal* for October, 1894, consists in giving at rather frequent intervals a considerable quantity of carefully roasted or broiled beef or mutton, raw eggs, stale bread, butter, sterilized milk, and vegetables. After a few days of treatment the meat should not be less in amount than a pound a day, and the quantity of bread and vegetables should be even, if possible, somewhat larger. When there is a disgust for the meat diet the stomach needs special treatment, for a short time only, by the addition of a digestant such as dilute hydrochloric acid and hot water to remove irritations.

Tuberculosis is the great destroyer, as it is the most frequent of all fatal diseases; and malnutrition and defective elimination, which will sooner or later break down the constitution, are at its foundation. It is estimated that in the United States nearly five hundred individuals die of this disease every twenty four hours. Its extreme prevalence and destructiveness have urged physicians in all countries to make strenuous efforts for its prevention and extermination.

It has been mentioned in this paper a number of times that constitution is one of the most important points in the development of tuberculosis. It may be well to show how the constitution of the patient can easily be determined under the microscope. Not only may this be done by the colorless blood-corpuscles, but also by the inflammatory pus-corpuscles which we will invariably find present in every sputum in which there is an inflammation of any kind whatever.

These views were first announced by Carl Heitzmann in 1879, and have since been corroborated by a number of independent observers both here and abroad.

[1] Read before the New York County Medical Association, October 21 1895.

They are the following: The amount of living matter within a limited bulk of a corpuscle varies greatly in different individuals. It is obvious that what is called a healthy or vigorous constitution is based upon a large amount of living matter in the body, the new-growth of which in morbid processes is very lively; while a phthisical or so-called scrofulous diathesis must be caused by a relatively small amount of living matter, the new-growth of which is scanty in morbid processes. In other words, a corpuscle will exhibit coarse granulation, or it will be almost homogeneous-looking, under the microscope, owing to the large amount of living matter in strong individuals of good constitution; while a corpuscle taken from a person with a weak or tuberculous constitution will be pale and finely granular, as but little living matter is present in it. In a given case, therefore, the more numerous the coarsely granular pus-corpuscles or colorless blood-corpuscles present, the better the constitution; and, on the other hand, the more abundant the finely granular ones, the worse the constitution; and when the corpuscles become broken up and disintegrated we can say that death is not far distant. As long, then, as we find the coarsely granular homogeneous corpuscles predominating, so long there will be no danger of the individual contracting tuberculosis; and when upon examination we find that the corpuscles do not contain a sufficient amount of living matter, that is, they have become more or less finely granular, we should at once resort to all possible means to increase the living matter, as otherwise tuberculosis may set in at any time.

Klebs, in the *Journal of the American Medical Association* for October 12, 1895, says, in speaking of antiphthisin in tubercular affections of children:

"It would certainly be unreasonable to demand that this remedy, which has a specific germicidal effect upon the tubercle bacillus only, shall also remove and cause the cure of pathologic changes, which result remotely from the primary cause and, more unreasonable still, that the remedy shall also favorably influence and cure complications, which like infection with other pathogenic germs have no relation to tuberculosis at all, more than that they may be associated in the same patient.

"In all such cases it is necessary to remove the complications by other treatment, either before or in conjunction with the application of the specific remedy; but the final results are determined by the importance and curability of such attending pathologic processes.

"We see thus, that the use of a specific germicidal remedy can only be fully effective when the disease is still uncomplicated by secondary degenerations, and is free from complications which, unfortunately, are present in most cases of tubercular disease as they come under our notice; there are, however, not a few cases of purely tubercular affections in an early stage in which the results of specific medication are highly satisfactory. . . . For these, as in all other therapeutic efforts, the only unavoidable condition is that the organism itself shall still have the power to use and appropriate the introduced curative substance; for under no circumstances can we otherwise conceive the cure of disease, than that the living organism must, itself, take an active part in its removal."

In closing his paper he says, "Finally, I wish to point out that, in all tubercular affections the same as in many other severe and serious diseases, their treatment in hospitals or special institutions offers great advantages over that of private practice."

The means of improving the general constitution have already been partly stated above, but I wish to dwell especially upon the good results obtained from regular systematic physical exercise. The medical profession has always deemed physical education a hygienic measure of the greatest importance.

The well-known Dr. Gustaf Zander says: "Experience having shown that regular muscular exercises, gradually made more strenuous, not only develop and strengthen the muscles, but promote the removal of pathological changes in the tissues, give tone to the nervous system, and vitalize the circulation of the blood and lymph, and the activity of many organs, it is natural that such exercises should be included among therapeutic agents. For this purpose there was, however, requisite the power to execute these exercises according to physiological laws, and to modify their action, like that of any other therapeutic agent, according to the needs of each individual case." Therefore those persons who take up physical culture without a competent medical instructor, may do themselves serious injury, or at least obtain no special benefit from it, by attempting methods unsuited to their physical condition, or neglecting to carry out a practical system in a proper manner. Physical culture at home soon becomes a matter of drudgery to the weak and illy developed, who especially require it. As the interest is lost, it is neglected or carried out in a desultory manner, and thus the beneficial results are not obtained. Under a competent medical instructor there is, along with sustained interest, a rapid and harmonious development of those portions of the body which most need it. Hysterical women and neurasthenic patients of both sexes especially, and also children, should not be allowed to take this exercise at home, as they perform it without system, overdoing it one day and entirely neglecting it the next. Very judicious passive exercise should begin the treatment, which should be gradually increased; at the same time they are under control, which strengthens their will-power, and they have to obey instead of ordering others about.

The indications and contra-indications for muscular exercise should be carefully determined. Exercise does not do everything; sometimes rest and drugs are needed. Therapeutics always belong to the physician, and not to the layman. The pleasurable massage following the bath is something difficult, and with many impossible, to obtain at home, and it should not be in the hands of laymen.

To overcome the deformity of round shoulders, the muscles of the back and abdomen must be systematically exercised and strengthened. The flattening of the chest, which is the result of the shoulders falling forward, tends to the production of lung disease, by interfering with their complete expansion. To overcome this deformity, the patient should stand with head erect, with the abdomen drawn back and chest projecting, and then forcibly draw the shoulders back as far as possible, as if to make the shoulder-blades meet. This should be performed from ten to fifty times daily; in fact, at frequent intervals during the day, whether exercising or not. All shoulder-braces are useless for this purpose.

For broadening the chest, assume the erect posture. The movement should be as follows: starting with the hands in front of the hips, to force them by a lateral and backward movement as high above and behind the head as possible. A modification of this movement, which is easier and more graceful, consists in starting with the arms extended behind the back, and letting them go up alternately as far as possible, while keeping the elbows perfectly rigid. All these exercises are best performed with light dumb-bells, from two to five pounds in weight. This last movement is of especial advantage in drawing upward and outward the sides of the chest, thus increasing its capacity.

Another beneficial exercise for deepening the chest and straightening back the shoulders, is to stand with arms projecting straight forward, elbows perfectly stiff. Let the arms go straight backward as far as they will, on a level with the shoulders. Meanwhile, the erect posture must be maintained—head erect, chest projecting, and chin drawn in. This is a splendid exercise for increasing the lung capacity. These movements should be repeated until the particular muscles involved become fatigued, when the instructor will

change them and bring into use another set of muscles, and so on. The respirations should be full and free, and the air perfectly pure. A system of this kind, carried out in a scientific manner, strengthens not only the muscles, but all the vital functions, and is adapted not only to adults but to children as well. Respiration and digestion are improved with the increase of vitality, and the elimination of the waste of the body is greatly enhanced. By specific exercises the chest cavity is broadened and deepened, and the chest expansion and manner of breathing greatly improved and permanently benefited. Not only the lungs, but the brain and nervous system are powerfully influenced by systematic bodily exercise The brain will accomplish only imperfect results if the body is not in a state of health.

Everywhere we see the lack of physical culture, men, women, and children, with narrow chests, pale, emaciated faces, and a general look of exhaustion, are met daily. If extreme leanness is not present, obesity produces ugliness of the human form. A comely, erect, well-formed body is much less common. Judicious, systematic muscular exercise, and a proper dietary, give vigor, activity, and courage, both mental and physical.

The supply of oxygen is greatly increased by deep, full inhalations in the open air, thus increasing the lung capacity, purifying the blood, and strengthening the nervous system. The temperature of the body is equalized as a result of the muscular exercise, and the eliminative system stimulated to increased activity; while digestion and assimilation are brought to their highest point of efficiency.

I desire to refer at this point to Dr. Wischnewetzky, who first established a complete mechanico-therapeutic Zander institute in this country, and directed it for five years, but at present has no connection with the institution. Therefore he cannot be held responsible for its present methods of advertising in the daily newspapers. He says, in "Contributions to Mechanico-therapeutics and Orthopedics," vol. i., No. 2: "By affording a basis for the scientific medical application and discussion of Mechanico-therapeutics, Dr. Zander has placed the subject above the level of a peculiarly Swedish method, and has enriched the science of medicine. Hence, although Dr. Zander is a Swedish physician, his method can no more be called Swedish than pathological anatomy, which has been so effectively promoted in Germany, is German, or antiseptic surgery English, because Joseph Lister was born in England. . . .

"The physician has here forced the mechanical progress of our age into the service of medicine for the solution of problems of an anatomical nature. He enables us to exercise any given group of muscles strictly in accordance with the laws of physiology; to exclude any other group at will; to determine which groups are called into action, and to what extent in every movement made.

"By subjecting to localization, measurement, and control a therapeutic agent which, for want of these qualifications, was not susceptible of rigid scrutiny, Dr. Zander has created the basis for the use of mechanical treatment as an agent capable of fulfilling all the conditions imposed by the most exigent scientific criticism.

"The importance of systematically organized muscular exercise is no longer a subject of debate. The question always open for the conscientious physician is: "How shall such treatment be administered without risk of harm and with all the benefit which is in many cases obtainable from it?"

In this article nothing has been said of the medical treatment by inhalations, creosote, terebene, and its allies, etc., which is often curative and of great importance in this disease.

776 Madison Avenue.

A REPORT OF A SERIES OF CASES OF MULTIPLE NEURITIS IN INFANTS IN THE CITY OF BRIDGEPORT, CONN.[1]

By GRAEME M. HAMMOND, M.D.,

NEW YORK.

Isolated cases of multiple neuritis in infants are of rare occurrence. A sequence of such cases occurring within a limited geographical area is particularly interesting, both from clinical and etiological points of view. Cases of neuritis in children are perhaps more common than is generally believed. Browning, of Brooklyn, pointed out a short time ago that many cases of so-called anterior poliomyelitis in childhood were, in reality, cases of neuritis, probably of malarial origin, and Sachs, in his text-book, refers to many cases of neuritis in children, who have been exposed to some toxic poison. But I have not been able within the limited time since this series of cases became known to me, to discover, at least in this country, any similar group of cases occurring in such a circumscribed locality.

Epidemic neuroses, with the exception of cerebro-spinal meningitis, are of very infrequent occurrence. In this country an epidemic of poliomyelitis was reported over fifty years ago by Dr. Colmer, and then not again until 1894, when a similar epidemic occurred in Vermont, the details of which were reported in full by Dr. Caverly in the Medical Record of December 4, 1894. In Europe epidemics of poliomyelitis have been reported by Briegleb in 1890, and in Stockholm by Medin in 1891. None of these were described to be epidemics of multiple neuritis, nor can I find any trace in literature of epidemics similar to the series of cases I propose presenting to you this evening. The Vermont epidemic affected many of the lower animals as well as the human species. I am inclined to believe, from a study of Dr. Caverly's cases, that only a certain proportion were examples of poliomyelitis pure and simple. In that epidemic there seemed to be some undiscovered morbid agent which profoundly impressed the nervous system affecting different individuals with a similar inflammatory process, but implicating different portions of the cerebro-spinal system. Thus it seems to me, merely from reading Dr. Caverly's account of the epidemic, that there were cases not only of poliomyelitis, but also of spinal meningitis and cerebral meningitis, either independently or in combination. Medin's analysis of forty-four cases in the Stockholm epidemic shows there was more than simple poliomyelitis. There were ophthalmoplegias, facial and laryngeal paralyses, and in a few cases distinct implication of the vagus, symptoms which are quite foreign to typical poliomyelitis.

The present series of cases, comprising ten, occurred between December, 1894, and the present time. This is hardly sufficient to be regarded as an epidemic, and yet the nature of the disease is such, and its occurrence in infancy is so rare, that ten cases discovered in one locality and all within a few months may properly be regarded as an epidemic. They may certainly be regarded as extraordinary, and the presumption does not seem unreasonable that some atmospheric germ as unknown to us as that which caused the Vermont epidemic, and probably similar to it, is responsible for the cases I propose to bring to your notice this evening.

Last January, Dr. J. W. Wright, of Bridgeport, asked me to see his little girl, then twenty-one months of age. The history of the case was as follows: She had always been a strong and vigorous child. About Christmas she did not appear to be feeling well, and after a few days of discomfort, complained of pain in her feet. The pain ascended and seemed to affect both feet and legs equally. With the advent of the pain, progressive paralysis appeared, beginning in both feet and gradually extending upward. When I saw her both legs were

[1] Read before the New York Neurological Society, October 1, 1895.

absolutely paralyzed. The muscles of the back were so weakened that she could not sit up, both arms were greatly weakened but retained feeble motion. The child seemed to be free from pain so long as she remained quiescent, but as soon as the limbs were moved or even pressed, particularly over the nerve-trunks, she shrieked with pain. There was apparently little or no pain in the arms. The gums were swollen and exquisitely tender. Tests in regard to the different forms of sensibility could not be made both on account of the youth of the patient, and because of the suffering such an examination would necessarily entail. I saw the patient about two weeks later, in consultation with Dr. Garlick. Her condition was unchanged, except that she had been seized with a double pneumonia, which may or may not have been part of the infectious process. From this she recovered. A few weeks later the symptoms of neuritis began to diminish. The pain subsided, motion gradually returned, and in about four months she seemed restored to her normal condition.

Case II.—About a hundred yards from Dr. Wright's residence, I found a child, three and a half years of age, who had had the first case, as far as I could ascertain. His initial symptoms began a few weeks before those of the case just described, and differed but little and immaterially in their clinical features. This case also recovered.

The notes of the next six cases have been given to me by Dr. John C. Lynch. They were all cases occurring in his practice in Bridgeport.

Case III.—Francis P——, 9 Grand Street, Bridgeport, Conn.; aged fourteen months; Irish parents, family history good; no syphilis, father intemperate. The child is the youngest of four and has always been healthy till the present trouble. Thursday, May 30th, his mother took him in a baby-carriage to see a parade. The child was restless that night and slept poorly, but the mother thought it was due to teething. Three or four days before this the child rolled out of the bed, but did not seem to be hurt very much as he did not wake up or cry. The next day the mother noticed that he could not use his right hand, then his left hand became affected, and finally both legs were paralyzed. On June 2d his mother brought him to my office. The temperature was 103° F.; pulse, 127; respiration, 38, with paralysis of both upper and lower extremities. There was hyperæsthesia and tenderness and stiffness on motion. Reflexes were abolished and the characteristic wrist and foot drop were present. Faradic excitability was lost, but the paralyzed muscles responded slowly to strong currents of galvanism. His condition remained about the same for ten days. It then remained stationary for fourteen days, and then slight improvement was noticed in the right arm, left leg, and right leg. The pain was very severe, markedly so at night, requiring one-quarter grain morphia six times a day to control it. The child recovered.

Case IV.—Annie S——, aged twenty months; born in the city; mother American and father Irish. No hereditary history. On June 13, 1895, the child was taken with a chill which recurred every other day for three days. On June 16th consulted Dr. W., who said she had malaria in the worst form. Tuesday evening, June 19th, patient was brought to my office, at that time had projectile vomiting, strabismus, and arching of the spine backward. The temperature was 105° F.; pulse, 90; respiration, 24. The bowels were costive, tongue heavily coated, urine highly colored and stained the linen. The diagnosis of meningitis was made. On June 20th, the condition was unchanged, the child very restless and seemed to be in extreme pain. On June 22d, I noticed loss of power of the right arm. A microscopical examination of blood showed the presence of plasmodia. On June 23d both legs became paralyzed. There was intense pain on passive movements of the limbs, and also on pressure particularly along the course of the nerves. The reflexes were absent and the muscles failed to respond to faradism, and the reactions to galvanism were greatly diminished. The patient's condition remained practically unchanged up to July 16th, then slight motion of the hands was observed. Patient has continued to improve gradually up to the present time, with complete use of both arms, but is still unable to use the legs.

Case V.—Francis G——, aged twenty-two months; born in the city; parents Irish; heredity negative. On May 16, 1895, had a mild attack of scarlet fever. On June 16th, after his usual afternoon sleep, awoke with headache and fever. His temperature was 101° F.; pulse, 110; respiration, 28. The next day the patient was comparatively well. Microscopical examination showed plasmodia. One week later, he was seized with the loss of power of both legs. His mother said she thought the right leg was first involved, and then the left one. She had noticed the loss of power coming on for three or four days. He remained about the same for three weeks, then he began gradually to improve. He has now fair motion of both legs. There was diminished reaction to the galvanic current and slight response to a very strong faradic current.

Case VI.—Thomas O'Brien, aged four years and six months; parents Irish, healthy; no history of intemperance or specific trouble. Youngest but one of eight children, two of whom are dead. One was still-born and the other died of cholera infantum, aged seven months. One child aged eight idiotic. The child in question presents stigmata of degeneration. On June 23d, it complained of appetite and general soreness, and there was vomiting and fever several days. When I was called, there was loss of power of both legs, the temperature was 101° F.; pulse, 120; respiration, 40. The muscles of both legs refused to respond to faradism, but did respond to galvanism. Plasmodium malaria in the blood. There was a loss of the reflexes, and there was foot drop of the left foot. The child slowly improved, and at the present time is able to stand.

Case VII.—John S——, aged twenty months; born in Hartford; parents American, healthy. No specific history or intemperance. Patient youngest of three children. Healthy, except congenital club-foot, which has been corrected by operation. On August 21st he awoke with severe pains at 3 A.M. Mother supposed it due to colic and gave castor-oil and paragoric. I saw the patient three days afterward and found him suffering from loss of power of both legs and right arm. Temperature, 102° F.; pulse, 130; respiration, 33. There was some opisthotonos, and also severe pain on attempting to move the limbs or on lifting the child. There was slight response to faradism, diminished reaction to galvanism. The patient gradually improved and now, nearly six weeks after the disease began, can sit up and has regained the complete use of the right hand. The legs are improving.

Case VIII.—Charles M——, twin child; aged nineteen months; parents American; good family history. Last January, 1895, had acute pneumonia. He is the youngest of six children. One child died of meningitis and complicated otitis media. On August 22d he was taken sick with fever, vomited three or four times during the afternoon and evening. I saw the patient at 9 P.M. His temperature was 102° F.; pulse, 105. He was restless and seemed to be in considerable pain. The mother thought the child suffered most pain on being moved or lifted up. Three or four days later it was noticed that the child could not draw his legs up, and finally both legs became paralyzed. The muscles responded slightly to strong faradic currents and also to galvanism. This patient has not yet recovered.

Case IX.—This case occurred in the practice of Dr. J. W. Wright. The patient was four months and a half old. The disease came on with fever, which varied from 101° to 105° F. The pain in this case began in the trunk on both sides of the body over the ribs.

Touching the skin over this region gave rise to great pain. There was vomiting, the head and back were stiff, and there was persistent insomnia. All the limbs could be moved, but the child would become rigid when he was picked up. The paralysis gradually ascended and finally involved the muscles of deglutition, and the infant died about one month after the beginning of the disease.

Case X.—This case I saw in consultation with Dr. Samuel M. Garlick and Dr. John C. Lynch. The sickness began with fever and vomiting. First one leg and then the other gradually became paralyzed until all motion was completely arrested. There was spontaneous pain in the legs, and increased pain when the limbs were moved. The nerve-trunks were sensitive, the reflexes were absent, and electrical contractility was entirely abolished. The arms were slightly paralyzed and for one day swallowing was interfered with. Like the others, improvement began after several weeks' illness and is still going on, but the child has not by any means recovered yet.

A brief summary of the most important details of these cases is stated in the accompanying table. The average age of the ten cases is two years and three months. Eight out of the ten cases began in the warm weather of June and August. Medin's cases of poliomyelitis all occurred in the summer months, and Saelis[1] states that seventy-five per cent. of his cases of poliomyelitis began between the months of July and October. In three cases both arms and both legs were paralyzed; in two cases both legs and the right arm were affected; in four cases only the legs were implicated, and in one case the intercostal muscles were the primary seat of the paralysis. The fourth and ninth cases presented typical symptoms of meningitis. The fourth case recovered, and the ninth case, who died, was unfortunately not subjected to a post-mortem examination, but it is quite possible that in both these cases the meninges were affected.

None of the physicians in Bridgeport whom I have questioned have ever met cases presenting these clinical features, until this series of cases began last winter. In regard to the diagnosis, I do not see how any other conclusion can be reached than that they were cases of multiple neuritis. The combination of sensory and motor symptoms; the gradual and symmetrical extension of the disease; the local tenderness over the nerve-trunks; the length of time the illness lasted; the gradual and, in some instances, complete recovery of the patients, and the absence of characteristic symptoms of other diseases, makes a diagnosis of neuritis comparatively simple. The succession of cases and their great similarity point to a common cause of origin. In one case Dr. Lynch discovered the grippe bacillus in the blood, and in two other cases the blood showed the characteristic evidences of malaria. But this proves nothing. Grippe and malaria are common among infants, but such a series of cases as these is almost unique. Careful inquiry in towns in the neighborhood of Bridgeport fails to bring to light any similar cases. In Fairfield, about four miles from Bridgeport, there is one case of anterior poliomyelitis. I did not see this case. The diagnosis was made by Dr. Garlick, of Bridgeport, and confirmed by Dr. N. P. Gibney. It is possible that the etiology of this case may be identical with that of the cases just reported.

Table of Cases.

Case.	Age	Disease Began.	Initial Symptoms.	Location of Paralysis.	Improvement Began.	Duration of Disease.	Associated Symptoms.
1	21 mos.	Latter in Dec., 1894.	Not observed.	Both lower limbs; both upper limbs (slightly) and muscles of the back.	Three months.	Four months.	None observed.
2	3½ yrs.	Early in Dec., 1894.	None observed.	Both legs.	Two months.	Three months.	None observed.
3	14 mos.	June 1, 1895.	Fever (101° F.).	Both upper and both lower limbs.	In about one month.	Not known positively, but about three months.	None observed.
4	20 mos.	June 13, 1895.	Chills, fever (105° F.), and vomiting.	Right arm, then both legs.	In about one month.	Recovery not completed at the end of three months and a half.	Strabismus and opisthotonos.
5	22 mos.	June 6, 1895.	Headache and fever.	Right leg, then left leg.	Three weeks.	Three months.	None observed.
6	4½ yrs.	June 23, 1895.	Vomiting and fever (101° F.).	Both legs.	Not known.	Four months.	None observed.
7	20 mos.	Aug. 21, 1895.	Pain and fever (102° F.).	Both legs, then right arm	Not known.	Recovery of arm at end of four months; legs still weak.	None observed.
8	12 mos.	Aug. 22, 1895.	Vomiting and fever (103° F.).	Both legs.	Not begun yet.	It is now five weeks since the disease began and patient is not yet well.	None observed.
9	4⅔ mos.	Aug., 1895.	Fever (105° F.).	Intercostal muscles and muscles of deglutition.	No improvement.	Died in one month.	Vomiting and stiffness of the back; rigidity of all the muscles when child was lifted.
10	4½ yrs.	Aug., 1895.	Vomiting and fever.	Both legs, upper extremities slightly.	In about six weeks.	Not yet recovered.	None observed.

THE LIMITS OF DISEASES OF THE RECTUM AS A SPECIALTY.

By CHARLES B. KELSEY, M.D.,

NEW YORK.

For two years now we have had, in America, a quarterly journal devoted chiefly to diseases of the rectum, but not exclusively. During the last meeting of the American Medical Association, an effort was made to organize a Society of Rectal Surgeons—whether successful or not I do not know.

I believe I may venture to say, without fear of successful contradiction, that no man has ever attained any great prominence in surgery who has confined himself absolutely to diseases of the rectum, to the exclusion of correlated lines of work and study.

Van Buren, up to the time of his death, was America's greatest authority on the rectum, but the rectum was never his "specialty." Allingham is, perhaps, the best living English authority in the same field, but he, although like Van Buren the author of a standard text-book on diseases of the rectum, has always been a general surgeon.

These facts lead one interested to consider the scope of this particular branch of surgery, and to question seriously whether the surgery of the rectum alone can ever properly take its place among the well-established specialties.

The simple fact is that the lower four inches of the alimentary canal do not afford sufficient scope for the mental activity of a man of active mind and surgical tendencies. To such an one, after a time, piles, fissures, fistulæ, and pruritus become simply routine practice, affording very little field for original thought.

Ten or twenty times a year he is called upon to do real surgery—capital surgery. Colotomy interests him, both in deciding when it should be done and in its

[1] Nervous Diseases of Children.

actual performance; and an extirpation calls forth all his powers. There is probably to-day no more difficult surgical operation than extirpation of the rectum, and there is little question but that the man who can do that well is more than equal to the average demands made upon the technical skill and nerve of the general surgeon. But the man who can do extirpations and colotomies will not be content to pass his life in discussing whether the ligature or the clamp and cautery is the better operation for piles; and the man who cannot do these operations when called upon, has little claim to the reputation of a surgeon, though he may be a very successful practitioner.

The fact is that piles are only piles even after a man has become familiar with them and knows best how to cure them; and so it is with fistula, fissure, and pruritus. The specialist will do better in all these cases than the general practitioner; he will know better when to operate and how to operate; and will get better results and less failures: but his work will still be confined in the main to minor surgery, and unless he can go a long way outside of and beyond these cases, he sinks sooner or later into a groove and must lose his place and his interest in the great surgical advances of the day.

On the other hand, the man who can successfully treat all the cases that are sent to the office of a specialist as cases of diseases of the rectum, must be familiar with a very wide range of work, and must be ready at any moment to step into the field of gynecology, abdominal, and genito-urinary surgery, and compete on equal terms with those who make a specialty of these lines of work; otherwise he must transfer a certain large proportion of his cases to them for treatment in the first place.

Outside of the plain cases of piles, fistula, pruritus, etc., about one half of all the cases that come to my own office are cases complaining of the one symptom of painful or irregular defecation, with or without some palpable disease of the rectum; and I do not hesitate to say that these are the cases that have really exercised my thought and surgical ability in a constantly increasing proportion for years.

Painful and irregular defecation! What may this not mean? What may be necessary to relieve it? It may mean anything from a fissure to uterine fibroids, from constipation to intestinal obstruction by a band in the abdomen; and for its cure almost any operation in rectal, abdominal, gynecological, or genito-urinary surgery may be necessary. It is just here that the surgeon may discover the great difference between curing a patient and curing a case of piles by operating on the manifest disease, and finding his patient no better after the operation than before.

In women one of the first things to learn is to make a complete and satisfactory examination of the pelvic organs, either with one finger in the rectum or by conjoined manipulation per rectum instead of per vaginam. In all of these cases of painful or irregular defecation in woman which come to a rectal specialist, an examination per rectum is expected, and I do not hesitate to say that when no mechanical or painful obstacle to a complete examination is found, a more thorough and satisfactory examination of the pelvic viscera may be made while the finger of the surgeon is still in the rectum, than by withdrawing it, changing the position of the patient, and introducing the finger into the vagina. To the man with a long finger it is simply surprising how high into the pelvis he can reach per rectum, when there is no vaginal vault to limit his digital exploration. I would not seem to argue for the substitution of rectal for vaginal digital examination—as the rule—in uterine cases, but would call attention to the fact that, when the finger has been inserted into the rectum for an examination of that canal, there is no reason to withdraw it and make a vaginal examination to find out the condition of the tubes, ovaries, ligaments, or uterus. To discover the condition of the cervix may require a vaginal examination, and it may also be impossible to tell which end of the pear-shaped uterus is pressing upon the rectum with only the finger in that canal, and without conjoined touch; but all other conditions may be made out at least as well, if not better, by the finger in the rectum as by the finger in the vagina. Every gynecologist knows this fact, and I state it now simply from the standpoint of one who for years has been in the habit of making his pelvic examinations in this way instead of in the usual way, simply because his patients come to him for a rectal, and not necessarily for a vaginal, examination, and because he seldom finds it necessary to interrogate both canals. The gynecologist proceeds merely in a reverse order, but the result reached is the same in both cases.

Ever since the country began to be flooded with "rectal specialists," it has been a standing joke whether a case of recto-vaginal fistula, or of laceration through the sphincters, belonged properly to the gynecologist or the rectal specialist. The answer, I conceive, is that it belongs to the man who by skill in technique and experience is best fitted to do the necessary operation. To whom does a case like the following, which was cured at my clinic last winter, belong? An unmarried woman, aged thirty-eight, had for ten years been living in sanitariums for difficulty in defecation, generally considered as chronic constipation. She was a miserable wreck, and most of her time confined to her bed. Once or twice a week she had a movement of the bowels by laxatives and enemata, and as a result of the consequent exhaustion, generally passed the balance of her time in her room. The mere introduction of a finger through the anus showed that the mechanical obstruction to defecation came from a retroverted movable uterus, closing the rectal canal like a ball-valve when any pressure was brought to bear upon it from above. A simple ventral fixation has made the woman a new creature.

My point is that if such a case as this does not come properly within the range of rectal surgery, then the rectum is no proper specialty for any surgeon; but that if it does, and if the so-called rectal specialist is prepared to treat all the cases that come to him complaining of symptoms referable directly to the rectum, then is his specialty no less a proper one than gynecology, and perhaps rather a larger, from the fact that his cases will include as many men as women.

This case is merely mentioned as one of a type. Every gynecologist knows how many of his cases of proctocele, laceration of the cervix or perineum, prolapsus of the uterus, misplaced and bound-down ovaries, uterine fibroids, and enlargement of the uterus—in fact how much of all his gynecology—comes to him complaining primarily of some trouble with the rectum. The same class of cases come as often to the rectal specialist for the same thing. Shall the gynecologist send his cases to the rectal specialist because they have pain in the rectum? If so he curtails his specialty at least one-half. On the other hand, shall the rectal specialist send the same cases to the gynecologist because they do not happen to have either piles or fissure? If so he becomes merely a "pile-doctor" and is little of a surgeon, nor is his specialty worthy the name, for all that he does can be done as well, with a little practice, by anybody else.

The question is larger than this, however, for not only must the rectal specialist be prepared to do the minor surgery of the gynecologist, but also the major. For example, take the following case, also cured at my clinic, last winter. A young married woman tells me that for twelve years she has had occasional attacks of severe pelvic pain, confining her to bed for a longer or shorter time, and that each has been followed by a free discharge of pus from the rectum, after which the severity of the suffering decreased, the discharge gradu-

ally diminished, and she sank back into her usual state of semi-invalidism with all the symptoms common to cases of old pelvic trouble. The case was sent to me by her physician, as one of abscess of the rectum, but examination revealed the source of the pus to be an old pelvic inflammation which had filled the floor of the pelvis with exudate, and which contained two abscess cavities. Under ether the smaller of these was punctured through the rectum, the opening thus made dilated with forceps introduced while closed and removed while open, and the cavity stuffed with iodoform gauze. After recovery from this a laparotomy was done for the removal of tubes and ovaries, or at least for the exploration and proper treatment of the second pus cavity, by whatever plan might seem indicated after opening the abdomen. It was found that all that could be hoped for by this method was the evacuating of the abscess into the free peritoneum, with drainage through the abdominal incision, and this was abandoned, the abdomen closed, and the second abscess treated like the first by free incision, and drainage into the rectum. The result was good, and although the patient will never be entirely free from symptoms caused by the old trouble, she has been relieved of her chief cause of suffering.

This certainly is gynecology, but is it not as much rectal surgery? Is the rectal specialist to say to a case like this, "If the pus came from an abscess outside of the pelvis or just below the peritoneum, it would be within my specialty; but coming from an inch or so higher, you should apply to somebody else for relief?" Is a perityphlitic abscess pressing upon the rectum and causing constant tenesmus to be shunned, while one originating in an inflammation of the peri-rectal cellular tissue high up and causing the same symptoms is to be incised? Is intestinal obstruction due to stricture within reach of the anus to be operated upon by laparotomy, while exactly the same condition due to stricture just beyond the reach of the finger in the rectum, but plainly within reach by deep palpation of the left side of the pelvis, and requiring exactly the same operation, is to be considered general surgery? The answer rests entirely with the men who make diseases of the rectum a specialty.

Reviewing the work at my own clinic for the past year, I find the usual number of cases of disease confined solely to the lower four inches of the alimentary canal—hæmorrhoids, fissure, fistula, etc. These cases are always interesting; they are the ones the average student comes to study; and I hold that the man who has devoted his chief study to them is better able to treat them successfully than the general surgeon. But it is also conceivable that after twenty years a man may become wearied of any particular routine of minor surgery, and may consign nine-tenths of all the current literature concerning it to the waste-basket without reading.

But in addition to these cases I find also laparotomies for pelvic trouble in women, cases of acute intestinal obstruction in men, perityphlitis, closure of fecal fistulæ both by suture and Murphy's button, intussusception, cancer of the prostate, abscess of the prostate, the usual lesser gynæcological operations, extirpations of the rectum, colotomies, and finally a case demanding Cæsarian section on account of what was supposed to be cancer of the rectum when it was sent to me, but what was also cancer of the uterus and vagina complicated by labor. This case was kindly operated upon by my friend Dr. Edebohls. The others were operated upon by myself. I do not speak of them in detail, because there was nothing remarkable about them except that one and all were sent to me as cases of trouble with the rectum, and almost all of them by fellow-practitioners; and in all of them one of two prominent symptoms was present—either pain in the rectum or difficult and irregular defecation, which had caused them to be considered as cases of rectal disease.

There has never been any question as to the propriety or the status of gynecology as a specialty, because the gynecologist has never considered and taught that his field of work was confined to the vagina, and that everything outside that canal should go to the man best fitted for abdominal surgery. And yet this is exactly the status of the rectal specialist, both in his own estimation and consequently in that of the medical profession at large and the public.

Our leading gynecologists have always been surgeons—bold, original, great surgeons. Men confining themselves to a certain line of work, it is true, but not limiting that work solely to the vagina, and capable of curing the patients who come to them. If the men who are constantly starting out as rectal specialists are willing to take the same broad view, and fit themselves by years of surgical training to live up to it in practice, then may rectal surgery as a specialty hope for a firm and honorable position in the future. But if to the coming generation as to the past, the rectal specialist is to be either an advertising quack, or a man who has taken a six weeks' special course at a post-graduate medical college, has seen a few operations for piles and fistula, and imagines himself thus fitted for his life-work as a surgeon; then is the future of the specialty not difficult to foresee.

ENDOCARDITIS IN COUNTRY PRACTICE.

By JAMES E. FREE, M.D.,

BILLINGS, MONT.

A TYPHOID-FEVER patient began to exhibit an irregular temperature after the fastigium. One day the thermometer registered 97.6°, next day 103°, another day 100° F. Profuse perspirations came on at irregular intervals, when no acetanilide had been administered. At the commencement of the fever this antipyretic had been used, and the hope was indulged that these symptoms were due to the cumulative action of the drug. An odd pulse, exhaustion, and dyspnœa supervened. Gradually the symptoms of enteric fever faded, tenderness abated, but the patient did not convalesce. He grew worse. There was a tricuspid murmur and a sort of blowing systolic thrill. Death ended the painful suspense, and at the autopsy there was found perforation of the auricular septum. There was no valvular disease on the left side of the heart. The perforation was large enough to admit the end of an ordinary lead-pencil. Around it was a collar of fibrin, which was the seat of a swarm of micrococci, the streptococcus pyogenes aureus. Injection of cultures of this microbe into a prairie dog produced no effect. Following out the ideas and directions of Wyssokovitch, a fine probe was passed into the carotid artery, and an effort made to abrade the aortic valves. Several dogs died from the pseudo-scientific handling, but one lived to develop symptoms of ulcerative endocarditis. Vegetations were found on all the valves of the heart. Injections of the same material into the intestinal canal and peritoneum, after wounding with the probe, were without results where the dogs lived more than twenty-four hours.

The typhoid process in the case mentioned brought to light a lesion of the tricuspid valve, perhaps, which had been unsuspected. Insufficiency and venous engorgement made their *debut*, vegetations developed, and an embolus was found located in the brain, in front of the fissure of Sylvius, which was the explanation of the difficulty of speech noticed for several days prior to death. This embolus was the resting-place of micrococci. An inflammatory process was lighted up by the products of the typhoid poison in the auricular septum and in the brain. Necrosis of tissue resulted. If the circulation could be carried on around these

dead spots, and the poisonous material could be encysted, nothing more serious than a temporary paresis of function might result, and the disappearance of the typhoid fever might have saved the body from further attack. The perforation of the septum permitted a side-tracking of some of the blood. Poisoned by the endocarditis, the blood did not nourish the tissues properly. Foreign substances demanded too much attention from the excretory organs, and the usual products of waste were not handled in a workmanlike manner. Nature, goaded to desperation, made heroic efforts to fulfil her contract to get rid of unnecessary material by vicarious perspirations. With every portion of the body invaded by the septic matter, the problem of getting rid of it was a serious one. What method was used to supply the enormous waste of fluid-constituents, further than thirst, is not known. Transfusion of normal saline solution might have been of value, but was not tried. Not having the true Athenian thirst for new things, in emergencies, is sometimes a misfortune to the physician, and a calamity to the patient. An artificial serum in such a case would at least be aseptic. The sweat did not remedy the difficulty. It was a gallant effort, but barren of results. An examination of the sweat would perhaps have shown some of the germs cleverly entrapped and forced out of the body. How the glands managed to make their captures would be an interesting study. Investigators tell of marvellous motions and selective actions in protoplasm, which it would be worth while to recognize, if possible, in country practice. Some of the ptomaines would be forced out of the circulation also. Ptomaines would not likely have an elective affinity for the solid constituents of the blood. From its ravages in the body it would seem as if it could penetrate any tissue in company with serum—for instance, into joints, peritoneal cavity, etc. The product of the sweat-glands may be infective in some disease.

The heart and uterus are two organs which can be seriously disabled without showing the red flag of pain. This cannot be from lack of nerve-supply, either direct or indirect, but must be a provision of nature with the object in view of pensioning these mainsprings of life.

The death of a patient is regarded as an intervention of Providence. Any other way of looking at the matter would consign the inexperienced medical man to a hell on earth, or, at least, to purgatory. Experience stimulates the hypothesis-centre and develops the thinker. In medicine we must think ourselves out of purgatory.

Most cases of tricuspid diseases are said to be congenital. It is easy to fall back on congenital excuses when the devil and the deep sea are on either hand. Cases of cancer and tuberculosis may be due to preventable hygienic causes. A woman might be called upon to bear about in her body wrongs due to having a sexual hog for a husband. Prolific childbearing wears out the uterine tissue, on the same principle that makes the gun-barrel wear out. Orgasm in the male may be like the firing of a rocket. The stick is coming down after the explosion before the female can attain the climax. Specific infection could be imagined to have some relation to orgasm and the ejaculatory act to absorption. The presence of seminal fluid upon the genitalia, when satisfaction has not been complete, may have an irritating effect on the mucous membrane. Heart-action can be irritable from ungratified sexual desire, just as it may be from the use of tobacco, loss of sleep, fatigue, and anxiety. The morbid habit once established takes care of itself. Chronic congestion, unhealthful function, permanent disability, abortive nerve force, and the birth of pathological cells, are steps in degeneration. A hunchback is nature's effort to make a correct vertebrate. Cancer and tuberculosis result from nature's failure to score one hundred per cent. If the healthy young woman, who marries and breaks down in middle life, and develops carcinoma of the genital organs at the climacteric, had remained single, worn bloomers, and cultivated her physical powers on a bicycle, she would have escaped the gynecologist. There is physiology in the new woman's knickerbockers. People tainted with tuberculosis who are in the habit of developing the air-cells of the lungs are laying up treasure for the future. Normal demand for oxygen is a good barometer to measure the demand and supply of fat. The inherited vice may not be in an organ, but depend upon a poorly developed nervous system, which, when stimulated, does not give the Macedonian cry to the passive parts of the body. What an organ does not do, may be from a lack of knowledge. It must be taught, developed, strengthened. Give it a crutch, or open its blind eyes, as the case may be. Club-foot, twins, red hair, spinal curvature, are evidences of abnormal tendency; so is spina bifida, or open foramen ovale. One man may give a monstrosity a start in life, another may write a French novel.

When a patient, who has had a reasonably healthy heart before an attack of typhoid fever, begins during convalescence to manifest a set of foreign symptoms, grafted on the original complaint, there is not a relapse, but a new birth. Pallor, diaphoresis, shallow and rapid respiration, Cheyne-Stokes breathing, murmurs behind the ensiform cartilage, and to the left, which die out toward the apex, jugular congestion, and venous pulse, are omens of evil. Tricuspid disease produces this picture. In the present case how are they explained? The blood-stream first strikes the right heart. It carries with it the product of the typhoid bacillus toward the nervous centres. Delirium of fever is one evidence of this intoxication, and the mental unsoundness and general systemic unsteadiness is further proof of the effects of the toxin. Deafness, insanity, and baldness are so many display advertisements.

If the patient, years before, had rheumatism, he need not be aware of the fact that it involved and crippled the heart. Carrying an insurance policy is not, nowadays, a certificate to the absence of the trademark of rheumatism, a valvular vaccination. The lactic acid, or whatever the deposit may be composed of, is just as likely to accumulate on the valves of the heart as around the joints.

There is a mechanical explanation for this result. Nature had a hard problem to solve in making a passable bridge for the soft structures over the jointed bones. The circulation does go over these bridges; but sometimes it requires the sacrifice of tremendous energy on the part of the heart. There is muscular force, often inevitably applied to the vessels and tissues, which makes some of their contents exude. It is not normal exosmose and endosmose, but the effect of the pressure of extension and flexion; abduction and adduction. The tricuspid valve, let us say, is fed internally and externally with rheumatoid blood. Constant systole interferes with nutrition. Motion and pressure cause an exudate. Once the process is lighted up, no winged angel of rest ever comes to its relief. The process is destined to extend and become chronic. Nature must cut her coat according to her cloth. An adjustment to surroundings takes place. Such is the condition of affairs when the typhoid poison is taken aboard. Before this time the only sign of inflammation of the tricuspid cusps visible would show themselves when violent exercise is taken. Sudden demands on the heart's reserve force would cause a circulatory commotion. It could not respond with vigor; shortness of breath, faintness, fluttering, would evidence an atheromatous degeneration. Sleeping on the left side is usually impossible in endocarditis. The liver, stomach, and lungs, all jumping up and down over the heart, would cause irregular blood-supply to the brain, which would be manifested by troublesome

dreams, nightmare, or sense of discomfort sharp enough to rouse the patient, or at least to roll him over.

Systemic typhoid infection would, of course, result in high temperature. That would mean a stimulated heart. The fluid it was engaged in pumping to every part of the body would be abnormally heated. It would have a deleterious action on cell elements. Rapid combustion of tissues would be going on. The candle is burning at both ends. The choicest protoplasm would be crippled or killed. The survival of the fittest is the rule in health. Tissues select the perfect article.

What is only half-baked is passed by. Any kind of a supply is thankfully received in diseases which interfere with the manufacturing process. To avoid starvation nature drops her standard.

The heart draws its sustenance from the blood *en passant*. A perforated auricular septum would lead to a mixed blood-current. Each contraction would send some of the material, destined to be excreted by the lungs, into the heart muscles. Here is a factor in endocarditis, because the enemy has obtained an entrance into the very citadel. Then the starved blood adds fuel to the flame, for failure to nourish would have its evil influences multiplied by matter fit only for excretion, to say nothing of possible putrefaction. The micrococci and ptomaines are still other elements of danger, likewise the rheumatic affection.

What measures can be adopted to relieve such a heavily handicapped heart? Occasionally quinine, sulpho-carbolate of soda, or some antiseptic may postpone the fatal termination. A heart often carries much poisonous excretory matter through the circulatory system. Witness the puerperal state, which is in itself a favorite stamping ground of endocarditis. Deposit of fibrin is another result of blood degeneration. The tricuspid insufficiency permits longer contact with valvular surface than health makes provision for. One of the laws of the circulation is that the blood must circulate. Blood brought to a standstill is liable to coagulate, deposit fibrin.

The condition of the spleen in endocarditis is an anomaly to a country practitioner. It becomes rapidly enlarged; circulation is interfered with. The function of the spleen seems to be to receive a large quantity of blood, for which no visible return is made to the body. It may be the pressure regulator in health and the garbage-box in disease. Enormous increase of function causes hypertrophy. The spleen is unprovided with an apparatus to manufacture a secretion. Otherwise there would be provision made to neutralize poisonous material sent to it. The virulence of the disease, probably, has some relation to the extent of the hypertrophic dilatation. Here the proteids of the blood not being required to elaborate an organic product are appropriated for food by the micro-organisms and ferments. The ulcerative endocarditis in this instance was a septicæmia, showing itself in the heart, because there it found a joint in nature's armor.

The Increase of Crime in France.—Professor Joly declares that crime is rapidly on the increase in France. In 1860 the number of minors brought up for trial was 5,400, whereas in 1891 their number exceeded 7,000. In 1892 the number of habitual criminals known to the police exceeded 100,000. The offences which escape punishment are also constantly on the increase. In 1891 there were 83,000 offences which escaped punishment, and in 1892, 89,000. With regard to the nature of the unpunished offences, M. Joly says that first of all come robberies, ninety per cent. of which were unpunished in 1890. Then follow criminal attempts against trains and railways, thefts, counterfeiting, arson, the infliction of personal injury by stabbing, etc., and infanticide.

Progress of Medical Science.

The Relation Between Serous Pleurisy and Tuberculosis.—Professor Eichhorst, of Zurich, at the annual meeting of the Swiss Medical Association, remarked that in a certain number of cases the relation between serous pleurisy and tuberculosis should not be overlooked, because patients cured of serous pleurisy run a great risk of becoming tuberculous later on. Bass has found that at the end of five years only thirty-three per cent. of such patients were still living. However, tuberculous areas are not always found at autopsies, and the two diseases are so frequent that it is often difficult to say which of them was the primary affection. For a long time he has submitted the pleuritic effusion to microscopical examination, and when bacilli were present the diagnosis is not doubtful; if they are not, however, one has not the right to exclude tuberculous infection, but should then have recourse to experiments. In a series of such experiments he injected with a Pravaz syringe fifteen minims of effusion into the peritoneal cavities of eleven guinea-pigs; ten of these remained perfectly healthy, while one only showed a tuberculous infection of the abdominal lymphatic glands. These results correspond to the observations of other authors. He thought that perhaps the volume injected was insufficient to insure the invariable presence of bacilli in the injected dose. He therefore had a syringe made, by means of which he injected one-half fluid ounce, and the results were entirely changed; twenty-three such injections of serous effusion to as many guinea-pigs infected fifteen, or sixty-five per cent. Five of the patients, whose pleuritic effusions have been used in these experiments and infected the animals with tuberculosis, returned to his service later on with tuberculosis. It must, therefore, be admitted that two-thirds of the cases of serous pleurisy are, in fact, tuberculous, and that recoveries in most of the cases are but conditional. The infection originates but rarely in the lungs, generally in the tracheo-bronchial glands. By the same method he found that in twenty-seven cases of serous pericarditis, eight, or twenty-nine per cent., were of tuberculous origin. It is probably the same with other serous affections, and those which are called spontaneous are without doubt very often infectious tuberculous cases. In the discussion which followed, M. de Cérenville, of Lausanne, expressed the opinion that tuberculous pleurisy presented differential characteristic signs: hyperthermia was much less, often not exceeding 100.4° F., and the effusion was more quickly produced. On the other hand, it sometimes happens that, even if the pleurisy were tuberculous, tuberculosis never develops. He considered the prognosis of Dr. Eichhorst as perhaps a little too gloomy. Dr. Socin, of Bâle, believed that in patients stricken with surgical tuberculosis, a history of serous pleurisy may be often found; in several hundred cases where no pulmonary symptoms could be proved, eight per cent. had had anterior serous pleurisy, and often many years had elapsed before the appearance of surgical tuberculosis. This form of the disease seems to develop sooner than pulmonary tuberculosis.—*Correspondenz-Blatt für Schweizer Aerzte.*

Alkalinity of the Blood and Infection.—Dr. Fodor records a number of experiments showing the influence of the alkalinity of the blood on diseases produced by micro organisms. Four series of experiments on animals are first reported which show clearly that, by the administration of alkalies (sodium bicarbonate by the mouth or by subcutaneous injection), the power of resistance against infection with cultures of anthrax bacilli is greatly increased. The normal alkalinity of the blood was determined by the examination of seventy-

six healthy rabbits, and four experiments are reported showing the increase in the alkalinity of the blood which occurs after the administration of sodium bicarbonate. The author then records the results of a large number of observations on the alkalinity of the blood in rabbits after infection with the bacilli of anthrax, cholera, typhoid fever, tuberculosis, and erysipelas. These observations show that in the living organism, after infection with certain bacilli, there is first an increase of the alkalinity of the blood and then a diminution of the same, more or less. If the infection is fatal, the diminution of the alkalinity is marked and progressive; if not fatal, the diminution is slight, and is followed by an increase of the same, in consequence of which the alkalinity of the blood becomes permanently higher than before the infection. Thus there exists a connection between the pathological action of certain bacteria and the alkalinity of the blood. Those rabbits having the greater alkalinity of the blood, as well as those in which the alkalinity of the blood is increased to a greater extent after infection, have greater power of resistance against certain infectious organisms (anthrax bacilli) than the rabbits in which the alkalinity of the blood is less. It appears, therefore, that the degree of alkalinity of the blood, as well as the power of the organism to increase this alkalinity with corresponding intensity after infection, is of essential influence upon immunity.—*Centralblatt für Bakteriologie.*

Suture of the Heart.—Dr. Del Vecchio, as the results of experiments on dogs, concludes that suture of the heart in cases of wound is possible. (*The British Medical Journal.*) At the Congress in Rome, he showed a dog whose left ventricle had been wounded in two places (one penetrating into the ventricular cavity) forty days previously. The author had sutured the two wounds with catgut and silk, and the dog appeared at the time of exhibition to be in perfect health; it was killed on the forty-second day after suture. The apex of the heart was found firmly adherent to the thoracic parietes. Both wounds were firmly healed, and in one the scar could be seen on the endocardium, proving the penetration. An interrupted suture was found to answer better than a double continuous suture, as necrosis generally followed the use of the latter. Dogs present a special difficulty in these experiments, inasmuch as one has to open the pleural cavity to reach the heart. In cases of wound of the human heart Del Vecchio proposes the following operative procedure: Two longitudinal incisions to be made from the lower border of the third rib to the upper border of the seventh, the one along the lower margin of the sternum, the other 5 to 10 mm. inside the nipple line; these incisions to be joined by a horizontal one made in the fourth intercostal space. The fourth, fifth, and sixth ribs and cartilages to be divided, and the outer cutaneous flaps turned up. The pleura to be separated and pushed on one side with the finger, exposing the pericardium, which is incised longitudinally. The wound is then united by interrupted sutures. Death in cases of wound of the heart seems to be chiefly due to pressure from the blood effused into the pericardial sac. Since this pressure is also a check to further hemorrhage, it is a nice question whether operative interference may not do more harm than good as far as the hemorrhage is concerned. Paracentesis may, however, be practised, to be followed, if necessary, by free incision of the pericardium. Fischer collected 376 cases of heart wound with a mortality (two to three minutes after injury) of twenty per cent. Death has been noted in periods varying from a few seconds to nine months after the injury.

Mechanism and Treatment of Complete Procidentia Uteri.—Dr. Grace Peckham-Murray, of this city, has presented in clear and comprehensive outline all definite information upon this subject developed in modern thought and experience. In regard to mechanism, the following summary and conclusions are given: 1. The pelvic floor has little to do in causing complete procidentia. The proofs of this are: It occurs in children, in young women, without so much as destroying the hymen. It is rarely, if ever, seen in cases of complete laceration of the perineum. 2. The vagina may have both an active and a passive action in the mechanism of descent. If the band of levator and muscles which surrounds its tube in the lower third is lacerated, and its lower portion is still held by the rectum, the muscles surrounding it act with powerful traction to bring down the posterior wall of the rectum; the traction, with traction of a like nature on the part of the bladder, causes a prolapse of the vagina alone if confined to the lower portion, but when it involves the upper portion there is dragging of the neck of the uterus, which, if the uterine supports are not lax, results in the great hypertrophy and lengthening of the neck which simulates complete procidentia. If the uterine ligaments are relaxed, the uterus will follow sooner or later. The softening and relaxing of the connective tissue during pregnancy make the detachment of the utero- and vagino-vesical attachments an easy matter, rendering and predisposing to prolapsus. The uterus can press down the vagina before it, making the vagina a passive agent in cases of rapid labor when the os is not dilated and the uterus descends toward the vulva with the expulsive force of the third stage; also when it is heavy from lack of involution, as when the patient gets up too soon after confinement, or when subinvolution does not take place. The vagina affords support to the uterus by its attachment to its neck; but it is a question whether it acts as a supporting column in the sense expressed by some writers, and whether the angle it forms with the uterus has a supporting value. Clinical experience shows many cases in which the walls of the vagina bulge and are prolapsed, in which the uterus retains its position, and also many cases of congenital retro-displacements, in which the uterus remains at its normal plane. 3. The action of the ligaments is more passive than active. They are naturally lax, owing to the necessity of uterine movements and uterine growth in pregnancy. If traction occurs from below, and the ligaments are lax, descent of the uterus is more facile. The importance of the utero-sacral ligaments is exaggerated by most writers. The appearance of the ligaments in cases of prolapse does not show their action; the stretching, breaking, elongating is the result of the displacement, not the cause. In this respect experiments on the cadaver may be trusted for displacements of the uterus on the normal plane, but not in descent. 4. The greatest factor to be considered in uterine displacements, and the least understood, is intra-abdominal pressure. In the normal state there is such an adjustment of this that the uterus is easily maintained in position, with little aid from ligaments, vagina, or perineum, in spite of weight of abdominal viscera, or the great and constantly recurring force of expulsive effort. When this equation is disturbed descent becomes easy. The maintenance of the uterus in its normal position is more a matter of physico dynamics than is generally supposed. 5. Owing to a laxity of tissues, inherited or the result of disease or subinvolution, there may be a greater predisposition to procidentia uteri. The loss of fat has nothing to do with it, cases occurring very frequently in women with great accumulation of abdominal and other fat. The shape and inclination of the pelvis may also favor this condition. Some writers think that too much is attributed to pregnancy as an etiological factor. Owing to its relaxing effects on all the ligaments and connective tissues, the heavy uterus of subinvolution, and insufficient care, it can, in the author's estimation, be held responsible for ninety per cent. of the cases.

The treatment resolves itself into two classes—non-surgical treatment, which includes therapeutics, support,

and massage ; and surgical operations. The summary of treatment is as follows : 1. Restore the uterus to place. If sensitive and eroded, use antiseptic tampons of cotton. If the tissues are soft and relaxed, astringents, as tannin and iodine, should be used. Heal the erosions with five per cent. solution of nitrate of silver. If the tissues are hardened by long exposure outside the vagina, astringents should not be used, but vaseline or oily preparations employed. 2. Massage has not been found of much benefit in these cases. If it is to be of use, the improvement will be immediate. It will not avail in cases where there is a congenital tendency to displacements, but in those in which involution has not gone on to completion, or there is trouble with the circulation, massage and gymnastics may be of service. 3. Pessaries which are well fitting may relieve the patient greatly, and should be used as soon as possible, as they hold the uterus better in place than any tampon. Many patients are made very comfortable with pessaries, which they learn to take care of themselves, and some cases have been cured after a time by the support of the organ ; the congestion has been relieved, the tissues have become normal, and the ligaments have regained their tonicity. 4. The surgical procedures have, from the earliest times, been without number. Not much reliance has been placed upon those which simply narrow the vaginal outlet. The most serviceable of all is Le Fort's operation, not as popular among American surgeons as it deserves to be, owing to its supposed interference with childbirth. French physicians say it is no obstruction. The partition which this operation forms, practically making two vaginæ, becomes thinned and attenuated in labor, and at the last moment can be cut. The cases operated upon by the author proved successful, the good results remaining after a lapse of years. For complete procidentia uteri many surgeons perform high amputation of the cervix ; and, if the case demands it, combine with it some of the operations for narrowing the vagina. The shortening of the round ligaments is generally conceded at the present time as not applicable to the cure of complete procidentia, and many believe that the day is not far distant when it will cease to be considered. Conservative surgeons regard ventro-fixation and hysterectomy as measures too radical to be employed generally, and the success of vaginal fixation, as recommended by Schücking and many others who have followed his method, has not been established. Gynecologists will look for the results of the new and simple procedure recommended by Freund with the greatest interest. This consists in encircling the vagina with silver-wire sutures, quilted in at equal distances, beginning near the cervix, and restoring the uterus to place in much the same way as in Le Fort's operation.

Displacements of the Liver.—Dr. Graham states that within certain limits the liver is freely movable, and that in women with pendulous abdomens it may descend one inch below its normal position without causing any unpleasant symptoms. Cases with marked undoubted displacement of the liver are rare, however (*The American Journal of the Medical Sciences*).

A short account of the literature on the subject is given, also a representation of Heister's remarkable case, published in 1754, in which the normal transverse diameter of the liver had become practically vertical. In 1892 Faure published fifty-four cases collected from the literature. Since then several others have been reported, and these have been collected, making a total of seventy cases, which are given in tabulated form.

The author is of the opinion that the recorded cases might be divided into two classes : 1, The wanderleber of the Germans, fegato ambulante of the Italians, floating liver, a condition found in women with pendulous abdomens, usually after frequent childbearing ; 2, cases in both males and females in which the causes of displacement are varied.

Floating liver is a comparatively rare condition, any marked degree of mobility of this organ being prevented by the number and strength of its ligaments. The ligaments are in all probability of sufficient strength to carry the full weight of the liver without the aid of the abdominal wall. This the writer has demonstrated in the majority of a series of experiments on the cadaver, the details of which are given. The strength of the ligaments of the liver are further shown by the results of several experiments which Faure conducted, in which he found that it took a weight twenty-five times that of the liver in order to rupture them.

Graham reports three cases which occurred in his practice, one of which illustrates well the great relief to the symptoms produced by hepatic displacement by the use of a properly applied abdominal support. In this case relative hepatic dulness did not begin till the seventh rib in the mammillary line was reached, and the lower border of the liver was distinctly palpable two inches below the umbilicus. The patient complained of a weight in the abdomen, dyspnœa, and was very cyanotic. These symptoms were relieved by an abdominal bandage, always returning whenever it was removed.

Winkler is quoted as giving the following causes for hepatic displacement, one acting in succession to the other : 1, Pregnancy of full term ; 2, pendulous abdomen ; 3, hepar pendens ; 4, stretching of the ligaments ; 5, tearing and twisting of the suspensory ligaments. Rapid emaciation and disappearance of the abdominal fat are considered by Landau as causes of displacement. Other etiological factors which have been mentioned are coughing, sneezing, vomiting, and tight lacing, the latter, however, tending more to produce a change in form rather than a change in position of the organ. Repeated pregnancies in women, producing pendulous abdomens, seem to be an important etiological factor. Of the cases recorded a synopsis shows that males and females are affected in the proportion of one to four. Displacement comes on later in life in females than in males.

The symptoms usually complained of by patients are a feeling of weight in the abdomen and a dull pain on exertion. A few instances have been recorded with a sudden onset of symptoms, which were those practically of shock. Other symptoms which have been noted are dyspnœa, cyanosis, nausea, vomiting, and, in some cases, jaundice. An examination of the abdomen should show the presence of a tumor, which can be easily felt and which resembles the liver in size, shape, and consistence. There should be tympanitic resonance over the area where hepatic dulness normally exists.

The conditions for which a floating liver is most likely to be mistaken are typhlitis, ovarian cyst, movable right kidney, and hydronephrosis. The former condition should be distinguished by the following points : 1, The tumor having an upper smooth surface and a sharply defined anterior border and notch ; 2, tympanitic resonance over the normal area of liver-dulness ; 3, possibility of partial or complete replacement, when dulness will be found in the normal area. Greatest relief to the symptoms seems to have been obtained by the use of a properly applied abdominal support.

The Woman's Medical Institute in St. Petersburg.—Professor von Anrep, formerly Director of the Russian Imperial Institute of Experimental Medicine, has been appointed Director of the Woman's Medical Institute, to be opened within a few months in St. Petersburg. He is at present the Government representative on the sanitary commission of the Pan-Slavic Exposition to be held in Nijni Novgorod in 1896.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 9, 1895.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE report of Surgeon-General Tryon of the navy, just submitted to the Secretary of the Navy, contains many important suggestions bearing upon the increase of the efficiency of the Medical Department and the consequent benefit of the sick and wounded of the service. With a zeal for necessary improvements which cannot be too highly commended, the chief medical officer of the navy has lost no opportunity for pressing the claims of needy ones under his immediate supervision. The recommendation to improve the general sanitation and ventilation of our war-ships is timely and necessary. Up to the present time so much attention has been given to the increase of the purely fighting resources of the ships that all other matters have been more or less neglected. Suggestions in this line are eminently proper from the Surgeon-General himself as the spokesman of his corps. He emphasizes the urgent need of improved naval architecture by the following significant facts.

During the year fifty-five cases of heat exhaustion among the engineer force have been reported, the greatest number of cases appearing on the following vessels: Bennington, 11; Bancroft, 8; Columbia, 6; Amphitrite, 5; Raleigh, 5.

These figures are significant and merit attention by the department.

The average temperature of the engine-rooms of modern ships, under ordinary cruising conditions, may range from 106° F., with hatches large and open like the Charleston, to 152° F., in badly arranged and closed ships like the Amphitrite.

In the fire-rooms the average temperature under the above conditions may range from 124° F. in ships with only one set of fires in each fire-room, like the Charleston, to 189° F. when the fire-room is between two sets of fires, like the Cincinnati and Amphitrite. In the case of the Cincinnati, when only one set of fires is used in each fire-room, the average temperature is reduced from 189° to 159° F.

The result of these high temperatures, together with overwork and other trying conditions, is plainly shown by the number of disabilities in the engineer corps attributed to this cause.

The necessity of an organized hospital corps for the navy, instructed, drilled, and equipped for all duties pertaining to such service, is fully set forth. A bill with this object in view, combining every feature required to meet the immediate wants of the service, has been prepared and will be submitted at an early date. The general plan proposes a naval hospital corps consisting of men enlisted for that special duty, and instructed from the beginning at preparatory schools for nurses, to be established at all naval hospitals, in order to qualify them for all hospital work ashore and afloat, giving the Secretary of the Navy authority to enlist, or cause to be enlisted, as many men in the hospital corps as the service may require, and to limit or fix the number and make such regulations for their government as may be necessary.

The demand for more space on shipboard for the use of the Medical Department is founded on the experiences not only of our own navy, but of that of every similar service throughout the civilized world. The number of wounded in action is not only surprising, but truly appalling. It is stated "that a battleship with a complement of five hundred men in action, if not sunk, will have within a few minutes 30 killed and 120 wounded."

In the battle between the Chinese and Japanese fleets, off the Yalu River, September 17, 1894, the fragments of one shell, fired at long range at the Tsi Yuen, killed 7 men and wounded 14. Commander McGiffen states in his account of the battle that one steel shell, having a bursting charge of ninety pounds of powder, struck the Japanese flagship and killed instantly 49 officers and men and wounded over fifty.

It is regretted that the number killed and wounded by every shot on board the several vessels in the engagement cannot be followed, for it would establish, approximately, the number of casualties probable in a naval engagement at the present day.

The figures given, however, must impress everyone with the gravity of the entire question and the necessity of making a commencement of better methods in the service. We are glad to learn that with this end in view a great deal of attention has been paid to the subject during the past year, and medical officers of the navy have been requested to present to the bureau their views regarding the subject.

Attention is also called to the utility of ambulance ships built specially for the care and transfer of sick and wounded during action and at other times, and protected from injury or interference by the flag of the Geneva Cross.

We regret to learn that vacancies in the medical corps still exist. Although there were two hundred and sixty-nine applications for information only thirty-three men were enrolled as candidates for examination, and of these only nineteen presented themselves before the Board, and only four were found to be qualified. This is in strong contrast with the similar corps of the army and hospital marine, positions in which are promptly filled by eager and competent applicants. All this proves, as has been stated often before, that the navy does not tempt the young medical man as does either the army or marine hospital service. Nor will this condition of things be different until the Navy Department makes the position of the surgeon, as to rank, pay, and privileges, equal to that of his brother in the tent or quarantine hospital. We are pleased to note that the general health of the navy has been good.

A SATISFIED REFORM COMMISSIONER.

On November 1st occurred the change in the attending staffs of the various city hospitals, whereby a number of experienced men who had given years of faithful service to the care of the city poor were replaced by representatives of the colleges. A reporter of an evening paper called upon President Porter, of the Board of Charities and Corrections, to ask him how the change was made. Mr. Porter expressed himself as charmed with the new move, and assured the reporter that "there was no friction whatever, and that everybody was pleased with the reform" (*sic*). "Not only," he said, "are the medical colleges delighted at the change as in the interest of the poor and of medical science and surgery, but the most prominent and eminent physicians and surgeons in the city have come to me to express their satisfaction."

Of course the medical colleges were delighted at the change "in the interest of the poor and of medical science and surgery." The interest of the poor is the special concern of the colleges, and we do not for a moment doubt this part of Commissioner Porter's statement; but it would be interesting to have the names of "the most prominent and eminent physicians and surgeons in the city" who took the trouble to call upon him to express their satisfaction. In the absence of authentic information we might hazard the guess that they would be found upon the roll of newly appointed visiting physicians and surgeons to the city hospitals.

The genial Commissioner has had opportunity recently of correcting this impression and modifying his views as to substantial endorsement after reading the condemnatory resolutions so unanimously adopted by the Medical Society of the County of New York and the New York County Medical Association. The New York Academy of Medicine is next to be heard on the question of fair play toward many of its most distinguished members. Probably, however, the gentlemen of these associations represent only "the riff-raff of the profession."

THE INCREASE OF GLYCOSURIA.

If we may believe Dr. Worms, of Paris (*Bulletin de l'Académie de Médecine*), one of the manifestations of advancing civilization is an increase in the production of sugar, not through the agency of the corn-stalk or sorghum plant, but through the activity of the human organism. M. Worms has come to the conclusion that in persons engaged in brain work and leading a sedentary life, the proportion of glycosurics is seven per cent. This conclusion was reached from examining the urine of one hundred such persons. Further investigations have raised the proportion of glycosurics to ten per cent., and he considers this the rate in any series of one hundred scientists, artists, business men, doctors, and lawyers, etc., between the ages of forty and sixty. Dr. Worms quotes Bertilly's statistics, which show that diabetes is on the increase, the mortality in Paris having almost doubled in the last ten years. The author's own experience tends to show that glycosuria is increasing, but, happily, it is not the severe type; in fact, he estimates that the proportion of true diabetes, of grave form, to glycosuria is only about five per cent.

It is interesting to learn that glycosuria is one of the innumerable attendants upon a progressive and "hustling" civilization, and also to know that it is not one of the painful and malignant manifestations of our evolution. Glycosuria, in its mild form, is quite compatible with long life, but it compels the sufferer to live a most hygienic existence, both as to diet and mental and physical activity. Glycosuria of this type especially is often associated with excessive nervous activity. The glycosurias that are bred in indolence and over-indulgence are much more severe and dangerous in form.

MEDICAL BIBLIOGRAPHY.

One of the editors of *Le Progrès Médical* discusses the problem of medical bibliography apropos *la mort lamentable* of the *Index Medicus*. The editor of the *Progrès* thinks that the death of this journal was deplorable indeed, but yet was a somewhat legitimate and natural event. He avers that the *Index Medicus*, while extremely useful and erudite and complete, did not solve fully the bibliographic problem; it was rather an opportunist effort, and he opposes, therefore, a rehabilitation of the journal in its present form. There is a science of bibliography, and the editor of the *Index Medicus* is, he believes, a master of it, but the periodical did not give the true solution of the best way to present to the medical public the current scientific work of the world.

This is precisely the idea which the Medical Record has presented and advocated on several occasions. We have disliked to show antagonism to so useful a journal, but it has always seemed to us as though the publication would be more popular if the arrangement were different, if the number of annual issues were less frequent, and if the classifications were somewhat more in accordance with modern nosology.

MONUMENTS IN AMERICA TO FOREIGNERS.

The proposal to erect a beautiful statue to the German poet, Heine, in the Plaza, at the entrance to Central Park, naturally aroused a good deal of protest. This was partly because Heine was a foreigner, partly because the same statue had been rejected by a German city to which it had been offered, and perhaps partly to the fact that Heine's genius did not warrant such a tremendous exploitation. A project quite as preposterous has been started by some enthusiastic admirers of Dr. Samuel Hahnemann. They propose to erect a statue to this particular foreigner in Washington. According to the *Journal of the American Medical Association* the subscriptions to the monument go on swimmingly, while those to the American, Dr. Benjamin Rush, are somewhat halting and insufficient. It would seem wise, apart from any questions of creed or sect, that America wait until a man's own country honors him before they do it themselves. Germany has never ventured to erect a statue to Hahnemann, although he has been dead long enough to allow all per-

sonal prejudices to subside, and there is no tendency in that direction among the Germans now. In fact, the prevailing opinion among his countrymen, so far as we can ascertain, is that Hahnemann, although an earnest student, was a self-deceived philosopher. However, if our American *confrères* wish to put up a statue, they have a right to do so, and we say, let the work go merrily on. We can't have too many good statues to great doctors.

MEDICAL LIBRARIES AND MEDICAL COLLEGES.

Dr. Bayard Holmes, of Chicago, has written an article upon the subject of the relations of medical libraries to medical schools. He asserts what now all agree, that the lecture system of teaching medical students is a relic of ancient methods that is ineffective, and should, in a large part, be done away with. Among the newer and better agencies for teaching medical students is the use of the medical library. Each school, he thinks, should have a well-equipped library, by the aid of which students would be enabled to study out special questions connected with their regular work, and by which they might be trained in medical bibliography and methods of bibliographical research. It would certainly be a great help if students, before graduating, were taught how to use medical books, where to go to hunt up special information, and how to present the results of their later practical work in a proper, scientific, and interesting manner.

News of the Week.

Tax upon Corsets.—A correspondent of the Académie de Médecine of Paris has written a letter proposing to the Académie to ask for the creation of a tax upon corsets.

The Hypo Club.—The death of a Chicago man, known popularly as "Hypo Joe," calls from the *Chicago Tribune* a statement that there exist in Chicago a small band of men habitually using opiates and other drugs. "Hypo Joe" was known as the president of this "Hypo Club."

The "Medical News" and "Life."—We tender our very warmest congratulations to our esteemed contemporary the *Medical News*, and more especially to its energetic editor, Dr. Gould, for the successful way in which he has "turned down" the anti-vivisection periodical known as *Life*, and circulated in this town as a humorous weekly. We also congratulate the editors of *Life* for the unusual courage and honesty shown by them in publishing a letter from Dr. Gould, which so luminously portrays their methods and their arguments. We are sure that all readers of the correspondence between the editors of *Life* and the *Medical News* will appreciate the fact that Dr. Gould is master of the situation.

Tri-State Medical Society.—At the last meeting of the Tri-State Medical Society (of Iowa, Illinois, and Missouri) the following officers were elected: *President*, Dr. Robert H. Babcock, of Chicago; *First Vice-President*, Dr. A. H. Cordier, of Kansas City; *Second Vice-President*, Dr. W. A. Todd, of Chariton, Ia.; *Treasurer*, Dr. C. S. Chase, of Waterloo, Ia.; *Secretary*, Dr. G. W. Cale, of St. Louis. The next meeting will be held in Chicago the first Tuesday, Wednesday, and Thursday in April, 1896.

The Southern Surgical and Gynecological Association meets in Washington, D. C., on November 12th to 14th.

First Naval Battalion of New York.—Dr. H. Hayle Butts has been appointed surgeon to the First Naval Battalion of New York, *vice* Dr. Van der Poel, resigned.

J. R. Tryon, M.D., LL.D., Surgeon-General United States Navy.—Union College, New York, conferred, at its recent Centennial Commencement, the degree of LL.D. on Surgeon-General Tryon, United States Navy. This is a well-merited compliment to the distinguished chief of the Naval Medical Bureau.

The Late Dr. Frederic M. Warner.—*Whereas*, The Medical Board of the French Hospital have learned of the decease of an esteemed colleague, Frederic M. Warner, in the thirty-ninth year of his age;

Whereas, For a period of three years the said Board derived great benefit from the wise counsel, scientific attainments and devotion of Dr. Warner;

Whereas, The patients in the hospital were uniformly attended with skill and exemplary solicitude by Dr. Warner;

Resolved, That an expression of deep regret and a testimonial of profound admiration be entered on the minutes in memory of our late colleague.

Resolved, That a copy of these resolutions be forwarded to the family of the deceased and be published in the medical press.

Egbert H. Grandin, M.D., *Vice-President.*
Ramon Guiteras, M.D.
J. Darwin Nagel, M.D.

Old Charity Hospital.—The Commissioners of Charities and Correction suggest that still another new name be given to Charity Hospital. Not long ago it was changed to City Hospital, and now Island Point Hospital is suggested. There never was any necessity for changing in the first place, but the Commissioners still believe in unreasonable and radical reforms.

A Pathological Institute for Dublin.—Ireland is usually as quiet a country, so far as medical science is concerned, as it is lively in the matter of politics. We learn that a little evidence of mental activity is taking place in Dublin. It is proposed to undertake the establishment of a pathological and bacteriological institute in that city.

The White Cross Society.—An association by this name has sprung up in Italy for the relief of civilians who, from illness or accident, are unable to work. An organization in Rome, bearing the name of the Crosce Bianca, has at its disposal a well-disciplined corps of young men and women, whose duty it is to pick up and transport to hospitals the victims of accidents or the wounded "soldiers of industry," administering first aid in urgent cases and attending or nursing them afterward.

Small-pox is slowly diminishing in London and in the provinces.

Erratum.—Dr. Frank W. Maloney, of Rochester, N. Y., writes that in his article on "Maternal Impression," in the MEDICAL RECORD of September 28th, his patient was about six weeks pregnant, instead of six months, as it there reads.

A New Dispensary for Brooklyn.—The plans for the Polhemus Memorial Dispensary, which is to be an adjunct to the Long Island College Hospital, have been drawn up and approved. This new dispensary will cost $250,000, and is to be a building six stories in height, with all the modern improvements for dispensary work. When complete, the Long Island College Hospital, the Hoagland Laboratory, and Polhemus Dispensary will form a complete set of buildings for purposes of medical education and philanthropic work.

Dr. Franklin Townsend, of Albany, died on October 31st, aged forty-one.

A Continental Medical Temperance Association has been organized in Europe, with Dr. Smith, of Groosherz, Baden, as president. The object of this association is similar to that of the American and English Medical Temperance Associations.

Red Cross Hospital Association.—This association, which was founded four years ago in this city by the American National Red Cross Association, recently held its annual meeting.

Dr. Catherine C. Runyon has been admitted to membership in the Virginia Medical Society. She is the first female physician admitted to membership.

Successful Excision of Spleen.—There have recently been three successful cases of excision of the spleen for injury at St. Thomas's Hospital, London. These, we are told by *The Lancet*, are the first successful cases that have occurred in Great Britain.

The Doctor on the Stump.—Dr. Alexander J. Stone, Professor of Gynecology in the Minnesota State University, has been stumping the State of Ohio in behalf of ex-Governor Campbell. Incidentally, he has promised to advocate the Mosgrove Bill for medical education. Professor Stone is wandering a little from the beaten paths of gynecological practice, but if he helps along the cause of higher education in Ohio he will be doing a good work.

The Doctors' Campaign in Ohio.—Judging from the activity shown by the Cincinnati *Lancet and Clinic* and the other medical journals in Ohio, the medical profession of that State have this year entered very heartily into the fall campaign. There are, it seems, in the State issues a number of political questions which have no especial medical interest, but the question of proper medical legislation has at last been forced into considerable prominence. Time and again attempts to regulate medical practice and oust the quacks and diploma manufacturers of Ohio have been tried and have uniformly failed. This time there is, we hope, some promise of success. Great credit is due to the *Lancet and Clinic* and its energetic editor for the activity shown in this matter.

The Testimonial Fund to Dr. W. G. Grace, the cricketer, has reached the sum of $25,000, and that sum has been forwarded to the distinguished gentleman. He should send a good contribution to the Sir Andrew Clarke Memorial Fund, which needs additions.

The Medico-Legal Society of Jersey City intends to secure a building suitable for a club-house, and large enough to accommodate all the doctors and lawyers in Hudson County.

Another Whiskey Cure.—Since the development of the Keeley cure there have not many months passed without some new cure for the alcohol or morphine habit appearing on the market. The latest of which we have seen an account is that published by Dr. Matchette in the *Medical World*. Dr. Matchette modestly claims that he has had but two per cent. of failures. He has this merit, at least, that he is willing to publish his method to the world, and does so. Dr. Matchette notes incidentally that the beer habit is more stubborn and resists treatment more than any other. We call the attention of this interesting fact to the civic patriots of the German Reform Union. The method of cure consists in giving the patient a hot bath and a cathartic. He is then given a hypodermic injection of the sulphate of hydrastine, beginning with one-fiftieth of a grain, which is increased until one-twentieth of a grain is given four times a day. If the patient is very nervous, he is given mixtures containing valerian and bromide. During the first few hours, or even days, the patient is furnished with a generous quantity of liquor of the best brand. The essence of Dr. Matchette's cure seems to be sulphate of hydrastine. Hydrastine is put down as "a simple bitter, a hepatic stimulant, an antiperiodic, an emmenagogue." This alleged property of being antialcoholic is certainly somewhat new.

New College.—A Woman's Medical College has been established at Kansas City, Mo.

Defeated Law.—A clerical error defeated the Medical Practice Act recently passed by the Michigan Legislature. The Governor refused to affix his signature.

Death from Riding a Bicycle.—Professor C. V. Riley, the well-known scientist, and for years entomologist of the Department of Agriculture at Washington, was killed while riding a bicycle, on September 15th, in that city. His skull was fractured at the base of the brain, his head coming in contact with the curb-stone when thrown from his wheel.

Medical Etiquette at Mineral-water Cures. — A French association, including a large number of physicians who practise at watering-places, has sent out a circular in which it is stated that when a physician sends a patient to a water-cure, he should give him a letter addressed to his *confrère* at that place, and that it is not etiquette for him to prescribe for his patient while there.

The Paris Académie de Médecine has appointed a commission, with Dr. Laveran as chairman, to investigate the means of combating malaria.

Reviews and Notices.

LEPROSY IN ITS CLINICAL AND PATHOLOGICAL ASPECTS. By DR. G. ARMAUER HAUSEN, Inspector-General of Leprosy in Norway; and DR. CARL LOOFT, Former Assistant Physician to the Lungegaards Hospital. Translated by NORMAN WALKER, M.D., F.R.C.P. Edinburgh, Assistant Physician for Dermatology, Edinburgh Royal Infirmary. With numerous Photographs and Colored Plates. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co. (Ltd.). 1895.

THOUGH contained in but 125 pages, exclusive of tables, and histological plates, this work is replete with valuable knowledge. The authors have had so fruitful a field from which to draw their information, and Dr. Hausen at least has had such wide experience in all matters pertaining to the question that one feels great confidence in all one reads.

Five photographic plates are added, which did not exist in the original German edition. The translator has apparently followed the original with great accuracy. The chapter on treatment has been rewritten, giving the views of the late Dr. Danielssen. The closing sentence is significant. It reads: "But we are firmly convinced that isolation *must* be carried out in some appropriate fashion." We commend the work to all interested in the subject.

PHYSICAL AND NATURAL THERAPEUTICS. The Remedial Uses of Atmospheric Pressure, Climate, Heat and Cold, Hydrotherapeutic Measures, Mineral Waters, and Electricity. By GEORGES HAYEM, M.D., Professor of Clinical Medicine in the Faculty of Medicine of Paris. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With 113 Illustrations. Philadelphia: Lea Brothers & Co. 1895.

THE editor has acted upon the author's text in such a way as to adapt it to the needs of the American physician, and short articles have been added on the climate and mineral springs of our own country. The author is regarded as one of the most advanced therapeutists of the day, and chapters on atmosphere, climate, thermic agents, hydrotherapeutic measures, mineral waters, and electricity all show not only a wide personal experience but familiarity with the views and writings of other recognized authors. Besides a very full general index there is a therapeutic index, giving the diseases in their alphabetical order and the various physical measures applicable to their cure.

CUTANEOUS MEDICINE. A Systematic Treatise on Diseases of the Skin. By LOUIS A. DUHRING, M.D., Professor of Diseases of the Skin in the University of Pennsylvania; Author of "A Practical Treatise on Diseases of the Skin," and "Atlas of Skin Diseases." Part I. Anatomy of the Skin, Physiology of the Skin, General Symptomatology, General Etiology, General Pathology, General Diagnosis, General Treatment, General Prognosis. Illustrated. Philadelphia: J. B. Lippincott Co. 1895.

AN American work on dermatology of which American physicians should be proud, and especially the members of the American Dermatological Association, "who," as the author says in his dedication to them, "by their faithful service and valuable contributions to this department of medicine have gained the universal respect and honor of the profession." The author's earlier work, which is now out of print, was for many years a standard text-book not only in this country but abroad. The intention has been to amplify, modernize, and improve upon the previous work, making "Cutaneous Medicine" a more comprehensive treatise. The chapters are characterized by a conservatism which has not been unduly influenced by the many attractive theories continually coming up. Where a theory has been proven true, it has been incorporated in the text.

Part I. deals with generalities. After seventy pages of anatomy and physiology we have "General Symptomatology," "General Etiology," "General Pathology," "General Diagnosis," "General Treatment," and "General Prognosis."

Under "Pathology" much pertaining to bacteriology will be new to those possessing Dr. Duhring's "Diseases of the Skin." Under "Treatment" chapters will be found on plaster-muslins, pastes, jellies, salve-pencils, skin-grafting by the various methods, electrolysis, cataphoresis, etc.

The illustrations are text-inserted cuts mainly of anatomical or pathological subjects, for the most part taken from standard works.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 17, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

The Question of Operative Interference in Abscess of Chronic Tubercular Disease of the Joints.—DR. NEWTON M. SCHAFFER read the paper. He said there was no other subject which had come before the orthopedic section of the Academy or before the American Orthopedic Association which had provoked more discussion or given rise to a greater difference of opinion. But while there had been much said about the treatment of chronic abscess in tubercular disease of joints, there had been no statistics. In September, 1891, he had ventured to read a paper on the benign course of abscess in Pott's disease under mechanical treatment, before the American Orthopedic Association, and there was much difference of opinion, but, as usual, no statistics on either side. Under these circumstances he then decided to treat all cases which should come to the New York Orthopedic Hospital without operative interference, and to report the result, which he now did at the end of four years. He first quoted his former paper, just referred to, in justification of this course, for it showed that there were many favorable cases under the mechanical, non operative treatment, while patients who were operated upon by himself or by others were likely to die of septicæmia. But a *sine qua non* of successful non operative treatment was long and efficient mechanical protection. The surgeon must give the same attention to it that he would in treating a fracture.

The fundamental principle in the treatment of chronic joint disease was protection of the diseased parts while maintaining the activity of other parts of the body. Dr. Schaffer said the plaster of-Paris splint was not suitable in these cases, and that it ought to be relegated to eighteenth century practice, where it belonged.

At this point he emphasized the fact that there was a great difference between the so-called cold abscess of chronic tubercular disease and ordinary acute abscesses which contained pus. The contents of cold abscesses were frequently quite sterile, their presence gave rise to no temperature: why, then, should we be in a hurry to incise them and admit pathogenic organisms? Such abscesses were simply a sign of disease, the location of which was often at a distance.

But a simple tubercular abscess might undergo change and inflammation occur, with some increase in size, or extension by burrowing. It was under circumstances of this kind that the judgment of the surgeon would be tested. The temptation was to use the knife at once, but Dr. Schaffer's advice was to wait a while, for the septicæmia progress would be likely to pass over if the joint were protected, the patient kept in the air and sunshine, and appetite and digestion maintained. Even if the temperature rise to 101° or 102° F., do not be worried, for in children this is not a serious menace. But if the symptoms should go on, make a free incision. He had often waited, and nature had solved the problem by causing absorption or making a spontaneous opening.

One heard a great deal about the burrowing of abscesses and the maceration of healthy parts. Dr. Schaffer had learned to have, under ordinary circumstances, no fear of burrowing, and maceration existed largely only in the imagination of the doctor. The slow burrowing of a chronic abscess in tubercular disease need not be feared. Rapid burrowing of a more acute process demanded immediate attention.

Did incision, asepsis, irrigation, drainage, etc., meet the indications in the present state of our knowledge of these cases? Did making an opening which communicated with the diseased joint favor ultimate cure? In the very nature of the case it was often impossible to remove all the tubercular material, and it was equally impossible to secure perfect sterilization of the opening or sinus for a long period of time.

The author then gave the results of the treatment of all the cases admitted to the New York Orthopedic Hospital during the four years commencing with May 1, 1892. During this time there had been admitted, 63 patients with hip-joint disease, 18 with Pott's disease, 12 with knee-joint disease, 93 in all. Of these 93 cases of joint disease, 35 had abscess. The treatment consisted of efficient mechanical protection, and the administration of cod-liver oil, etc. The patients were up and about nearly all the time. In most cases only simple external dressings were used; in a few, drainage and irrigation.

Of the 35 cases which included all the abscess cases which had entered the hospital during these four years, 27 remained under the care of the institution a sufficiently long time to test the value of non-interference. In 6 of the 27 cases the abscesses, all large ones, underwent complete absorption. In 2 of them there were two abscesses, making eight abscesses which became absorbed. In 15 of the 27 cases the abscess, after opening spontaneously, closed completely in periods varying from two months to twenty-one months. Of the 27 cases 5 still had small sinuses, but nearly all were practically well and suffered no inconvenience. In 1 case a large abscess was in the way of applying proper mechanical apparatus. Of the 7 other cases out of the 35, 5 died for reasons not attributable to the treatment. The other two patients still had small sinuses which discharged slightly.

Dr. Virgil P. Gibney opened the general discussion. However much we might differ from Dr. Schaffer in our treatment of these cases, we certainly must admire him for having the courage of his convictions in carrying out the plan of non-interference in all cases for four years. The results, too, had been good, but he imagined general hospitals received severer cases.

Probably Dr. Schaffer's results in private practice were even better than those just narrated. The question of best mode of treatment was still an unsettled one, but he was inclined to believe that when the surgeon could make himself master of all the details of aseptic surgery, he would obtain even better results by operative interference than those given by Dr. Schaffer. He did not, however, believe in simply opening an abscess, scraping out the sac, and sewing it up. It was our duty to take a little more time and follow the abscess or sinus down to its origin, and scrape away the dead bone which was feeding it. Of course, he realized the difficulty of reaching all the foci of disease, yet we had to work in that direction in order to accomplish much by surgery.

He summed up his opinion about tubercular abscesses as follows: Where the abscess was small, or even where it was large, if it did not interfere with the application of a protection apparatus to the spine, hip, or knee, it was well to let it alone, but watch it carefully, and if it seemed to be undergoing absorption, proceed with this mode of treatment. But if the abscess should become larger and larger, or if it should become pyogenic after bursting, then it was our duty to open it freely if aspiration failed to cause its permanent disappearance. If the sinus led up to the dorso-lumbar vertebræ we could often reach bits of bone and scrape them away with the long curette; then pack the abscess well, and aim to get healing from the bottom. That meant a long period of patient aseptic dressing. If the abscess stood in the way of efficient mechanical treatment, it should be opened as soon as possible. The kind of abscesses most difficult to handle were those which had sinuses and pockets in different directions. They often went on for years, and finally the patient succumbed to lardaceous disease. Then there were some patients who came from the slums, and who could not be made to thrive do what we might. Again, some did poorly in the hospital, but on being taken to their filthy homes they began to improve. For some, it might be advantageous to make a change of climate, as in pulmonary tuberculosis.

Dr. A. B. Judson said: I have arranged a few propositions which I will present briefly, as my contribution to the evening's discussion. Opening an abscess of chronic tubercular disease of the joint is equivalent to treating a symptom and not the disease. So is dealing with an unimportant incident of the disease under treatment. It distracts attention from the seat of the disease in the bone, where attention is most urgently needed. It is the application of a minor surgical proceeding in the course of a surgical case of the greatest importance. It subjects the patient to the distress and inconvenience of a prolonged discharge, which would be readily submitted to if recovery depended upon it, but which, if these other propositions are correct, is indefensible. It exposes the patient to the danger of an infected wound.

So far as my short experience goes, it is in accord with these propositions. Beginning studies in this direction twenty years ago, I followed the authorities of that day and the traditions of the naval medical service, and made early and free incisions. But I saw reasons to change, and for several years have not seen, and do not expect to see, abscesses of this kind that require opening or any local treatment beyond a simple dressing.

This rule of practice has led to some gratifying observations; for instance, the not infrequent absorption or disappearance of fluid collections coincident with recovery from the bone disease; the spontaneous, painless, and bloodless opening and collapse of abscesses, followed by rapid and permanent closure with recovery from the bone disease; and in other cases, in which wide tracts of the skeleton were deeply diseased, multiple abscesses pursuing a long course without serious reaction or impairment of general health, and followed by recovery, delayed not by the deportment of the soft parts, but by the obstinate nature of the disease in the bony tissue.

These statements would be misleading if I did not also recall attention to the necessity of urgent and assiduous treatment of the disease.

Mechanical Treatment Prevents Abscess.—Dr. Samuel Ketch thought efficient mechanical treatment was important, not only for the cure of chronic tubercular abscess, but also for its prevention, when resorted to at the commencement of the disease. He felt sure that all orthopedic surgeons would agree to let those abscesses alone which produced no symptoms. He had been connected with the New York Orthopedic Hospital and Dispensary for many years—since he served as house-surgeon ten years ago. At that time the staff consisted of general surgeons, and all abscesses were opened under full Listerian dressings. The cases in which this treatment was applied, and those in which exsection was made, continued to have abscesses which gave much more trouble and for a much longer time than abscesses which were allowed to open spontaneously.

Regarding the suggestion of Dr. Gibney, that the cases treated in the hospital might have been selected, he would say that the results of the same treatment in the dispensary cases had been similar, and there cases had to be accepted as they came. Abscesses of acute character, however, should be opened.

Dr. John Dane, of Boston, had made some studies pointing to the number of leucocytes as an indication of mixed infection in the abscesses under considera-

tion. Cases in which permanent drainage was attempted almost invariably showed that they had been contaminated, although in the beginning they might have contained no germs capable of producing pus.

Dr. John A. Wyeth said: Modern pathology holds that a tuberculous abscess does not contain true pus. While in gross appearance it resembles pus, the microscope shows that the normal elements of pus do not exist. Under such a condition the danger of general infection from the bacillus of tuberculosis is very small. This bacillus produces a subacute inflammatory process, which results in a rich granulation tissue, the base of which is composed of newly formed cells, the embryonic tissue of the inflammatory process, which hedges in the tuberculous focus and prevents systemic invasion. The tendency of these products of the tubercular process is to undergo rapid degeneration, due in part to the toxic product of the bacillus of tuberculosis (chemical action) as well as by anæmia, party local and partly systemic. As a result of this retrograde metamorphosis, caseation and liquefaction of caseous material occur, the product being a white liquid of varying consistence, resembling but not being pus.

Under favorable conditions these collections of tuberculous fluid tend to absorption. In the majority of instances the wall of embryonic cells offers sufficient resistance to invasion of the tuberculous germs into the general system. The liquid is absorbed ultimately and carried away as a harmless product, and the remaining caseous matter undergoes granular metamorphosis and of itself ultimately disappears. Such pathological processes do not have symptoms in any way in common with abscesses proper, which are the seat of acute inflammation caused by pyogenic germs. Pain is not a marked symptom, since they can exist for months, as in psoas abscesses, and are not suspected until the collection of this milky fluid is sufficient to attract attention by its pressure upon the abdominal viscera, or protrusion due to its bulk.

It is a recognized fact that these tuberculous foci can become infected with pyogenic micro-organisms without a direct or external wound. Certainly if the medulla of bone can become infected without a direct or external communication, it is just as easy to infect a deep-seated tuberculous fluid when conditions for infection are favorable, the germs travelling through the blood and being deposited in a suitable pabulum.

Accepting as I do the foregoing, the treatment of the two classes is clearly indicated. The simple tuberculous focus, under ordinary conditions, may be left alone to undergo absorption, taking pains by careful nourishment and hygienic precautions to increase the normal resistance of the tissues and prevent general infection. On the other hand, when a tuberculous accumulation is the seat of a mixed infection, as determined by the ordinary symptoms of septic infection, local and general, then a careful aseptic invasion and evacuation of these abscesses is indicated.

Believes in Operating.—Dr. A. M. Phelps said he had to express a somewhat different view. He believed that the surgical profession was fully agreed that abscesses, including those of tubercular nature, should be opened wherever they existed, whether in the shaft of bones, in the joints, in the liver, in the cellular or muscular tissue, or elsewhere. The reason was, that when these tubercular abscesses were left to themselves they, by contact with surrounding tissues, invaded and destroyed them.

He knew that some cases recovered without operative interference, as quoted by the reader of the paper, but one swallow did not make the summer, and in proof of his view he quoted several cases which had gone wrong until in his hands they were submitted to excision of the diseased tissue. In hip-joint disease accompanied by abscess, in all cases in which he had operated for exploratory purposes, he had found the head of the bone separated from the neck, and had removed it as a foreign body. In neglected cases of disease of the knee-joint he had found both articulating surfaces destroyed, and in some instances the shaft of the bones invaded. Excision had been followed by cure. Dr. Phelps showed numerous photographs, illustrating, he said, destruction of bone by maceration from neglected and burrowing abscesses.

Dr. Phelps said he operated, and the surgical world operated, for the following reasons, and others: 1. Years of suppuration and mechanical treatment were avoided. 2. To intelligently explore the joint. 3. To get rid of the foreign body. 4. To avoid amyloid disease of the liver and kidneys. 5. To prevent burrowing into important structures and cavities. 6. To prevent destruction by maceration and infection, which in turn led to destruction by necrosis and caries. 7. To get rid of extra-capsular disease and prevent invasion of the joint. 8. By early operation prevent destruction of bone. Finally, he believed that nearly all abscesses should be opened and explored with the finger. But to simply scrape a sinus when dead bone was at the bottom of it was bad practice. It opened the way for infection. All the diseased tissue at the original seat of the disease should be removed if possible.

Dr. R. H. Savre took issue with one or two statements in the paper. 1. That the recumbent posture in Pott's disease was a failure. In a certain proportion of cases he had found it essential. 2. He disagreed with the statement that plaster of Paris was useless in affording protection in Pott's disease. Regarding the general treatment of chronic abscess, he said Dr. Wyeth had expressed his views better than he could do it himself.

Dr. Leroy W. Hubbard, Chairman of the Orthopedic Section, under whose auspices the discussion was held, said his training had first been in a general hospital, and favored operative treatment in nearly all cases of abscess. Therefore, when he entered upon his service at the New York Orthopedic Hospital and Dispensary, he found himself rather prejudiced against the non-operative methods adopted there; but the results of such treatment soon led him to change his views. He could certainly endorse the conclusions presented so clearly by Dr. Wyeth, that there were some abscesses which should be let alone, others which should be opened, and if opened, it should be treated aseptically, while at the same time efficient protection and mechanical treatment of the joint should be applied.

Dr. Schaffer, in closing the discussion, said his cases had not been selected. He would like the gentlemen to do as he had done, bring forward all the cases which they had treated for a term of years, and not isolated ones intended to support opposing views. Judging by some of the photographs passed around, he would doubt whether the bone disease attributed in some of the cases to burrowing and maceration by pus had that origin.

SECTION ON SURGERY.

Stated Meeting, October 14, 1895.

B. Farquhar Curtis, M.D., Chairman.

Nephrectomy for Pyonephrosis.—The Chairman, Dr. Curtis, presented a man, aged twenty-three, on whom he had performed nephrectomy for surgical kidney. When twelve years of age he had received a kick in the left lumbar region, after which he passed bloody urine for three days, and had severe pain for six weeks. There was also a history of two attacks of urethritis, the latter taking on a chronic form. Five years ago he had had severe pain in the left side, sometimes over the bladder. Later the urine contained a large amount of pus. When he entered the hospital, a year ago in July, Dr. Curtis felt a tumor, the size of a man's head, immovably fixed in the left side, and

extending as high as the diaphragm. On operating, a vertical incision was made anteriorly on the left side, joined by a shorter transverse incision extending outward. Through this opening the shell of kidney was felt, filled with pus, which was evacuated and the tumor then removed. The patient had done well since the operation.

Dr. Curtis thought nephrotomy should be reserved for those cases of nephrosis less in extent than in this case, or where a considerable portion of the kidney yet remained healthy, or where the other kidney was also diseased and one did not care to sacrifice any healthy tissue whatever.

Congenital Backward Displacement of the Head of the Humerus under the Spine of the Scapula.—Dr. A. M. Phelps presented another case of dislocation of the head of the humerus backward under the spine of the scapula, probably of congenital origin. It was by courtesy of Dr. Le Roy W. Hubbard that he was able to present this boy, aged about twelve, and it was proposed that the same operation be done which he had performed for the first time in a case reported at the Section last spring. This patient had visited various surgeons in San Francisco, Chicago, and New York, and, strange to say, all were of opinion that nothing could be done. The operation performed in the former case, and proposed in the present one by Dr. Phelps, consisted in cutting down posterior to the deltoid, freeing the head of the humerus, and shaving this off so as to make it fit the glenoid cavity. It was not advisable to enlarge the glenoid cavity at the same time, as it would endanger anchylosis. Dr. Phelps believed these dislocations at the shoulder, and also dislocations at the hip, arose from trauma inflicted at birth, or possibly they occurred sometimes during intra uterine gestation.

Dr. Le Roy W. Hubbard thought it rather remarkable that within two months after he had seen his first case of the kind described by Dr. Phelps, two others had come under his notice. It seemed strange that so many surgeons had discouraged operation, for, apparently, it was a simple procedure, and a very necessary one in view of the fact that the patient's arm was quite disabled and he was obliged to earn his own living. He was of the opinion with Dr. Phelps, that it was better to reduce the size of the head of the humerus than to enlarge the glenoid cavity.

Dr. Royal Whitman was disposed to think that these cases may originally have belonged to that rather numerous class called obstetrical paralysis leading to subluxation, and that the arm having for years been left in this position assumed the attitude shown.

Dr. Phelps said that against this supposition and in favor of dislocation, was the fact that in his first case he found the posterior border of the glenoid cavity broken away, where the head of the bone had slipped back to make a new articulation.

Carcinoma of Breast; Excision, including Glands and Pectoral Muscles.—Dr. F. J. A. Torek presented a woman, about forty years of age, on whom he had operated for cancer of the breast, removing not only the breast, but also both pectoral muscles and the axillary and clavicular fat, all in one mass, as recently described in the Medical Record by Dr. Willy Meyer. His reason was that the operation for carcinoma could not be made too radical. In this instance a gland, the size of a lentil, was found in the pectoralis minor, which could not be felt before the operation, and which would have been left to bring on recurrence, had the ordinary operation been performed. The patient was able to move her arm in every direction, but there was some stiffness in the deltoid, which was gradually disappearing with use.

The Chairman thought this more radical operation for carcinoma of the breast ought to be encouraged. It did not destroy the utility of the arm.

Recent Advances in the Surgical Treatment of Malignant Disease of the Larynx.—Dr. D. Bryson Delavan in this paper described the three methods of operating in malignant disease of the larynx, and gave the recent statistics of Semon, Butlin, and others. The three varieties of operations were, 1, thyrotomy; 2, laryngotomy; 3, complete laryngectomy in cases of extensive laryngeal disease with glandular involvement.

Thyrotomy had been practised chiefly by Butlin and Semon, of London, and was applied to cases in which the disease was absolutely confined to the interior of the larynx. The second variety of operations was only more extensive. Dr. Delavan was of opinion that in all the cases preliminary tracheotomy ought to be performed, at least a week in advance. Among the cases of intrinsic epithelioma which had been operated upon by Butlin and Semon, one was well after five years and a half, one after three years, and one after two years. Recent statistics showed a percentage of cures by operation of from twenty-eight to forty per cent., as contrasted with ten to thirteen per cent. given formerly.

The method of Solis-Cohen, of Philadelphia, whereby the mouth was shut off from the trachea, removing danger to life, yet permitting of swallowing with ease, had been followed in at least three cases so operated upon by acquiring power of phonation. The comfort of the patient was greatly increased, and the disfiguration of the other operation was largely done away with. It was a question, however, whether these cases were not the result of a happy accident which might not repeat itself in the future. Regarding the third variety of operations, the author said that experience had shown glandular enlargements not to be so serious an obstacle as had heretofore been supposed.

The suggestion of Mr. Butlin, that every tumor of the larynx which was suspected of being malignant disease justified exploratory thyrotomy, seemed to Dr. Delavan unsafe even if acted upon by one so expert as Mr. Butlin. He thought, however, that Mr. Butlin had in mind only such cases in which all other possible means of diagnosis had been exhausted. Papilloma might be suspected to be malignant disease, at least by one not so expert as Mr. Butlin, and he had seen tumors of this sort disappear under repeated use of the alcohol spray.

Finally, it must be admitted that cases of malignant disease demanding these operations were dangerous at best, and Dr. Delavan thought that not every laryngologist or surgeon should undertake to operate, but should send cases to those who had already had some experience, until the limits of the operation could be better defined. The possibility of certain accidents must be admitted and guarded against, such as entrance of foreign substances into the air-passages, bad management of the tube, poisoning by antiseptic dressings. The reader was of opinion that poisoning by antiseptic dressings had occurred in four cases, iodoform being the chief offender. The substitution for this of compound tincture of benzoin had been attended with success.

Dr. Delavan then showed some new tracheal tubes

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 24, 1895.

Henry C. Coe, M.D., Chairman.

Unusual Entanglement of Umbilical Cord; Death of Fœtus.—Dr. L. F. Bishop related the case, illustrated by pencil drawing. A woman, about twenty-eight years of age, had been delivered previously of one living child by forceps. Pregnant again, nearly full term; fœtal movements had ceased for some days. Examination showed a justo-minor pelvis, no fœtal heart, left occipito anterior position. The head would not engage, and Dr. Bishop was about to do craniotomy,

when suddenly, under a strong uterine contraction, the head collapsed and delivery was soon completed. The cause of the death of the fœtus then became apparent, for the cord was found entwined around the left thigh in the form of a slip knot, so that every movement of the leg caused it to draw tighter. The leg was œdematous, showing that the knot had only gradually drawn so tight as to completely obstruct circulation. He had found no record of exactly a similar case, and Dr. E. A. Tucker, of the Sloane Maternity, said he had seen none.

Multilocular Cyst of the Ovary.—Dr. Polak related a case of multilocular cyst of the ovary removed by cœliotomy. The peritoneum was torn while strapping up the vesico-uterine fold, and troublesome hemorrhage followed. The patient was doing well after the operation, when scanty urinary secretion was noticed, which was attributed to ether and digitalis. Later abdominal fluctuation was felt, the original incision was reopened and a pint of pus was evacuated. The temperature then fell, but an unusual amount of fluid escaped through the drain, which was shown, by administration of methylin blue and by Kelly's method of direct catheterization of the ureter, to be from a uretero-abdominal fistula. The ureteral fistula closed of its own accord ; the abdominal fistula was still open, but the patient was doing well.

Rupture of the Uterus.—Dr. S. Marx related two cases of rupture of the uterus during labor to which he had been called in consultation after the accident. They pointedly illustrated the necessity for great care when one thought it necessary to use forceps. The first case was in a woman who had previously given birth to four children. The attending physician made a diagnosis of knee presentation, and without attempting to rectify the position the forceps were applied under deep chloroform anæsthesia. As soon as traction was begun symptoms of intense collapse developed. The baby was extracted and the diagnosis was made of chloroform heart failure. The second day acute symptoms of peritonitis developed, and Dr. Marx saw her within six hours after the initial chill, and made the diagnosis of rupture of the uterus at once, which was then confirmed by introduction of the hand. The only thing to do was to wash out the entire peritoneal cavity through the ruptured uterus and drain. The patient died a few hours afterward.

The second case occurred in a very stout woman, in her fifth labor, all previous labors having been normal. She had not felt life for several days. The os dilated slowly, and the physicians in charge applied forceps to the head through the undilated os. The fœtus was macerated and the head was torn off. Then, instead of doing version immediately, the doctor drew down an arm and pulled it off, then the other arm was pulled off. He then introduced a sharp hook, intending to perforate the body ; but, instead he penetrated through the uterus into the peritoneal cavity. When Dr. Marx saw the patient she was in collapse. On careful examination he found that the uterine wall was between his hand and the remainder of the fœtus, this having escaped into the abdominal cavity. He was able to express it between his hands, as in expressing the placenta. The rent had been enormous. Here again the only thing to do seemed to be to wash out the cavity and pass up a large amount of gauze. The patient died. Still, the question always arose, in ruptures of the uterus into the peritoneal cavity, whether to do laparotomy and sew up the tear or to remove the uterus. In the two cases related the patients were already moribund, and any operation attended by shock would have caused immediate death. Saline solution was injected into the bowel. It was not injected into the veins, as these under the circumstances were collapsed and difficult to find ; it was not made under the skin, since with the fountain syringe and a large needle —the only instruments at hand—it would have been a slow, painful process, requiring twenty to twenty-five minutes to inject a pint of the solution, which by that time would have become cool.

Dr. Marx said that in these cases of rupture of the uterus, and in some others which he had seen, there had been emphysema of the external genitals, a fact of diagnostic value, the cause of which was to him unknown.

The Chairman, Dr. Coe, thought that not infrequently rupture of the uterus passed unrecognized, the patient's condition being attributed to collapse, without careful examination being made. As to treatment, he remembered seeing cases in Vienna which made a good recovery without operative interference, only drainage being established. Of four cases in which Dr. Coe had sewed up the ruptured uterus only one, operated upon within an hour, recovered. The operation was always a formidable one, and done usually under very unfavorable conditions, and the mortality must always be high. He had about made up his mind not to do laparotomy again unless the case were quite recent and there were a fair chance that the patient would not die of shock.

Dr. P. A. Harris said the uppermost idea with practitioners usually was, when they had a case of labor which they did not understand, to get the baby into the world. It did not seem to make much difference to them how, if only the child were born. It was only those who did a good deal of consulting work in obstetrics who knew of the frequency with which difficult and bad cases were made much worse by undertaking to deliver under disadvantageous circumstances or without sufficient experience. As Dr. Marx had stated, it was the duty of the attending physician to seek experienced help before he had made the case a hopeless one.

Turning versus Forceps.—Dr. Malcolm McLean said that practitioners too often applied high forceps where the head refused to engage, theoretically claiming that they were placed in relation to the longer axis of the superior strait, but in reality across it, thus making a bad case worse. Having, perhaps, torn the uterus, they resorted to version, and afterward the case was reported as one showing the great danger of rupture or other accidents attending version.

The Chairman remarked that high forceps should be considered a capital operation, one not to be undertaken without the best counsel and assistance.

Dr. Marx said he had only recently had to take a teacher in one of our medical schools to task for advocating forceps instead of version. Dr. McLean had done a service in pointing out the greater danger of forceps.

Morphinism in Women.—Dr. J. B. Mattison, of Brooklyn, read the paper. Morphinism in women was not rare. He had not found it less frequent than in men. Physical necessity, relief of pain, and not a tendency to do wrong, was the chief cause among the better class. Usually the diagnosis was not difficult, but some morphinists were able to hold out for years with little departure from mental or physical health. In refusing a second trial of Carlyle Harris, Recorder Smyth had said that if a wife were a morphinist the husband would surely know it. This was a grave judicial error, for the writer had known again and again of morphinism on the part of the wife, of years' duration, without the knowledge of the husband.

There were two tests of morphinism, one by urine analysis, the other by enforced abstinence. The urine test consisted in rendering the specimen alkaline by addition of bicarbonate of sodium, to this add a certain proportion of chloroform or amylic alcohol, shake thoroughly, let settle, draw off, add a small proportion of hydriodic acid. If morphine were present there would be a violent tinge to the urine. Regarding enforced abstinence from morphine, no morphinist could stand it for forty-eight hours without showing reflex symptoms.

Morphinism in women, like in men, was disastrous. Regarding its effects upon the functions peculiar to the sex, he said menstruation was almost always disturbed, often long absent, sooner or later there was sterility, although to this rule there had been some marked exceptions. The case reported by the late Dr. Earl, of Chicago, was referred to, in which the newly born children had the disease and died.

The prognosis of morphinism in women eligible for treatment was good, and based on his personal experience it was better than in men. Recovery took place sometimes in apparently hopeless cases. In fact the most hopeless case which he had ever seen was cured completely, and was well to-day, eleven years after the treatment. It was the only case in which he had ever seen hullucination of touch. Hallucination of sight and hearing was common.

The treatment depended upon the individual case, for the patient, as well as her disease, must be treated. Speaking generally, a more prolonged treatment was required than for men. The extremes of recovery under his management had been five weeks and six months. Abruptly taking away all opium was brutal, entailed needless suffering and sometimes fatal collapse. The withdrawal should be more or less gradual.

Prevention of morphinism was more important than cure, and physicians should be careful in prescribing the drug for menstrual and other pains.

Morphinism and Melancholia.—Dr. Bishop had had occasion to treat melancholia two or three times with opium, and he had felt that in doing so he was running the risk of establishing the morphine habit, notwithstanding the fact that very good authorities had claimed that no danger attended the use of the drug in these cases. He would like Dr. Mattison to express his opinion upon that point.

Opium in Dysmenorrhœa.—Dr. H. N. Vineberg said he knew of some women who used preparations containing opium for dysmenorrhœa, but personally he never prescribed it, finding that he could give relief by a compound containing bromide of potash, antipyrin, and phenacetin. In the few cases of morphinism which had come under his observation the drug had been given less frequently for acute pain than for mental depression.

Dr. Collyer remarked that there were many conditions giving rise to pain, and that patients obtained opium not alone from doctors, but even more frequently from druggists or in patent medicines. The physician who put a hypodermic syringe and morphine into the hands of a patient did a great wrong. Morphine patients should be treated in the most humane manner; the brutal handling to which they were sometimes submitted was inexcusable.

Susceptibility to Morphinism.—Dr. Malcolm McLean had observed that some patients would contract the morphine habit after use of the drug two or three times, others could take it safely for several weeks. Morphinism should never be regarded as hopeless. He related one instance in which he cured the patient at her home, in ten weeks' time, by gradually diminishing the amount of opium in the solution, both at the drug store and at the patient's room, until it consisted essentially of water.

Dr. Mattison, in some closing remarks, expressed his belief that this was not a habit, but a disease. While it was a generally accepted fact among neurologists that patients suffering from melancholia or insanity were less likely than the sane to contract the disease, yet it was true that morphinism was possible under all conditions provided the drug were taken sufficiently long. He did not believe the man or woman lived who could resist the snare of opium, should they take it for some time.

Codeine was much less dangerous than opium or morphine, and should be given in its stead if necessary for the relief of pain. It had to be used in about three times the quantity. It had not that exhilarating effect on the mind, which was the basis of the morphine disease when opium was given. Dr. Mattison recognized, however, some risk even in the careless use of codeine.

Notes on Ectopic Gestation.—Dr. Egbert H. Grandin gave as a reason for presenting this paper the fact that in the practice of individuals there occurred cases or groups of cases of sufficient interest to make them worthy of report before a scientific body, even though the subject to which they related had been gone over frequently before.

Electricity Abandoned.—The author had repeatedly stated his conversion from the erroneous doctrine which for years he, in common with many others, had promulgated—the doctrine that ectopic gestation might very properly, from the eighth to the tenth week, be treated by non-surgical means, particularly electricity. His conversion from this doctrine had been due to the fact that experience had taught him that even before the eighth week there might be hemorrhage of a slowly progressive character. Thus, in a number of cases where the symptoms had not been very urgent, abdominal section had shown free hemorrhage and old clots. Further, his wider experience had taught him to accept the view enunciated by Dr. Janvrin, that so called colicky pains in these patients were, in fact, signals of hemorrhage. Further, his experience had taught him that women might bleed internally even though there had been absence of colicky pains. Hence he had ranged himself in line with those who claimed that in the presence of diagnosis of ectopic gestation immediate section should be the rule. Indeed, his personal experience had led him to think that even if the diagnosis were only presumptive, a clean exploratary puncture was safer than expectancy. It was only a question of very early diagnosis, and this was not impossible. In his experience strong presumption prior to operation was the rule, and absolute diagnosis the exception. Yet if due weight were given the earlier symptoms, he was satisfied that, as specialists, we would be less frequently called upon to operate on women practically in collapse.

It was stated that the symptoms of ectopic gestation were the following: Relative sterility, with recent disease of the pelvic organs; amenorrhœa; enlargement of the uterus; sympathetic disturbance; change in the breasts; irregular hemorrhage; colicky pain; presence of tumor at one side of, or behind, the uterus. With such a history, ectopic gestation could be predicted. Unfortunately, however, the woman seldom consulted a physician before the colicky pains had become severe and rupture had already occurred. An early operation would in all likelihood rescue the patient from her peril, and in order to carry it out women, as well as physicians, should be educated to recognize the first signs, stress being laid upon hemorrhage even before the occurrence of colicky pains. Hemorrhage was inconsistent with normal pregnancy, and it was the symptom which should call for pelvic exploration, not colicky pains. Hemorrhage after a period had been passed meant that, even though uterine pregnancy existed, there might be a complication. The woman should be put to bed, and if daily examination should reveal progressive increase in the local findings, we would often have strong enough presumptive diagnosis to warrant exploratory section before the woman was *in extremis* or had lost so much blood internally as to greatly retard convalescence. Two cases illustrative of this point were cited.

The first case was that of an unmarried woman, aged twenty-four, regular in menstruation; had suffered only occasionally from pelvic pains. After exposure to pregnancy, she missed a period and consulted a professional abortionist, who passed a sound into the uterus. Two days afterward, or five weeks after exposure to pregnancy, she passed a clot. Having some pain, she consulted Dr. Grandin, but he was not prepared to

give an opinion until at the end of the sixth week after the exposure, pain continuing, a hemorrhage having occurred, and a somewhat greater swelling existing at the site of the tube, he expressed the presumptive belief in ectopic gestation and advised that she enter an institution to undergo exploratory laparotomy. He found not only free hemorrhage, but old clots as well. The tube was removed, the belly washed out, and the patient made an uneventful recovery.

The second case was similar, except that there had been atypical hemorrhage for three weeks, and the colicky pains were not at all marked. He removed the unruptured tube, which lay between the uterus and bladder, there being ample evidence of ectopic gestation in chorionic villi. The patient made a good recovery.

After relating two other cases of more advanced ectopic pregnancy, Dr. Grandin concluded his paper by impressing the value of atypical flow as a diagnostic sign of ectopic gestation, and the fallacy of placing too much dependence upon the symptom of colicky pain.

The paper was discussed by the Chairman and by Drs. McLean, Leroy Broun, E. A. Ayers, Tull, Collyer, Jarman, R. A. Murray, and the discussion was closed by the author.

Dr. Malcolm McLean had not discarded electricity altogether in ectopic gestation.

Dr. H. J. Garrigues exhibited several instruments, principally those used by Jacobs in operations by the vaginal route, and also showed two uteri which he had removed by the latter method, and stated that clamps had interfered with easy control of hemorrhage which had taken place in one of the cases. He said the vaginal route, of which we heard so much at present, was only a revival.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 21, 1895.

Samuel B. W. McLeod, M.D., President, in the Chair.

Autoscope. — Dr. J. W. Gleitsmann demonstrated Kirstein's perfected autoscope, an instrument for examination of the interior of the larynx. It had a handle, an electric light calling for twelve volts and thirty ampères, a spatula covered by a horizontal plate. Its chief advantage over the laryngoscopic mirror was the fact that it enabled one to see not only as much as was shown by the mirror, but also the posterior wall of the larynx. Usually patients were tolerant of examination but about a minute at a time, but the young man shown permitted a demonstration of ten minutes' duration. Kirstein, of Berlin, had also devised instruments for operating.

Lymphoid Hypertrophies at the Vault of the Pharynx — So-called Adenoids: their Relation to Rhinopharyngeal Catarrh.—Dr. J. Solis Cohen, of Philadelphia, read this paper. The first part was a brief historical review. Only recently had the attention of the general profession been directed to disease of the glands at the vault of the pharynx, although the anatomy of the parts had received attention from Winslow and William Hunter. The paper of the late Wilhelm Meyer, of Vienna, had been so complete as to leave little for future elucidation. Its only defect lay in grouping hypertrophies with vegetations. Having described the gross appearance and stated that the structure of the follicles was identical with that of the solitary follicles of the intestine, Dr. Cohen took up the diseases to which they were liable. The adenoid structure at the vault of the pharynx might take on inflammation, hypersecretion, and even ulceration; it was liable to take on simple hypertrophy or vegetative hyperplasia, and also, as had been claimed, certain varieties of rhino-neoplasm.

Hypertrophy of the lymphoid nodules showed itself either *en masse* or as an enlargement of individual or groups of the nodules, irregularly distributed upon the vault and lateral walls of the pharynx. Both forms might occur independently of other disease, or in connection with changes in the mucous membrane of the naso-pharynx, etc.

The clinical history of these affections related to obstruction of respiration, mouth-breathing, the so-called nasal voice, irritation of dropping and dried secretions, leading to snorting inspiratory acts, headache, inability to concentrate the attention upon school or other work; when of long standing in children, in whom it occurred most frequently, it caused the lower jaw to drop, the nose became pinched, the chest sunken, the shoulders round. Deafness might accompany the condition. The subjects looked stupid and were stupid. This was not surprising when one remembered that only the occipital protuberance intervened between the lymphoid bodies and the brain, and that the lymphatic system within the cranial cavity was connected with that in the pharynx.

The treatment was by astringents, caustics, electrolysis, cauterization, extirpation by the gouge, the forceps, the snare, the finger. Dr. Cohen preferred in general to use forceps. They brought away the hypertrophied tissue, and thus avoided the possibility of suffocation by the pieces dropping into the larynx, as had happened in a few cases. If the mass refused to be withdrawn, twist the handle of the forceps round and round. Hemorrhage was rarely excessive. Topical after-treatment was superfluous, but astringent and caustic applications were sometimes made. If repeated operations were required, an interval should elapse for inflammation to subside, otherwise otitis media might result.

This treatment, which also relieved the rhino-pharyngeal catarrh, was followed by disappearance of the symptoms already named, and also in some patients by disappearance of pain in the sternum, beneath the mammæ or scapula, of nightmare, asthma, etc. Catarrh of the vault of the pharynx was by no means infrequent in tuberculosis. Constitutional treatment should be carried out according to the indications. Various instruments were shown for operating. Dr. Cohen was not in the habit of using an anæsthetic except in very nervous patients. It was not so important to get all the tissue away, but enough so that the hyperplasia would subside. The lymphoid structure here, like all other tissues, had some necessary function which should not be destroyed by removing it entirely.

Dr. Gleitsmann thought that every rhinologist found less difficulty in diagnosticating these conditions than in treating them, for the appearance of the child suggested the nature of the trouble. All were agreed that the hypertrophies should be removed, but there were many procedures for accomplishing this. His own plan was to make removal thorough, so as to prevent recurrence; he therefore gave an anæsthetic. But it was not always incomplete removal which caused return; the disease seemed then to invade the mucous membrane to its full depth. Hemorrhage was sometimes severe, but it usually stopped, although there were about six cases on record of fatal hemorrhage. Disease of the lymphoid structure in the vault of the pharynx was not infrequently accompanied by disease of the accessory sinuses.

Advocates Thorough Removal.—Dr. D. B. Delavan practised the method described by Dr. Gleitsmann, which was known as the English method, for in England it had been adopted by every man of note. Anæsthesia was one of the greatest aids in thorough removal of the growths. The proportion of recurrences had been increasing, and he thought it was due to lack of thorough removal. A fact which he thought had not been sufficiently appreciated was the frequency of

these troubles in tubercular patients, and it was extremely important to treat the local difficulty without delay.

Dr. Delavan called attention to the fact that money was being raised to erect a modest monument to the memory of Dr. Meyer, of Vienna, who had done so much to advance our knowledge of throat troubles.

Dr. Francis J. Quinlan believed that nearly seven out of every twelve children showed the facial manifestations of the pathological conditions at the vault of the pharynx under discussion. These conditions were like an open wound through which the system was being constantly infected. They were very commonly present in children contracting diphtheria and scarlet fever. It was almost impossible to cleanse the parts thoroughly. The patients were often sleepless, suffered from pains, had trouble with the ear, became dull, had chorea, etc. These symptoms had repeatedly disappeared under treatment directed to the pharynx. He presented some patients in illustration of Dr. Cohen's paper.

Diet and Muscular Exercise in the Treatment of Tuberculosis.—Dr. T. J. McGillicuddy read the paper (see p. 654).

Dr. J. Blake White did not doubt but what diet and exercise were the most important factors in the treatment of tuberculosis. When one recalled the fact that all flesh was but solid blood, he could readily see the necessity for a plentiful supply of the normal circulatory fluid whereby the system was built up and effete material was carried away. The author had properly laid stress on the importance of attention to details in exercise. He thought, however, that it was best to take exercise in the open, pure air, and he recommended bicycle riding, which permitted the body to remain passive while the respiration and circulation were active. With regard to the diagnostic value of the bacillus tuberculosis in the sputum, he believed the physical signs were often present first.

Butter for Phthisical Patients.—Dr. Max Einhorn said tuberculous patients should take plenty of food in almost any variety so long as they had not much distress from it. Butter was one of the fats most easily assimilated, and should be given freely. A quarter of a pound of it contained about as much heat as a quart of milk, and could easily be taken if it were accompanied by some meat, bread, and milk. He usually told phthisical patients to take some milk at each meal, and to take five meals a day. To the milk might be added some meat broth. He would certainly advise exercise, but it was best to take it out of doors. The patient should not overdo.

Hot Water and Ulcer of the Stomach.—Dr. Achilles Rose said he was aware that drinking hot water had become very popular, and it had become necessary to sound a warning. It had been shown by collective investigation that a great many cases of ulcer of the stomach occurred in cooks. This had led to the supposition that it might be due to tasting hot soups, etc., consequently laboratory experiments were instituted on dogs by pouring water, about of the temperature usually prescribed for patients, through a tube into the stomach. These dogs were killed from day to day and week to week, and it was found that the hot water first caused a hyperæmic spot, and, in the course of time, ulcer of the stomach. Dr. Rose was once visited by a cook whose master's physician had prescribed for her drinking very hot water. Dr. Rose found that she was suffering from ulcer of the stomach, a condition contraindicating hot-water treatment.

Exercise and Expansion of the Chest.—Dr. Jacob Teschner showed tables and photographs, illustrating chest expansion and lung capacity as increased by systematic gymnastic exercise which had been carried out under his supervision in eight cases of spinal deformities. In one case the capacity of the lung was increased forty cubic inches in two months.

Dr. McGillicuddy believed that many phthisical patients had been killed by milk punches. Milk did not contain enough proteids, and was too liable to ferment. Yet it was an excellent food for those with whom it agreed.

An Improved Uterine Nozzle.—Dr. Samuel Brothers demonstrated a method of making a uterine nozzle by holding the hollow glass rod across the alcohol flame until it became hot enough to bend. By passing the rod along and heating it and bending it at several points successively, it could be made to assume any desired shape. The canal could be cleansed by introducing a fine wire and pulling a brush through.

Therapeutic Hints.

Paludic Pathology.—There is very little doubt that the periodicity of ague depends in part on the sudden production, and subsequent liberation in the blood, of the toxins of this specific sporozoön. In certain forms of paludism, segmentation proceeds rapidly; the subjects of these forms suffer from the tertian and the double tertian forms of ague: while the long evolutions lead to a quartan, and the irregular forms are accounted for by different generations of germs, running independent courses, at times parallel but not coincident. The stirring events which underlie the phenomenon of periodicity in ague are intensely interesting. Let us take, as an example, the phases in the evolution cycle of the parasite of quartan fever.

First Day of Apyrexia.—There is a progressive growth of the parasite, with progressive transformation of hæmoglobin into a kind of melanin.

Second Day of Apyrexia.—The parasite has invaded the greater part of the blood-corpuscle.

Third Day.—This is the day of the paroxysm. It is understood that the paroxysm begins about midday; at this time the blood-pigment collects in the centre of the protozoön, the parasite breaks up, segmentation being complete, and the toxins of the organism are suddenly liberated in the circulation. They soon reach the nervous system, for which they appear to possess an elective affinity. These toxins may arrest the downward metabolism of the tissues, leading to a fall of temperature, or they may stimulate the thermogenic centres, which would lead to an increase of body heat.—Edward Blake.

Anti-Fat.—

In order to reduce his weight
He purchased him a wheel;
Before he'd ridden it a week
He fell off a good deal.

Fetid Diarrhœa.—

℞. Calomel..... 10 cgr.
Sulpho-carbonate of zinc..... 15 cgs.
Subnitrate of bismuth..... 8 gm.
Pepsin..... 2 gm.

M. Sig.: Sufficient for twelve powders. Three per diem in a child of one year.

—Tompkins.

Morphine Habit.—M. J. Luys reports the case of a physician who had been accustomed to take about seven grains of morphine daily. Small doses of sodium phosphate were given subcutaneously with glycerine and water, and as they were gradually increased the morphine was progressively diminished. In two months the morphine was discontinued entirely, and then the doses of sodium phosphate were progressively diminished and finally stopped altogether in two weeks more. There remained no desire for the morphine.—*New York Medical Times.*

Lupus Verrucosus.—A woman, aged forty, had slightly wounded the back of her hand while making the bed for a phthisical patient. The wound did not heal, and eighteen months later a patch of lupus ver-

rucosus appeared in the scar, and reached the size of a two-franc piece. It is specially to be noted that the warty form of lupus is that usually observed after professional inoculation.—THIBAUDET.

Ardor Urinæ of Gonorrhœa.—Cubebs is useful in gonorrhœa, not because it possesses any specific action against this disease, but because it has a beneficial effect in modifying the ardor urinæ, which is generally the most distressing symptom in gonorrhœa.—HARE.

For Seminal Emissions.—Hyoscine has not proved successful in my hands, but I have attained perfect results by the administration of Thuja occidentalis (fluid extract) in six- to eight-drop doses, thrice daily, half an hour before each meal.—DE WITT.

Diarrhœa in Infants.—

℞ Benzonaphthol,
Bismuth subnitr.,
Resorcin ..... āā gr. jss.
M. Sig.: For a child one or two years of age one such powder every two hours until six have been taken.

—EWALD.

Diphtheria.—

℞ Alcohol ..... 60 parts.
Toluol ..... 36 parts.
Liq. ferri perchloridi ..... 4 parts.

For the relief of pain menthol may be added. The infected patches are to be swabbed with this every two to four hours.

—LOEFFLER.

Reflex Causes of Nervous Disease.—1. The essential feature in the production of many neuroses is the neuropathic state—the degeneracy of the subject. 2. In hysterical subjects suggestion plays an important part both in the development and in the cure of the symptoms. 3. Disease of any organ may give rise to referred pain in some definite area, but not to other nervous disturbances, except as a secondary result of local disease of the organ. This local disease manifests itself by the ordinary local symptoms, and the nervous phenomena are due to exhaustion, anæmia, intoxications, etc. 4. In a few rare cases injury of a sensory nerve may give rise to epileptiform seizures. 5. Surgical operations for the relief of nervous symptoms should never be performed unless there are clear indications, apart from such symptoms, for an operation.—KNAPP.

Croup.—Use pilocarpine as a specific in all cases in which the mucous membrane becomes covered with a transudate apt to coagulate. The abundant secretion of mucus produced by the pilocarpine tends to loosen the fibrinous exudate adherent to the membrane, and it is readily expelled from the larynx. The pilocarpine not only assists in dissolving and removing the membrane present, but also tends to prevent its reforming. It can be administered to children from one to three years of age in doses of 0.01 to 0.03 gm.; three to six years of age, 0.03 to 0.04 gm.; six to ten years of age, 0.05 gm.; ten to fifteen years of age, 0.06 to 0.07 gm.; adults, 0.07 to 0.1 gm.—SZIKLAI.

Chorea.—The disease to which the term chorea has come to be almost entirely confined, viz., chorea minor, or Sydenham's chorea, is essentially a disease of childhood, the vast majority of cases occurring between the ages of five and fifteen; but common though it be in childhood, it is very rare indeed in early infancy, very few cases having been recorded under four years of age. One or two have been met with in children at the breast, and from time to time accounts appear in the medical journals of instances of "congenital chorea." In systematic treatises on medicine these cases, as a rule, are not even referred to.—JOHNSTON.

Insomnia.—

℞ Antimonii et potass. tartrat. ..... gr. i–ss
Morphia sulphat. ..... gr. ss–j
Aq. laurocerasi ..... ℥ ij
M. Sig.: Teaspoonful every two, three, or four hours as required (in wakefulness of fevers).

—BARTHOLOW.

Nasal Catarrh.—In cases of chronic nasal catarrh where the mucous membrane is congested and irritable, a solution of equal parts of distilled extract of hamamelis and water sprayed in the nose often does very well, but first the nasal cavities must be well cleaned.—HARE.

Chronic Constipation.—

℞ Aloës ..... gr. iv.
Strychniæ sulphat. ..... gr. ½
Extract. belladonn. ..... gr. ½
Ipecac. pulv. ..... gr. ss.
Divide in pil. xij.
M. Sig.: One every evening.

Chronic Pharyngitis.—

℞ Iodi ..... gr. vj.
Potassii iodidi ..... gr. xij.
Mentholis,
Glycerini, q.s. ad ..... āā ℥ i.
M. Apply with a camel's-hair brush twice or thrice daily.

The Argyll-Robertson pupil has, in its typical form, three symptoms, viz., loss of light reflex, retention of accommodative movements, though they may be sluggish, and myosis, as minute, perhaps, as the pin-point pupils of opium narcosis.—GORDINIER.

Bronchitic Asthma.—

℞ Potassii iodidi ..... ʒ ij
Ammon. carb. ..... ʒ j.
Tinct. lobeliæ ..... f ʒ ij.
Sp. chloroformi ..... f ʒ iv
Vin. ipecac ..... f ʒ j.
Infus. senegæ, q.s. ad ..... f ʒ vj.
M. A tablespoonful in a wineglassful of water every four hours.

Blisters of Feet from Long Walks.—

℞ Saponis nigri ..... 52 parts.
Aquæ ..... 27 parts.
Vaselin. ..... 15 parts.
Zinci oxidi ..... 6 parts.
Essentiæ lavandulæ, q.s.
M.

Incontinence of Urine.—

℞ Tincturæ belladonnæ,
Tincturæ cubebæ ..... āā f ʒ j.
Tincturæ nucis vomicæ,
Tincturæ rhei aromaticæ ..... āā f ʒ j
Tincturæ cascarillæ ..... f ʒ j.

Twelve drops at bedtime for a child from seven to ten years.

Conjunctivitis.—

℞ Acidi borici ..... gr. xx.
Sodii chloridi ..... gr. viij.
Aquæ destillatæ ..... f ʒ iij.
M. Sig.: Use freely as a lotion every four hours, first washing.

Membranous Dysmenorrhœa.—The os externum is scarified at intervals of three or four days between the periods; just before the flow is expected the cervix is dilated, the interior of the uterus is thoroughly curetted, and a spiral wire stem is introduced, which is worn continuously during at least three subsequent periods, the patient being directed to take hot vaginal douches even when menstruating. No harm has resulted from the use of the stem, and the patient is able to attend to her ordinary duties.—DUKE.

Herpes Zoster.—

℞ Boric acid ..... gr. x.
Glycerinæ, q.s., vaselinæ ..... gr. xl
Cocaine hydrochlorate,
Extract. of opium ..... āā gr. ss.
M. The neuralgia following the eruption is best treated by Fowler's solution.

—KAPOSI.

"**New Drugs** are added every day for the benefit chiefly of those who do not know how to employ the old ones."—BROADBENT.

Gonorrhœal Rheumatism.—In an equal number of males and females attacked with gonorrhœa the males will be found to suffer more frequently from gonorrhœal rheumatism than the females.—LUSHRETH.

Heart Disease Treatment.—The system comprises bathing in a mineral water, associated with slowly cor-

ducted exercises. The water, which is strongly impregnated with common salt, is also charged with large quantities of carbonic-acid gas, the presence of which causes the water to escape from a depth of several hundred feet below the earth's surface at considerable pressure. The water is conveyed to the baths by this natural pressure, and when the tap allowing its entrance into a bath is turned on, the foaming water rushes in with such rapidity and force that, unless care is exercised, spray may be scattered over the bath-room. After the tap has been turned off the turmoil quickly ceases, but multitudes of small bubbles rising through the clear water reveal the presence of carbonic-acid gas.—SCHOTT.

Psoriasis.—

℞. Ichthyol,
Acid. salicylic.,
Acid. pyrogallic.,
Aristol.....ää gm. 2.
Vaselin,
Adipis,
Lanolin.....ää gm. 30.
M. A powerful ointment, to be used in small quantities.

Hæmostatic Action of Antipyrine.—One of the antipyretics most in use, namely, antipyrine, has a powerful hæmostatic action. This property I discovered in 1884, in the course of some experiments with the drug. The hæmostatic action is local, and its mechanism is vaso-constriction and retraction of the tissues, with formation of a minute clot which is extremely retractile and aseptic. Antipyrine has also a favorable effect on cicatrization.—HENOCQUE.

Chronic Rheumatism.—

℞. Sodii salicylatis..... ℥ iv.
Potassii iodidi..... ℥ j.
Methylis salicylatis..... f ℥ j.
Extracti cimicifugæ fluidi ..... f ℥ ij.
Alcoholis ..... f ℥ iv.
Aquæ anisi.....q.s. ad f ℨ iij.
M. Sig.: Shake well and take a teaspoonful in water three times a day.

High Altitudes in Phthisis.—It is unsuitable for those in whom a large area of lung is involved, or when pyrexia, sweats, and great loss of flesh exist. Nervous cases and those with cardiac complications should avoid the higher altitudes.—WANHAM.

Tuberculosis.—The process extends in the lungs in the following ways: First, by direct continuity, preferably along lymph channels; secondly, by the formation of fresh foci by tubercular bacilli, which are carried in the lymphatic circulation for some little distance in the lung; thirdly, the most important of all, a cavity having formed in the lung, its secretion escapes into the surrounding bronchus, and is expelled by cough. But the discharge of sputum is apt to be incomplete, and their infective material is liable to be sucked back into other bronchi, and into healthy lung tissue, and thus arise fresh centres of disease.—PERCY KIDD.

Marasmus.—From the bodies of dead bacilli a toxic product is formed, unaffected by light, heat, drying, or time, causing marasmus even when in the most minute doses. It is transmitted to the fœtus from the parent, and sets up chronic bronchitis, and during life it is very rarely diagnosed from simple chronic bronchitis. —MAFFUCCI.

A Grave Offence.—Whoever adds one tittle that is unnecessary to medical education is guilty of a very grave offence.—HUXLEY.

Tuberculosis.—

℞. Morson's creosote..... ℥ cxxviij.
Ol. menth. pip..... ℥ xxx.
Spts. chloroform..... ℥ ij.
Tr. gent. co..... ℨ j.
Tr. nux vom..... ℥ iij.
Spts. frumenti.....ad ℨ viij.
Sig.: One drachm three, four, or five times a day in water (a wine glassful).

—MARR.

Surgical Suggestions.

Abdominal Incision.—1. The line of parietal incision should be made parallel with the direction of the most important muscular fibres. 2. Separate where possible and do not divide aponeurotic fibres: where division is necessary, let it be in a direction which will permit of the leaving intact one or other of the muscular layers behind the division, or in front of it, or parallel to it. If no one of these practices is possible, then a flap entrance should be made, that is to say, the weak points do not all overlie; they are made at different levels in the parietes when union is made. 3. Keep away from the bony margins, and avoid the thickest and most mobile parts of the parietes. 4. Let the incision be as short as is consistent with efficiency. A long incision with separation of muscular and aponeurotic fibres is better than a short one with division of fibres. The leading principles for our guidance in the closing of a parietal incision are: 1. The apposition of raw surfaces should be as broad as possible. 2. Each divided structure should be placed and kept opposite its fellow. 3. The sutures should not be removed early. If the parts are kept together firmly for three weeks or a month, we have done the best we can to prevent stretching of the cicatrix.—GREIG SMITH.

The Causes of Shortening of the Femur may be classified as follows, viz.:

(*a*) Impacted fracture of the neck of the femur. (*b*) Arrest of growth of the neck following disease the result of injury. (*c*) Disease of the hip-joint. (*d*) Arrest of growth at the lower end of the femur from disease of the epiphysis. (*e*) Arrest of growth of the lower end of the femur following disorganization of the knee-joint.—THOMAS BRYANT.

Furuncles.—In the treatment of boils coming in crops, colchicum is recommended in doses of from one-third to one-half of a grain each day.—*Dominion Medical Monthly.*

Appendicitis.—In operating, as a rule, remove the appendix. It is bad surgery to leave the appendix unless the adhesions are very marked and cannot be separated without the risk of harm. Where there is liability of breaking into the general peritoneal cavity, do not search for the appendix. Where there is a tumor make the incision over the tumor. We should not go through the peritoneal cavity. It is rare to have an appendicitis going on to a condition of distinct tumor without pus being present. It is better to operate before any appreciable tumor has formed. In cases of tumor operation is advisable, even with a normal temperature or a declining temperature.—KEEN.

Keloid.—While a keloid is growing, its removal by the knife should not be attempted; repeated scarification or multiple electrolytic punctures sometimes succeed in destroying it.—KEEN.

Ulceration of Rectum.—The three great factors, therefore, in my opinion, in producing ulceration of rectum are tuberculosis, syphilis, and cancer.—MATTHEWS.

Fistula in Ano.—1. Never sever the sphincters at more than one place at the same operation, no matter what the complications may be, otherwise incontinence is sure to follow. 2. Unless all the channels are followed up and laid open, the operation will fail of its purpose. 3. Fistula resulting from tubercular abscess must not be operated upon if there is sufficient tissue destruction of lung to produce hectic fever, sweats, etc., unless the fistula is causing severe painful spasms, of the sphincters, then it should be divided at any stage. 4. After laying the fistula tract open, the wound must be made to heal from the bottom, and as the cutaneous or mucous side of the wound is better nourished, it will throw out a more healthy granulation

that tends to bridge over and close the slower granular surface at the bottom, thus leaving a fistula remaining. 5. When the fistulous tract is not too complicated it should be dissected out entire and the wound brought together, beginning at the bottom with continuous catgut sutures and approximating the surface in successive layers until the whole wound is closed.—Bacon.

Pott's Disease is an osteitis, usually tuberculous, of one or more vertebræ, resulting in necrosis or caries.—Burr.

Extra-uterine Pregnancy.—Every diagnosed extra-uterine pregnancy calls for surgical interference.—Pinard.

Carbuncle, it is said, has been arrested in its development by the injection into different parts of the tumor of five drops of pure liquid carbolic acid at each point.

Fungus Cerebri.—Pressure by sponges or dressings sometimes yields good results, but at other times convulsions follow the application of pressure, when it must be abandoned.—Keen.

Hemorrhoids.—

℞. Acid, gallic ..... gr. x.
Extract, opii ..... gr. iv.
Extract, belladonnæ ..... gr. v.
Unguent, simplicis ..... ʒ iv.
M. Sig.: Apply locally night and morning.

—Hare.

Tuberculosis.—Surgical tuberculosis is of far more frequent occurrence than is generally supposed. Kocher states that ninety per cent. of the bone and joint cases in his clinic are tuberculous. Tizzoni, in Italy, has lately examined lymphatic glands of 47 persons who met violent deaths and who were, apparently, in perfect health. Strange to say, he found tubercle bacilli present in 43 of the subjects.

Suppurative Nephritis.—1. Pyelonephritis is the result in the great majority of cases of infection by the bacterium coli commune; in a fewer number of cases through proteus or the more ordinary forms of suppurative cocci. 2. In a certain number of cases in which the ordinary pyogenic microbes are the cause of irritation a consecutive pyæmia results. 3. Pyelonephritis resulting from the irritation of staphylococci and streptococci is not to be differentiated from the other forms alone by the pyæmia present, but also microscopically by the marked necrosis of tissue, and the absence of increased inflammatory tissue-formation which is produced by the bacterium coli commune. 4. It is not probable that the typical ascending pyelonephritis can be produced by the passage of micro-organisms from the bladder through the circulation.—Von Wunschheim

Epithelioma.—The formula for Marsden's paste is as follows:

Acid arsenious ..... 2 drachms.
Pulv. gum arabic ..... 1 drachm.
Cocaine muriate ..... 18 grains.

When you are ready to use this it should be made into a paste by adding water. The paste should be of the consistency of rich cream and should be applied on a small piece of cloth, which is left on from eighteen to thirty-six hours. This can be repeated as often as is necessary. The above is the formula for the stronger paste. In the weaker preparation use only one drachm of arsenious acid and twelve grains of cocaine. Marsden's original formula consisted only of equal parts of arsenious acid and gum arabic. The cocaine has been added to counteract the pain.

Essentials for Administration of Anæsthetics.—Allis's ether inhaler and ether bottle (graduated), Esmarch's chloroform inhaler and chloroform bottle (graduated), hypodermic syringe and tablets of morphine, morphine and atropine, atropine, strychnine, digitalin, and nitroglycerin, whiskey and aqua ammonia F., mouth-gag, throat sponge-holder and small sponges, catheter, pocket-case, and tracheotomy tubes. By many the battery is considered an additional safeguard, although I have found little or no use for it.—Strouse.

Carcinoma of Stomach.—1. The treatment of these tumors differs in no respect from that of cancer elsewhere. It is purely surgical. 2. Operation is to be recommended when possible, before the tumor is palpable. 3. Examination should only be made under deep narcosis, and an exploratory incision made if required. 4. Those cases only should be recommended for resection of the pylorus where the tumor is freely movable, and there is no metastatic involvement. 5. If these conditions are not present, the formation of a fistula between the stomach and jejunum is indicated. 6. This operation should not be delayed until the patient is nearly dead of hunger, and the knife then used as a last resource, for the mortality is then much greater.—Klemm.

Tumors of the Subcutaneous Tissue or of the intermuscular facia should be removed as often as they recur, and if a limb is deeply involved it should be amputated.—Keen.

Fractures.—The time has come when all compound fractures should be treated by uniting the ends of the bone, the wound being thoroughly irrigated. Five cases of apparently hopeless fractures of the ankle-joint are reported by Balch as terminating in very good results.—Tyson.

I indorse the view that the angle between the neck and the shaft was normally unaffected by age, and that osseous union might take place in several forms of fracture of the cervix femoris.—Sir William Stokes.

Coccygeal Dermoid Cysts.—Points of interest in connection with them are: 1, Their comparative frequency; 2, their tendency to suppurate; 3, the difficulty of getting healing by first intention after excising them (doubtless on account of the close proximity of the anus); and 4, the tendency they have to undergo epitheliomatous degeneration.—Weeth, Abbe, and Others.

Fear in Chloroform Narcosis.—From the effect just named I should be inclined to put down fear as one of the most determinate causes of fatality from chloroform. I have before me several instances in which it is impossible that chloroform, minus fear, could have been the direct cause of death, because sufficient of it was not administered to produce death.—Richardson.

Boils.—Gouty people are often attacked by successive crops of boils. Treat such cases by the internal administration of colchicum. In one case the boils quickly disappeared under the influence of the colchicum, but reappeared when the drug was stopped. Locally apply strong tincture of camphor.—Brocq.

Sycosis.—The following treatment is recommended for sycosis dependent on staphylococci: In slight cases I apply a sulphurated zinc paste, to which a five-per cent. solution of carbolic acid has been added, and in severe cases advise cauterization with a twenty to fifty-per cent. solution of resorcin in alcohol. In the most rebellious cases use an ointment of pyrogallol or of chrysarobin.—Leistikow.

Trusses.—Trusses for hernia were known to the Phœnicians nine hundred years before Christ, as is shown by a votive image recently found at Soussa, in the possession of Dr. Poucet, chief medical officer of the French army in Tunis. The statuette is of terra cotta, representing the Egyptian god Bizou; but around its waist is an elaborate and efficient metallic truss. Various forms of hernia are shown in the figure, which *The Lancet* calls a perfect museum of hernial pathology.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING SOCIETIES — INEBRIETY — HOSPITAL SATURDAY FUND—CHARING CROSS HOSPITAL—AGED PROFESSORS—PUBLISHING SEASON—DEATHS OF SIR T. LONGMORE AND SURGEON-GENERAL MASSY—SCARLET FEVER—TYPHOID—MEDICAL PAPERS AT A TEMPERANCE CONGRESS — THE SOCIETIES, CLINICAL, MEDICAL, OBSTETRICAL, PATHOLOGICAL — LORD WOLSELEY AND ARMY SURGEONS—DEATHS OF SIR T. CRAWFORD AND DR. THOMAS KEITH.

LONDON, October 12, 1895.

Now that the schools are in full work, the societies are waking up, and we shall soon be flooded with papers and discussions. Some societies, indeed, have already met, and one or two took very brief vacations. There is some sort of a fixture for every day in the coming week, and those who have hardly digested the papers of the several Congresses which have been held here or on the Continent, may well sigh at the copious pabulum provided. As an oppressed one lately observed, there are too many courses at our dinners, and our intellectual diet is just as heavy.

The Society for the Study of Inebriety puts in an appearance early in the session. On the 3d, Dr. Norman Kerr, president, opened a discussion on Probationary Curative Detention, and pointed out the difficulties of the poor as compared with the rich. The latter can enter an asylum as voluntary boarders, without being certified as lunatics, but the poor have not this opportunity. He advocated hospitals for the treatment of mental disease, in which patients could remain six or eight weeks, and if then not improved could be sent to an asylum. He predicted that twenty years hence we shall have, 1, probationary curative mental hospitals; 2, asylums in separate blocks as in some American buildings; 3, convalescent homes to render the re-entrance of patients into ordinary life less abrupt and less trying to them. The proposals were well received and supported by several speakers.

The Hospital Saturday Fund is appealing for further support. It has been established twenty one years and has disbursed about £200,000, but the need of the hospitals is always increasing. For some time now this society seems to have been well managed. It is free from the absurd prejudices of the Sunday Fund, which is gathering up against it all the supporters of special hospitals. The Saturday Fund treats all applicants fairly, and assists ambulance service and the societies which provide surgical appliances.

Charing Cross Hospital appears to be the owner of Toole's Theatre, and the lease having lately terminated the County Council insists on some alterations. These will cost money, and the hospital is in low water. Of course, the Council is bound to see that its requirements are carried out for the protection of the public. If the hospital managers are in such straits for money, they might have been wiser to fall in with the recent proposal to remove to South London, and sell their very valuable site. We could well spare it, as there is ample hospital accommodation within a short distance.

Worn-out professors are threatened. A treasury committee has presented a report recommending fixed rules to be applied as to the retirement of professors. It is proposed that at the age of sixty-five years the president of his college shall make a report as to the working of the incumbent's chair. If satisfactory, he may occupy it up to seventy years, but not longer. Presidents themselves are to retire at seventy years—in special cases, seventy-five years. What will be the good of such rules? A president of sixty-six years say, reporting on a professor of sixty-five! Should not each case be considered on its merits by competent persons, outside the probability of prejudice for or against?

The medical publishing season is likely to be a busy one. A number of new books and new editions are already out, and fresh announcements are following fast. The three first volumes of the "Twentieth Century Practice" have reached subscribers, and the scheme excites some interest among the more literary members of the profession. The undertaking is considered a great one, and the publishers are commended for their enterprise and the editor for his industry and care.

The first volume of a report of a committee of the Medico Chirurgical Society, on "The Climates and Baths of Great Britain," forms a notable publication. The committee is continuing its labors. It consists, of course, of Fellows of the Society, so that some of our chief climatic authorities are conspicuous by their absence, and one or two names almost excite a smile—though it is quite possible they know more about climatology than their devotion to other subjects would lead us to suppose. This volume is devoted to our southern climates and our chief springs; it includes a mass of facts more or less interesting, collected with no little trouble, and it will prove a good storehouse for those who are capable of critically examining the subject; for a critical digest is not attempted in this report, and would hardly be expected from a committee constituted in this manner, and which has spent much of its energy in collecting facts from local doctors, and deputing one or other of its members to visit some of the resorts.

Of other works ready or announced, I may mention "Munk's Life of Sir H. Halford," who was physician to four of our sovereigns; "Translations of Kaposi's Skin Diseases," "Herab's Ophthalmoscopy," "Knie's Eye Diseases in Relation to Other Diseases," a new edition of "Barr's Ear Diseases," and a book on "Deaf-mutism," by Drs. Love and Addison. Professor Macalister has ready a "Text-book of Physical Anthropology," and a second edition of Darwin and Acton's "Physiology of Plants" is announced. Then the first volume of "Transactions of the Recent Congress of Hygiene and Demography" is being delivered to members, and the others will follow in due course.

Sir Thomas Longmore, formerly Professor of Military Surgery at Netley, died suddenly on the 30th. He went to see his son start by an early train, and died within an hour and a half. He served through the Crimea and the Indian Mutiny, and was a Surgeon-General, Knight Commander of the Bath and of the Legion of Honor, Honorary Surgeon to the Queen, etc. His "Optical Manual" is a standard on the eyesight of soldiers, and besides contributions to journals he wrote "Gunshot Injuries," of which a new edition is just out, "Transport of Sick and Wounded Troops," and other works, including a "Life of Wiseman," the surgeon of Charles II.

Surgeon-General Massy, C.B., died on September 27th, aged seventy-five. He had a distinguished career, served through the Crimea and the Indian Mutiny. He received the Crimean medal with four clasps, the Turkish medal, the Medjidie, and the Indian medal with clasp. He retired in 1880, with a "good service pension," after thirty-six years' army service.

Scarlet fever is prevalent at the West End. In Marylebone, Dr. Blyth, medical officer of health, reported last week that day after day cases were occurring for which the asylums board failed to find room in their fever hospitals. The chairman of the sanitary committee proposed to provide for such cases, but his vestry rejected the motion in order to compel the asylums board to do their duty. But this board's hospitals are crowded, and the difficulty of obtaining sites for new ones is notorious. Still a dead-lock must not be permitted in presence of a threatened epidemic.

At the East End typhoid fever is prevalent. Diphtheria, if not spreading, seems to be taking a fatal type.

London, October 18, 1895.

Among the recent congresses that have demanded attention from the public and profession, that held at Chester by temperance reformers claims notice, inasmuch as it devoted a section to the scientific aspect of the questions involved. The congress was called by the National Temperance League, an organization which attempts to promote its views exclusively by moral suasion, and not by any form of compulsion or legislation. It was a bold stroke to assemble at Chester —the bishop of which diocese is the author of the programme for improving public-houses. The congress was a remarkable success, largely due to the energy, zeal, and organizing capacity of the Secretary of the League, Mr. Robert Rae. But it is to the scientific section I must confine my notes, and in this the doctors had it almost to themselves. Sir B. Richardson presided in his usual genial and confident manner. He was President, too, of the whole congress, and gave a capital address. If any fault can be found with his appearance in such a capacity, it is on account of the self consciousness which he wears so obviously. He has done very good work, none better than his temperance advocacy: but he is not the only scientific student, and may excuse an American journal for reminding him of this fact, so patent to others.

Dr. W. Carter, Professor of Materia Medica in the Liverpool College, and Physician to the Infirmary, laid down in his paper that: 1, Abstainers from alcohol live longer than those who use it moderately; 2, they work harder and longer; and, 3, their intellectual energy is as great and as well sustained. Allman showed, in 1879, that as little as 1 of alcohol in 800 was injurious to protoplasm, and yet, said Dr. Carter, moderate drinkers send to their several organs more than 1 in 800 at least once, often several times daily.

The next paper was by Dr. Cosgrove, Professor of Biology at the Royal College of Surgeons in Ireland, who said various observers in the last few years had tested the effect of alcohol on the special senses, and all agreed that it was a narcotic *ab initio*, and not, as formerly supposed, a stimulant first. "Short Life, Less Work, Worse Work, that is the Output of Alcohol," was the burden of this paper. In exchange it "narcotizes the mind as well as the body, hides from us the truth about ourselves, and makes us satisfied when we ought to be ashamed."

Mr. Vacher, Medical Officer of Health for the County of Cheshire, read a paper entitled "Alcohol, the Antagonist of Hygiene." He maintained that partaking of alcohol was opposed to personal hygiene and stood in the way of sanitary improvements, thwarting the efforts of the authorities by rendering the people less capable of distinguishing between the good and evil of their surroundings as they drink of the river of Lethe.

Dr. Walmsley, Superintendent of the Metropolitan Idiot Asylum, took as his subject, "Drink as a Factor in the Production of Insanity." He pointed to the well known fact that alcohol is responsible for more mental and physical suffering and incapacity than any other single cause. We do not cure insanity, he said, but of 11 persons who became insane, 9 ultimately died insane, and of the other 2 only 1 recovered. A single law forbidding the marriage of tainted persons, and one preventing people driving themselves mad with drink would, he declared, be worth more than all our lunacy laws. The discussion was joined in by one or two laymen, and several suggestions made respecting the manner of prescribing alcohol when physicians thought it proper to do so. After which Dr. Williams, of Flint, remarked on the difficulty arising from the public faith in alcohol, for they were continually asked if a little wine or spirits would do good, and when the doctor said no, other advice was sought and he lost the patient. He thought the battle could only be fought by the doctors becoming abstainers themselves.

The Clinical Society met last Friday, when Mr. Godlee, Vice-President, took the chair in the absence of the President, whose inaugural address was therefore postponed. Mr. A. Lane read notes of four cases of bony ankylosis of the temporo maxillary joint on which he had operated with success. Several such cases were mentioned by the speakers who discussed, and it was remarked that it would be well if the cases could be seen, as it would be interesting to notice whether any deformity resulted. One or two other speakers said they could bring cases.

"Cardiac Syphiloma" was the next subject, several cases of sudden death being mentioned, in some of which gummata were found. It was held that cardiac symptoms, which could not be due to an ordinary lesion, if they occurred in a patient who had had syphilis, might be ascribed to gumma or fibrosis of that character, and should be treated by iodide. A case of injury to the knee-joint, for which arthrotomy was performed, was then related, and some other cases mentioned.

The Medical Society of London held its first meeting on Monday, when the new President, Sir Crichton Browne, delivered an inaugural address on the "Generalization of Specialism," after which a paper on the "Radical Cure of Hydrocele by Excision of the Sac" was read by Mr. Lockwood, and discussed by several of the surgeons present.

At the Obstetrical Society there was a paper on the "Variation in Height of the Fundus above the Symphysis during the Puerperium," and another on "Certain Micro organisms of Interest to Obstetricians and Gynecologists." It was stated that the next meeting should be special for the purpose of considering proposed alterations of rules.

The Pathological Society opened without an address and went straight to work. There was a good show of specimens. Most of the other societies are in full work.

I told you Lord Wolseley would be no improvement on the Duke of Cambridge, so far as friendliness or justice to army surgeons is concerned. I predicted the change would only be between King Stork and Log. The *Pall Mall Gazette* seems wakening to this, and alludes to rumors of drastic changes contemplated by the new commander-in chief. He had better take warning, or he may yet be held responsible for the destruction or disorganization of the medical department. At one of his last parades he said of the medical staff corps: "They are not soldiers, but civil attendants on the sick." He has on other occasions been most offensive; in fact, his conduct toward medical officers has more than once been rather that of a snob than of an officer or a gentleman.

Sir Thomas Crawford, K.C.B., died on Saturday last. He entered the army medical service in 1848, and had a distinguished career. He served in the Crimea and India, and became Surgeon-General of Her Majesty's Indian forces. Eventually he became Director-General of the Medical Department of the Army, from which he retired in 1889. As head of the department he was assiduous in his office and careful of the rights of officers serving under him. Though there may perhaps be here and there one who thinks he deserves more than he has received, he may be sure Sir Thomas carefully weighed the circumstances and did what he believed to be justice, as far as it was possible for the head of the department to do. He was a man capable of an immense amount of work, was a master of detail, and the success of the department in every expedition in which he was the chief, is a standing proof of his zeal and forethought. His wife died in the spring, this year, leaving him with eleven children. His intimate friends noticed that Sir Thomas never seemed the same man after Lady Crawford's death. Lately he

suffered from bladder trouble, and uræmia came on and closed the career of one of the most zealous and conscientious public servants. All who knew him—of which I am one—speak well of him.

Another distinguished surgeon, with whom also I was acquainted, has passed away; Dr. Keith, the successful ovariotomist, is dead. His greatest results were obtained in Edinburgh, where he passed most of his life, but for the last few years he has lived in London. He was one of the pioneers in ovariotomy, having performed his first operation in 1862, from which time he continued to have remarkable success: his mortality-rate on the average not exceeding five per cent. Before the antiseptic period his extreme care to insure perfect cleanliness was noteworthy. Nevertheless he embraced the Listerian views, and his successes increased, and once he had, I believe, eighty consecutive successful operations. Dr. Keith was more or less of an invalid throughout his career, yet he bore his troubles so bravely that many may be surprised that he endured them. Those who knew him wondered rather at the spirit he displayed, and that, handicapped by ill-health, he should have achieved so much. It is needless to dwell on what he did, for his name is a household word with your readers. America mourns with England his loss.

THE ETIOLOGY OF CANCER.

To the Editor of the Medical Record.

Sir: In your recent editorial in answer to the question, "Is Cancer Inoculable?" you state that "A person predisposed to any disease is always an easy victim when any definite exciting cause presents itself, while one without such tendency escapes every time." This remark is the very key that unlocks the secret cause of this terrible disease. Years ago I became satisfied that such predisposition exists in every case, and this predisposition, or remote cause, I have found to be slow mercurial poisoning. Such a condition existing, any traumatism may develop the disease. Smoking a dirty pipe may start it on the lips or tongue, irritation of the breast or uterus in female, or any other traumatism that may accidentally occur in any part of the organization. I have carefully searched out the history of many cases and have never yet failed to discover that such persons had been subjected to a process of slow poisoning from the use or abuse of this poison. Remember this, and see what the future brings to light on this subject.

Truly yours,

J. S. Prettyman, M.D.

Milford, Del., October 1, 1895.

HOSPITAL REFORM—A GROSS INJUSTICE.

To the Editor of the Medical Record.

Sir: As one who is not a "Professor," and has long since retired from active hospital work, permit me to express my indignation at the methods of the medical schools and the "combine," that has resulted in the precipitate dismissal of a number of much respected and well-equipped medical men from hospital positions they have long and honorably held. Why a small body of men should arrogate to themselves the right to keep the larger number of their fellows who have had no college position either from choice, bad fortune, or modesty, from the privilege of practising in the hospitals is a distinct infringement of individual liberty, and a showing of conceit which should promptly be met by a refusal to call any of them in consultation by the rank and file of the profession whose rights have been assailed.

I find by referring to the *Medical Register* that only about two hundred men are directly connected with the five medical schools in this city, while the entire number of regular physicians exceeds three thousand. This seems a ridiculous minority to dictate to the larger number, which includes some of the best and most distinguished physicians and surgeons, not only of New York but of the world.

It is high time that some organized movement was instituted to combat the college rings, for not only do we find through their agency abuses of medical charity, such as exist at the Vanderbilt Clinic and New York Hospital particularly, but at least one institution that has been run for the financial benefit of the faculty has made an application for, and obtained, a $60,000 appropriation from the city for next year.

An Outsider.

New York, October 29th.

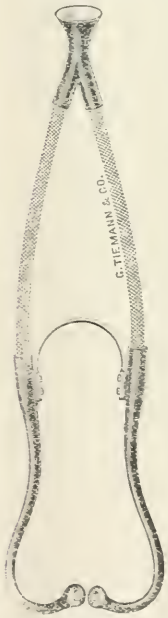
New Instruments.

A NEW AND IMPROVED STETHOSCOPE.

By MARK I. KNAPP, M.D.,

NEW YORK.

The proximal and distal parts of this instrument consist of the hardest suitable metal, German silver, covered with a layer of hard rubber. The elastic tube is made of a spiral German silver wire, the rings of which are in very close apposition, so as to practically be one solid tube. This is also covered with rubber, which is either soft vulcanized, to retain its elasticity without breaking, or remains entirely soft and is then woven around with wool or silk. This metal elastic tube is soldered on to the heart and ear parts in such a manner as to present one continuous equable calibre. For that reason the ear parts at the point of joining with the middle part bulge out so as to receive the latter. The spring is screwed into a projection of hard rubber in such a mode that the screws do not touch the metal of the ear-pieces. Besides the specific intention of such a union between the spring and the ear-pieces, it has the advantage that the spring, when rusted or otherwise injured, can easily be replaced.



Now, as to the absolute superiority of this instrument, or rather to its being the ideal stethoscope, long sought for.

When beginning to learn the value and practice of auscultation, as a student, I found what all of us know, that while striving to perceive the pure cardiac or pneumonic sounds, I heard along with them the humming, buzzing sound so familiar to us with all stethoscopes but one—Denison's. As a consolation for that misery our teachers told us that we would have to get used to it; but unfortunately, by the time we can get used to these disturbing sounds we are able to do away with the stethoscope altogether.

Meditating over the possible causes, so plentifully inquired after, it occurred to me that the buzzing came not from within, the stand taken by all my predecessors, but from without. It seemed to me that the humming came from the sound-waves always and ever

present in the atmosphere—not heard by the naked ear, although appreciated by some animals—and which are noted through the medium of the metallic ear-pieces, which are good conductors of sound. Sound-waves are always present, due if to nothing else than to the motion of the several layers of the atmosphere which are of different density. The remedy suggested itself at once. Retain the good sound conductor—metal—to convey the sounds which we want, and stop the sounds we do not want by a bad sound conductor. I therefore covered my metal stethoscope with a piece of soft-rubber tube, and my reasoning proved to be successful.

The instrument I now present to the profession, made by the best firm in surgical instruments, Messrs. Tiemann & Co., is of unexcelled quality as a stethoscope, based upon a true scientific, physical, acoustic law. It is all metal within, to best convey the sounds we search for, and all rubber without, to cut off all external sounds, thus giving us not only a very clear and distinct, but a very much intensified, sound. If I should be permitted to use microscopic terms, I would say that this new instrument is the high-power stethoscope. True enough, we hear no buzzing with the Denison stethoscope, it being made of rubber, but unfortunately we hear with it yet less than with the ordinary instruments.

Therefore I recommend this new stethoscope, tested by prominent gentlemen, for its unexcelled, ideal qualities, and its very neat and pleasing appearance.

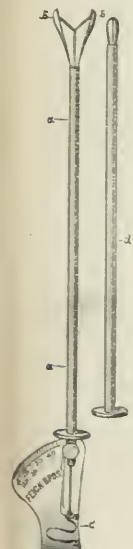
141 SUTTER STREET.

A NEW URETHROMETER.

By R. W. STEWART, M.D.,

SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

A GOOD urethrometer should have the following requisites: 1. It should be simple in construction and easily taken apart for the purpose of cleansing. 2. It should be small in calibre in order to permit of its passage through a narrow urethral canal. 3. It should be so constructed that it will automatically exert a uniform degree of pressure against the urethra, regardless of the variability in the size of the different portions of the latter.



After considerable experimentation, with the view of constructing an instrument that would conform to the above requirements, the writer begs to submit to the profession the following instrument.

The cut given of the instrument illustrates it so well that a detailed description would be superfluous. Suffice it to say that it consists essentially of a cannula *aa*, terminating in two measuring arms *bb*, which open by virtue of their spring-like action aided by the spring *c* on the handle of the instrument. The measuring arms are closed and liberated by moving the tube *d* up or down on the cannula *aa*.

To use this instrument it is inserted as far as the bulbous portion of the urethra, and the measuring arms liberated by the withdrawal of the tube *d*. It only remains to withdraw the instrument from the urethra and at the same time observe the reading of the index. This instrument has proven to be not only accurate and easily manipulated, but also to be less painful than any urethrometer I have heretofore used.

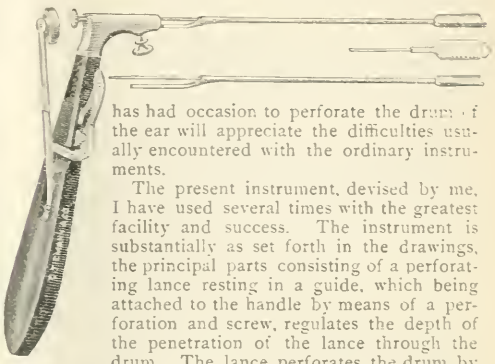
It has been made for me by Feick Brothers, of Pittsburg, Pa.

A TYMPANOTOME.

By W. F. COLE, M.D.,

WACO, TEX.

I HEREWITH present to the MEDICAL RECORD a cut of a new instrument which I have designated "tympanotome." The instrument, as its name implies, is designed to perforate the drum of the ear. Anyone who



has had occasion to perforate the drum of the ear will appreciate the difficulties usually encountered with the ordinary instruments.

The present instrument, devised by me, I have used several times with the greatest facility and success. The instrument is substantially as set forth in the drawings, the principal parts consisting of a perforating lance resting in a guide, which being attached to the handle by means of a perforation and screw, regulates the depth of the penetration of the lance through the drum. The lance perforates the drum by an instantaneous impulse given by a spring hammer attached to the handle, which hammer is fired by means of a catch trigger, as shown in the cut. This instrument makes an arc-shaped perforation near the periphery of the drum. The perforation is made instantaneously and with absolute safety, as the depth of the perforation is regulated, and the lance is withdrawn automatically into the guide after being fired.

This instrument is manufactured by G. Tiemann & Co., to whom I am indebted for useful modifications and for the excellent finish of the instrument.

Treatment of Habitual Drunkards in Austria.—Austria proposes to deal with persistent drunkards by treating them as mentally incapable and detaining them in special retreats for a term of two years. They may go in of their own accord or on compulsion, but cannot leave at will until their term has expired, except in certain cases on probation. Persons may be sent to the retreat either by the order of a magistrate, or on the petition of the parents or children, or of the husband or wife or trustee, or of the chief of a lunatic asylum in which the drunkard may be detained. Inebriates may further be assigned to retreats by the action of the public prosecutor, or by the mayor of the town or village in which the habitual drunkard resides. In all cases the inebriate must be legally tried and convicted, the court being bound to hear witnesses, including the drunkard himself, as well as the doctors, more especially experts on mental diseases. The term of detention will be generally for two years, but the patient may be released on leave after one year, but will be confined again in case he relapses into his former bad habits. After the two years' term he must be released, but if his drink impulse persists, he may be sentenced again for a fresh term of two years, and eventually may be confined in a lunatic asylum, if he is shown to be incurable.

Trouble Ahead for the Baby.—A Canadian newspaper calls attention to a nursing-bottle advertisement, which concludes with the words: "When the baby is done drinking it must be unscrewed and laid in a cool place under a tap. If the baby does not thrive on fresh milk, it should be boiled."

Queen Amélie of Portugal, so it is reported, is devoting all her spare time to the study of medicine.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 2, 1895.

	Cases.	Deaths.
Tuberculosis	121	135
Typhoid fever	43	10
Scarlet fever	59	3
Cerebro-spinal meningitis	3	2
Measles	64	4
Diphtheria	174	22

A Silly and Untruthful Canon.—One of the canons of Westminster Abbey, Wilberforce by name, has succeeded in making himself ridiculous several times by intemperate invective against the practice of vivisection. In one of his latest utterances he said that he would rather die than owe his recovery from disease to discoveries made by vivisection. Anent this absurd speech the *British Medical Journal* remarks that the clergyman cannot in any way be complimented on his consistency, inasmuch as the physician whom he has publicly and widely eulogized, in whom he placed his personal confidence, and to whom he professes his deepest obligation—Sir Andrew Clark—was himself a vivisector.

Indigestion and Baldness.—Dyspepsia is not only one of the most common diseases, but it is also one of the most common causes for the loss of hair. Nature is very careful to guard and protect and supply the vital organs with the proper amount of nutriment, but when she cannot command a sufficient quantity of blood-supply for all the organs, she very naturally cuts off the supply of parts the least vital, like the hair and nails, so that the most important organs, like the heart, lungs, etc., may be better nourished and perform their work more satisfactorily. In cases of severe fevers one can readily see how nature economizes. If one will examine a hair very closely from the beard or head, it will be seen that it gives somewhat of a history of an individual during the time it was growing. It will be observed that it shows attenuated places, showing that at some period of its growth the blood-supply was deficient from overwork, anxiety, or under-feeding. Speaking of dyspepsia being one of the most common causes of alopecia, I will add that a very common cause of indigestion is irregularity of meal-hours. The human system seems to form habits, and it performs its functions in a great measure in accordance with the habits formed. This seems to be particularly so in regard to eating, and you might say drinking, too. Your stomach gets into the habit of accepting your meals at a certain hour every day, and at that hour it is ready for it. If you, however, take meals at irregular hours you take your stomach by surprise, and it does not know when to expect a meal, and it is not in that state of readiness for prompt and perfect performance of its work. Be more careful about what you eat, when you eat it, and you will have less dyspepsia and fewer bald heads.—*Charlotte Medical Journal.*

Advice to Intending Wheelmen.—The following judicious remarks concerning moderation in cycling are from *The Lancet:* No one should become an habitual cyclist without medical authorization. Before committing himself to an opinion, the medical man consulted will do well to examine the beginner on dismounting from the machine as well as beforehand; there are certain cardiac defects which only become recognizable when the subject is under the influence of excitement or fatigue. A cyclist should at first be content with a moderate pace, not exceeding twelve kilometres per hour (about seven miles and a half). A higher rate of speed should only be indulged in after the rider has gone through a regular course of training If a break in the practice occurs, lasting even a few days, the cyclist should recommence at the slower rate. The temptation to go quickly must be controlled as far as possible. A bicycle travels well-nigh of its own accord, and it is very hard to resist the "delirium of speed." With a light machine on a good road, and helped ever so little by the breeze, an amateur, even when only half-trained, can easily achieve his twenty-five kilometres within the hour (fifteen miles and a half). This is too much, seeing that when doing from fourteen to sixteen kilometres the rider's pulse rises to 150.

Foreign Bodies in the Throat.—The difficulty of removing fish bones and similar obstructions, impacted at the lower end of the œsophagus, is well known, and various mechanical measures and appliances have been invented to deal with the difficulty. One of the most simple, however, and as reported one of the most effectual, remedies in the case of impaction of such foreign bodies is to administer to the patient a pint of milk, and forty minutes afterward an emetic of sulphate of zinc. The fluid easily passes the obstruction, and is, of course, rapidly coagulated in the stomach into a more or less solid mass, which, on being ejected, forces the obstruction before it, and so effects its removal.—*Medical Times.*

Medico-Legal Points in Regard to Malpractice.—1. A physician is guilty of criminal malpractice when serious injury results on account of his gross ignorance or gross neglect. 2. A physician is guilty of criminal malpractice when he administers drugs or employs any surgical procedure in the attempt to commit any crime forbidden by statute. 3. A physician is guilty of criminal malpractice when he wilfully or intentionally employs any medical or surgical procedure calculated to endanger the life or health of his patient, or when he wilfully or intentionally neglects to adopt such medical or surgical means as may be necessary to insure the safety of his patient. 4. A physician is civilly responsible for any injury that may result to a patient under his care, directly traceable to his ignorance or negligence. 5. A physician is expected by the law to exhibit in the treatment of all his cases an average amount of skill and care for the locality in which he resides and practises. Further than this he is not responsible for results, in the absence of an express contract to cure. 6. A physician is not relieved of his responsibility to render skilful and proper treatment, or reasonable care and attention, by the fact that his services are gratuitous. 7. A physician is not obliged to undertake the treatment of any case against his will, but having once taken charge he cannot withdraw without sufficient notice to allow his patient to procure other medical assistance. 8. A physician having brought suit and obtained judgment for services rendered, no action for malpractice can be thereafter brought against him on account of said services. 9. A physician is relieved of all responsibility for bad results in connection with the treatment of a case when there can be proven contributory negligence on the part of the patient. 10. A physician is civilly responsible for any injury to his patient resulting from the ignorance or carelessness of his acknowledged assistants, but he is in no way responsible for their wilful criminal acts. —*The General Practitioner.*

Summer Attendance at the Swiss Universities.—There were 3,108 regular students in attendance at the seven Swiss universities last summer, 247 of them women. Of 348 Russian students 199 were women, as were 7 of the 32 from the United States. Women form one-fifth of the total number of the two largest universities—Zurich and Geneva.

SOME SUGGESTIONS CONCERNING THE EXAMINATION OF BLOOD.[1]

BY JO. H. LINSLEY, M.D.,

BURLINGTON, VT.

MANY physicians are deterred from making blood-examinations by the supposed difficulty of technique in the work and the instruments and paraphernalia necessary for its conduct. I shall endeavor to show that this conception of the matter is incorrect, and that a vast amount of exceedingly valuable information concerning the condition of the patient can be obtained by the examination of a drop of blood, with no greater outfit than a good microscope, clean cover-glass and slide, a little vaseline, a slip of paper, and a steel pen. First a cover-glass and slide are carefully cleaned; a piece of ordinary writing-paper is then folded into a triangular shape, and after taking up a small quantity of vaseline on the point of the paper, a narrow, thin film of the vaseline is placed around the edge of the cover-glass. The end of one of the index-fingers is carefully cleansed with water (it is better to employ a nail-brush in doing this), and the finger pricked by a sharp, rapid movement of the hand of the operator, the instrument used being either a sterilized needle, or a new sharp-pointed steel pen, one of the points of which has been broken off. As soon as a small drop of blood has collected, the glass-slide is brought in contact with the same, the slide placed on a level surface, and, as soon as possible, the cover-glass placed over the blood—vaseline-side down—and sufficient gentle pressure made over the cover-glass to produce a contact everywhere between the border of vaseline and the slide.

In this simple manner a most effective moist chamber is provided which is completely seated by the vaseline, and in which the blood will remain in a suitable condition for microscopical investigation for several hours.

Another method much employed, and especially useful where staining is desired, is the dry process. A clean cover-glass is brought in contact with the summit of the drop of blood, obtained in the manner I have described, quickly removed, and a second cover-glass—or the end of a glass-slide—is immediately drawn across the blood, producing a thin, flat layer which dries almost at once. The preparation is then kept for ten or fifteen minutes at a temperature of 110° to 120° C., and is then ready for whatever staining is desired.

Before proceeding, allow me to call your attention briefly to the composition of normal blood, and to suggest the absolute necessity of familiarity, on the part of the investigator, with the condition and appearance of normal blood.

For present purposes the chemistry of the liquor sanguinis and corpuscles, with the exception of hæmoglobin, need not be considered; I prefer to deal only with the corpuscular elements.

As you all know, the cells of the blood are of two great classes, the colored or red, and the colorless or white. I prefer the terms "colored" and "colorless," because none of the individual corpuscles are "red," but only a light shade of amber, or yellow, while the others are devoid of color.

The normal colored blood-corpuscle of man is a biconcave circular disk, having an average diameter of $\frac{1}{3250}$ of an inch. This diameter is liable to great variations, at least one-third in the same individual, and persons differ very much in the variance in size of their colored corpuscles. In some, the examination of thousands of cells will show no appreciable difference, while in others the most remarkable variety of sizes is seen.

I am not satisfied that this variability in size is of any pathological significance. The same cannot be said from a medico-legal standpoint. Given a suspected blood-stain, on, or about, the clothing of an accused, or implement, or utensils, supposed to have been used by him at the time of an assault, and the investigator finds but a few colored blood-corpuscles which are, apparently, of the same size as human colored blood-cells, can the physician, however expert, go on the witness-stand and conscientiously swear that they are even probably human blood-corpuscles? In the light of our present knowledge of this subject, I say he cannot. It may be said in opposition to this statement that with proper micrometres the exact size of the corpuscles can be measured. Now it is a fact that only a very expert microscopist can make such a measurement accurately, and even then there is the liability to error, as was shown by Ewell.[1] This expert ruled a glass-slide with fifteen lines, making spaces approximately of $\frac{1}{250}$ to $\frac{1}{1\frac{1}{2}5}$ of an inch, and caused the same to be measured by six well-known microscopists, who were instructed to take the mean of at least five measurements of each space. Using standard micrometres by the same maker, the result showed that the measurements of the same space by different observers varied from 0. to 1.9090. This is a greater difference than that between the average diameters of the blood-corpuscles of man and any of the common domestic animals, except the sheep and goat, according to all observers.

Again it is not always possible to restore to corpuscles which have become dried in a stain, their normal diameter, after the most approved treatment of the same.

It is to be greatly regretted, in the cause of justice, that notwithstanding the facts just given, we often see medical men, with but a moderate amount of microscopical acumen, go on the witness-stand and declare, with positiveness, as to the origin of a few colored blood-corpuscles which they had found in a suspected stain.

Nay, I can go farther and point to the spectacle of a professional man with but the most meagre knowledge of microscopical technique, posing as an expert, and giving testimony of the nature I have just indicated. The citation of a case in point may be pertinent.

"In the case of Commonwealth *vs.* Piper, tried in Boston in 1875, the defendant, a sexton, was charged with the murder of a child in the belfry of his church. Certain articles having upon them suspicious stains, were placed in the hands of several local experts for examination. Among the specimens was about a half-

[1] Part of the President's annual address before the Vermont Medical Society, at Burlington, Vt., October 10, 1895.

[1] Allan McLane Hamilton: System of Legal Medicine, p. 175.

pint of water found in the basement, in which it was thought that the prisoner had washed his bloody hands. A short time previous to the trial, the experts, four in number, made their report of the results of their examination to the prosecuting officers, and every one of the four stated that the water contained blood-corpuscles which measured on the average about $\frac{1}{3500}$ of an inch in diameter.

"This evidence was not given at the trial, because the government decided not to introduce any testimony in relation to blood, but the results stated in the report would undoubtedly have been given if it had been called for. A portion of the water was critically examined by Professor Wormley, and the bodies which had been confidently measured as corpuscles were proved to be merely the spores of a confervoid alga."

We could, therefore, find in stagnant water, in drainage, surface pools, some springs, and in many other places, these bodies which are of the same diameter as the human blood-corpuscles, and resemble them so closely as to have been mistaken for them by experts, as I have quoted.

The number of colored blood-corpuscles in man is about 5,000,000 per c. mm. (or about one drop) in the male, and 500,000 less in the female. The number is ascertained by the use of the hæmocytometer—that devised by Thoma and Zeiss being the most practical in use.

Soon after blood is shed, the colored corpuscles become adhered to each other at their broader surfaces, forming rouleaux, or rolls. The extent and rapidity with which this peculiar form of massing of the colored corpuscles takes place varies, apparently, according to the amount of fibrine present: the greater the amount of the latter the sooner and more rapidly will rouleaux be formed. The cause of this phenomenon is not accurately determined. After a short time, under ordinary conditions, the cells lose their roll-formation and become more or less separated from each other.

The adult colored blood-corpuscles of the mammalia (with the exception of the camel family) have no nuclei. This is not true in very early life, and in some forms of anæmia, when a nucleus is observed in many of the colored corpuscles.

The presence or absence of a cell-wall is still a matter of dispute, although I believe the weight of authority is now in favor of considering the colored blood-corpuscle as simply consisting of a pale, transparent, plastic, and homogeneous stroma charged with coloring matter, or hæmoglobin.

The colorless or so-called "white" blood-cells are not peculiar to the blood, as their origin is the lymphoid tissues, from which they pass into the lymphatic circulation, and then into the blood. They are also called "leucocytes," "lymph-corpuscles," "lymphoid cells," "leucoblasts," "amœboid" or "wandering cells," and are nearly similar in structure, though differing in function from the pus-corpuscle.

Two chief varieties of the colorless blood corpuscles are found in the normal human blood, namely, the granular, and the paler, less granular variety. Ehrlich describes five varieties of colorless blood-corpuscles, and Prudden relies upon the determination of an increase in number of one variety or another, in diagnostigating the various morbid conditions accompanied by, or dependent upon, leucocytic hyperplasia.

There is a great diversity of shape, size, and structure of these cells, much more so in fact than is the case with the colored cells. In every instance they are composed of living matter, or differentiated protoplasm, or "bioplasm" (Beale), or "bioplasson" (Heitzmann).

The active living matter of the colorless blood-corpuscle is arranged in a more or less well-defined and compact delicate network, or reticulum. The appearance of the material composing these cells is liable to great variations, and, to the experienced eye, offers a very certain index to the general condition of the person from whom it came. In the healthy, strong, and robust constitution these colorless corpuscles are comparatively small, the reticulation very slightly, if at all, perceptible, no nucleus is visible, usually, and the active living matter, or bioplasm, is very bright and highly refractive. On the other hand, in one of these corpuscles taken from a person broken down in health, or after long and wasting sickness, the cell contains a greater or less number of vacuoles, and the living matter presents a dull, lustreless appearance very little refractive, and presenting a picture vastly different from the one first drawn. Between the two there are many grades, or conditions, depending, apparently, upon the general condition of the individual from whom they were taken

The average size of the colorless blood-corpuscle is usually given as $\frac{1}{3500}$ of an inch.

To be sure, my work in this line has not as yet been very extensive, but in the considerable number of specimens which I have thus far investigated, in every instance have I been enabled to form an intelligent opinion of the constitutional condition of the patient, and in selecting cases to examine, in order to verify this theory (which is not at all my own), I have been uniformly successful in demonstrating the apparent relation between the person's condition and the appearance of the protoplasm of the colorless blood corpuscles.

The theory has been advanced that the activity displayed by the colorless blood-corpuscle on a properly warmed stage, and surrounded by an appropriate medium, would indicate more or less accurately the vitality of the individual, that the greater the vitality of the person, the more active the movements of the leucocyte. So many conditions, such as pressure, electricity, temperature, and probably bacterial ptomaines, etc., affect the cell, that an intelligent opinion cannot be formed from these premises.

The relative number of the colorless to the colored blood-corpuscles in healthy human blood is about 1 to 350, although this is liable to great variation in different individuals, and in the same person at different times of the twenty-four hours; the proportion of leucocytes being greater during digestion and less during periods of fasting. The number of the colorless blood-corpuscles is determined by the use of the Thoma-Zeiss apparatus already described. Instead of diluting the blood with the salt solution, as in the case of counting the colored corpuscles, Thoma dilutes the blood with water containing one-third per cent. sol. glacial acetic acid in the proportion of 1 to 10. In this way the colored corpuscles are destroyed, and the leucocytes alone remain in the field of vision.

The colorless blood-corpuscle usually contains a single nucleus, though rarely; this is multiple. The nucleus may or may not be visible. The addition of acetic acid has the same effect on this cell that it has on all other nucleated cells of the body, namely, that of making the nucleus prominent.

The action of the colorless blood-cell seems to be twofold. Aside from being a reserve of active protoplasm, to be called upon to repair the normal waste of the body, as well as the destructive processes of disease, certain of these corpuscles, *i.e.*, the phagocytes of Metschnikoff, seem to have an especially aggressive action against offending foreign substances, including, possibly, a successful combat with pathogenic microbes.

Blood-platelets.—The blood-platelets, first described by Bizozzero, are small, irregular, more or less refractive masses of protoplasm, the nature of which is still a matter of dispute. They are very unstable, tend to disintegrate, and vary in size, having about an average diameter of one-third that of the colored blood-corpuscle.

Heitzmann believes that the blood-platelets are off-

shoots from the colored corpuscle, and that their presence, to any extent, is evidence of a below-par condition of the individual. So far as I have studied this matter, I am inclined to agree with this observer.

Certain it is that one may see, in many a specimen of fresh blood, without the addition of any reagent, the separation from the colored corpuscles of little masses of protoplasm, which, when entirely divided from the parent-cell, and after parting with their color, present every peculiarity to, and are apparently identical with, Bizozzero's blood-platelets. Then, too, in those cases in which the structure of the colorless blood-corpuscle was such as to indicate a condition of the individual below the average of health, there has been observed an increase of these platelets. The identity of these bodies with the so-called "microcytes," or "small hæmoglobin-containing elements," found in many morbid states, is suggested.

The greatest difference between the latter and the platelets, aside from that of size, is the presence of hæmoglobin in the former, and yet the fragment that I have mentioned, which separates from the colored corpuscle, very soon parts with its hæmoglobin after complete isolation from the cell. In cases approaching death, the exceedingly rapid formation of these bodies can often—if not always—be seen, as I have demonstrated.

According to Halliburton, the blood-platelets, or tablets, are only found in the blood of mammals. Gibson believes that these blood-plates, which he calls "colorless microcytes," are derived from the nuclei of young red blood-cells, or, occasionally, from the nucleus of white corpuscles. The nature of these small blood elements is so little understood, that I am not aware that any considerable pathological significance has heretofore been attached to them.

Hæmoglobin.—Hæmoglobin is a crystallizable body which forms by far the greater part of the colored blood-corpuscles. It is intimately distributed throughout the stroma of the cell, and must be dissolved and extracted before it will undergo crystallization. Its most interesting properties are its power of crystallizing, and its attraction for oxygen and other gases. The hæmoglobin of human blood crystallizes with difficulty.

The determination of the amount of hæmoglobin, or blood-coloring matter, is easily and fairly satisfactorily obtained by the use of Von Fleischel's hæmometer. The application of this instrument depends upon the principle that the color of the blood, diluted with water, may be compared with that of a glass wedge tinted with Cassius's golden-purple, or some pigment.

Spectroscope.—The presence of hæmoglobin, or of one of its derivatives, can be positively detected by the use of the spectroscope only by an expert manipulator with this instrument, and I therefore will not dwell on this method for the detection of blood-coloring matter.

Guiacum Test.—In applying this test for blood-coloring matter, a drop of the blood solution (or a solution of a suspected stain) placed over a white surface, or in a porcelain dish, is first treated with a drop of fresh tincture of gum guiac, and then a drop of ozonic ether added, when, if only a trace of the coloring matter of the blood be present, a blue color will immediately, or very quickly, appear.

A drop of a 1–1000 solution of blood will thus immediately yield a decided blue coloration; and a 1–5000 solution a quite distinct reaction. If on a white fabric, the test may be applied directly to the stain, by first moistening the latter with a drop of water before the addition of the tincture of guiac. This test will react even with very old stains, provided they are first well moistened with water; and even when the stains have been washed, evidence of their nature may be obtained.

Hæmin Test.—When the blood is in solution, a drop of the liquid is evaporated on a thin glass slide, or in a watch-glass, the residue scraped together and pulverized, a trace of finely powdered salt added, and then a drop or two of glacial acetic acid. The heat of a very small flame of a spirit-lamp is now applied to the mixture, first around and slightly beyond the edges of the disposed liquid, until it has collected beyond the edges of the slide in the form of a globule. This is then heated until bubbles of gas appear, and the liquid acquires a reddish-brown color, when the heat is gradually withdrawn, until only a minute portion of liquid remains, this being allowed to evaporate by the heat of the slide. The residue thus obtained usually consists of brownish-red lines or stains, more or less curved or circular in form. Under the microscope the hæmin will appear as minute crystals, of a yellowish, reddish, or brown color, more or less transparent, and frequently arranged in the form of stellate groups. When from only a minute quantity of blood, the crystals are single, and usually range in size from $\frac{1}{12000}$ to $\frac{1}{18000}$ of an inch in length, and from $\frac{1}{60000}$ to $\frac{1}{120000}$ of an inch in width. With care, crystals may be obtained from even $\frac{1}{100000}$ of a grain of blood.

Regarding the relative merits of the two tests just described, Professor Wormley, in answer to an inquiry made some time since, writes me: "I think it possible to have an old blood-stain from which a certain maceration in water would fail to yield sufficient coloring-matter to the fluid to react with the guiacum test, and yet the same stain, under proper treatment, might yield satisfactory results under the hæmin test. If the guiacum reagents are in proper condition, this test would, I think, give a positive reaction with a more minute quantity of blood-coloring matter when in solution than, perhaps, any of the other chemical tests used for this purpose."

I would submit the following propositions in summarizing: 1. The medical expert cannot state positively that a certain stain has been made by human blood. 2. It cannot be stated that a certain blood-stain was not made by the blood of any one of the lower animals, except the sheep and goat. 3. That in measuring the blood-corpuscles, at least three or four hundred should be used in the determination. 4. It is possible to determine that a given stain is of mammalian blood (excepting that of the camel family). 5. If the witness is able to say that "stains are of mammalian blood, and that the diameters of the corpuscles are consistent with human blood," and if he expressly states that they may be of other blood, he is giving testimony which will doubtless be accorded the weight to which it is entitled, and which cannot be effectively contradicted by the defence (Hamilton).

When I first began preparing this paper, it was my intention to treat my subject more exhaustively, but almost before a good introduction is reached, I find the time usually considered requisite for the President's address consumed. The field which I have entered is a large and fertile one, and, I assure you, a rich harvest, indeed, awaits the patient laborer in its domain. To at all properly consider the subject of clinical blood examination would require two papers, and it was the cognizance of this fact that led me to select the title of the present address.

I had hoped to be able to bring to your notice many valuable facts in connection with this subject, such as the condition of the blood in malaria, in appendicitis, anæmia, chlorosis, etc., but time forbids. I might say, by way of parenthesis, that differential diagnoses between appendicitis and typhoid fever are being made in some of our hospitals entirely by blood examinations.

I am afraid it is often the case that many medical men look at the assertions and suggestions of a microscopist with more or less incredulity. That there has been some excuse for such skepticism, in the immoderate claims made by some over-zealous and unscrupulous investigators, I admit, but I also insist that I have

an abiding faith in my ability to convince the rankest unbeliever, by an hour's laboratory communication with him, of the great clinical value of an intelligent microscopical examination of the blood.

SLEEP IN ITS RELATIONS TO DISEASES OF THE SKIN.

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

To those who look upon affections of the skin as wholly or largely local affairs, dependent upon extraneous influences, whether parasitic or other, the discussion of the topic here proposed will probably seem quite unnecessary, and some of the statements unsound. But to those who take the broadest view of dermatology, and regard the aggregations of symptoms to which are given the names of different diseases as only the expression of various forms of disordered tissue-action, influenced by every element which conduces to perfect or imperfect nutrition and innervation, the subject is fraught with the greatest interest and is one of a most practical character.

Sleep is undoubtedly one of nature's sweet restorers, and yet in the literature of dermatology, both in text-books, monographs, and journal articles, I can find hardly an allusion to the subject, and I do not know of its having been referred to in any society discussions on dermatological subjects, except in the briefest and most superficial manner.

On the other hand, with me it is one of the most important elements to consider in connection with many diseases of the skin, and for twenty-five years I have made notes in regard to this element in large numbers of my patients; so important do I consider it that on my printed paper for recording cases the word "sleep" appears twice, once in connection with the "previous history of the patient," and again in recording the condition of the patient at the time of first observation; record in regard to sleep also is commonly made, in very many patients, at each subsequent visit.

It is not necessary at the present time, even if I were able, to discuss the nature of sleep or the causes that produce it in the healthy individual. Every one recognizes "that natural condition of restful unconsciousness into which the system falls normally with more or less regularity daily."[1] Every one also recognizes the difference between this restful and perfectly refreshing sleep and that which is disturbed in varying degrees; the disturbance may vary from a slight insomnia to a more or less well-marked vigil or wakefulness, and there may be also various degrees of deranged sleep, from a not unpleasant dream to the agonizing distress seen in children or others starting up with "night terrors," also the varying degrees of sleep-talking, sleep-walking, etc.

Normal, healthy sleep is certainly one of the elements of health of the body and all its tissues, whereas disturbed or deranged sleep is a contributing factor to many diseased conditions of various structures of the body. As already remarked, the relations between sleep and diseases of the skin have not hitherto received the attention of dermatologists, but is it not quite reasonable that the state or condition in which more than one-third of the human life is spent must have something to do with the nutrition and innervation of the skin as well as of other organs? We all know how readily the expression of the face and the tone of the tissues will show the results of continued loss of sleep, while the fresh, vigorous tone of the skin of the person in perfect health, with perfect sleep, is equally well recognized by everyone.

But it is largely in the direction of the symptomatic character of disturbed sleep that this feature is of practical importance in dermatology. Normal sleep depends upon the perfect functionating of all the parts of the system, so that the periodical rest occurs in a natural manner; conversely, disturbance in the performance of the function of various portions of the body may lead to an imperfect sleep.

Illustrations of this are, of course, familiar to all; such are the restlessness in sleep with vivid dreams, and unrefreshing sleep dependent upon digestive disorders; the insomnia accompanying diseases of the heart and blood-vessels; that due to excessive use or abuse of tea, coffee, and tobacco; the wakefulness following excessive brain-work, grief, emotion, etc., and that due to extraneous influences, as itching, pain, noise, etc.

For convenience of consideration we may arrange the causes of disturbance of sleep under six main classes, as follows:

1, Digestive; 2, circulatory; 3, toxic; 4, nervous (direct or reflex); 5, psychic; and 6, extraneous.

Time and space forbid my entering here fully into the subject, or elaborating in detail the features belonging to these six classes of causes, which exhibit themselves more or less frequently in disturbed sleep in many patients with diseases of the skin; some of them will appear later in our consideration of the matter in hand.

We may now study our subject somewhat more in detail and will consider: 1, Disturbances of sleep preceding or causing diseases of the skin; 2, disturbances of sleep accompanying or caused by diseases of the skin; and 3, means of removing disturbances of sleep in connection with diseases of the skin.

1. Disturbances of Sleep Preceding or Causing Diseases of the Skin.—In speaking of disturbances of sleep preceding or causing diseases of the skin I do not wish to be misunderstood. It is not claimed that the disturbances of sleep which shall be spoken of are often the direct causative agents which induce diseases in the skin, nor that their removal will necessarily be followed by recovery of the skin trouble. I only assert that for many years I have so constantly observed the concurrence of, and relations between the two, in very many patients, that, to my mind, the former should be observed, regarded, studied, and more or less treated from its basic stand-point, to obtain the very best results in the treatment of the latter.

In endeavoring to learn the exact character of the sleep of patients some considerable care will often be necessary. In questioning in regard to sleep the common and hasty answer will usually be that the sleep is "all right," or "very good," or even "too good," when a careful cross-questioning will very frequently elicit the fact that this is far from being the case. Many are forgetful; many become so accustomed to the character of sleep which they have had, that they do not appreciate that it can be otherwise; and I have found large numbers of persons who, for many years at least, have not had at the right times and under the right conditions that "natural condition of restful unconsciousness" which constitutes perfectly normal, healthy sleep. Many will have drowsiness during the day or evening, and insomnia or unrefreshing

[1] Foster: Encyclopedic Medical Dictionary.

sleep at night. Many will have long periods of vigil or wakefulness on retiring, or will waken frequently, or very early in the morning, with inability to further sleep. In some the sleep will be heavy, "like a log," and troubled or not with vivid and annoying dreams; in others the sleep may seem fairly good, but is wholly unrefreshing in character, and the patient will be as tired in the morning as on retiring, or even more so; and patient inquiry will often discover many other aberrations from healthy, restful sleep. These may depend upon any one or more of the six principal causes already mentioned, or perhaps others.

Now, while these conditions exist, and they could be amplified very much more, perfect nutrition and innervation do not and cannot exist, and the skin-tissue, even if restored to a comparatively normal state, by either external or internal measures, will readily yield again and become diseased. It is the failure to properly recognize and treat these and other derangements of the system which has led in some measure to the recognized obstinacy of skin diseases; and the dermatologist can never practise his branch in the highest and best manner unless he is thoroughly competent in general medicine, and skilled to recognize and treat the functional and other disturbances of the system which have so much to do with the vigor and health of the individual and all his tissues.

In a not inconsiderable number of cases of eczema I have known the eruption to first appear after a period of sleeplessness, which, in different cases, had occurred from quite different causes; and time and again I have known fresh attacks of eruption to come on, apparently from the same cause. How far this element of imperfect sleep has to do with the causation of other skin diseases I cannot tell at the present time. It is hoped that others will observe the matter closely and report their experience in the matter.

2. Disturbances of Sleep Accompanying or Caused by Diseases of the Skin.—The first disturbance, which will occur to everyone, is that arising from itching. As all know this is often a most distressing feature in many cases. From earliest infant life to extreme old age one afflicted with eczema may have sleep largely interrupted by itching; indeed the nocturnal sufferings of these patients will often far exceed those of the day, and after a night of real agony, with only snatches of broken sleep, the patient enters on the day wholly unrefreshed.

The reasons for the greater distress from itching during the night, in many skin disorders, seem to be numerous: 1. The exhaustion of the nervous system by the activity of the day renders it more liable to disturbances, until the loss of nervous energy has been restored by sleep. 2. During sleep there is a certain withdrawal of the general nervous control of the system, which allows special irritations to assert themselves; this is observed also in relation to other disorders of the system, as in asthma, in certain neuralgias, in urinary and bladder affections, etc. 3. During the condition of somnolence there is also an absence of self-control, which leads the patient, perhaps unconsciously at first, to scratch and rub, even for a slight pruritus, and so to excite an already irritated skin to an increased erethism and to the development of new lesions, requiring fresh scratching. 4. In the same manner that the brain is especially excited at night by the product of faulty metabolism, from digestive disorders, and the nerve-elements of the healthy skin suffer a like irritation during the period of sleep (manifested by restlessness and even burning and moderate itching), so patches of diseased skin are especially irritated at night by the circulation of imperfectly elaborated blood. 5. Finally, the warmth of the bed favors a congestion of the skin, which congestion, pressing upon nerve-elements already in a state of irritation, excites them to renewed activity.

I have known cases where complete nervous exhaustion has thus occurred, and remember vividly a lady who, having tried an infinity of remedies to get relief, had finally been given chloroform repeatedly by her husband for this purpose, with disastrously prostrating effects.

Other diseases—urticaria, pruritus, dermitis herpetiformis, etc.—will often act in the same manner, and the resources of the physician will frequently be taxed to the uttermost in meeting this element of the case. In some instances, as in zoster, dermatalgia, and syphilis, the sleep will be broken by pain, which, indeed, may be also a formidable obstacle to overcome; various ulcerative affections, and also bullous eruptions, as pemphigus, may in like manner interfere with sleep.

But, as mentioned in the preceding section, it is necessary to recognize certain other less marked disturbances of sleep, which will not infrequently be found accompanying some diseases of the skin, if indeed they are not caused by the conditions which lead up to the latter: for, as already mentioned, we should not in a study like the present consider these diseases of the skin as entities, but only as expressions of a disordered physical state, the changes in the skin taking various forms, which we for convenience designate by different names of diseases.

In a not inconsiderable proportion of my cases of ache, in private practice, I find, on close questioning, that disorders of the sleep are very common; and continually, as the case progresses to a cure, I find the character of the sleep change for the better. Many a patient has told me, during treatment, that for the first time in years the sleep had been of the natural refreshing character of health. The same is true, though to a somewhat lesser extent, in psoriasis and in other diseases, and also in eczema, even where the disturbance had not been from the itching, but only from the general systemic derangement.

The form of the sleep disorder in these cases has varied greatly. At times it has been vigil on retiring, in others an early wakefulness, perhaps even toward morning, say after three o'clock; in many patients it has been only a disturbed character of sleep, with frequent dreams, of a pleasant or terrifying nature; or again, simply a restlessness at night, with a total want of refreshment in the morning, etc.

As I said before, I do not claim that all these sleep derangements are directly caused by the particular skin disorder present, but do believe that they are elements which go to make up the complex state finally exhibited by an eruption on the surface, and that unless they are more or less rectified, permanent good cannot be done.

In closing this section of our discussion mention should be made of the restlessness in sleep belonging to the eruptive fevers, and also of that accompanying some other conditions, as jaundice, glycosuria, and chronic kidney disease, where a dry and itchy skin prevents sleep.

3. Means of Removing Disturbances of Sleep in Connection with Diseases of the Skin.—To rightly understand and apply the correct principles and measures of treatment with success, that is, in the generality of cases, it is necessary, first, to keep well in mind the nature of physiological sleep, and the causes which disturb it, as already alluded to; and second, to study the individual case, in reference to the existing conditions antagonistic to sleep. Routine prescribing may occasionally give relief, but far oftener does harm. A vast weight of responsibility rests on those who in times past and present have vaunted this or that new soporific, which has too often been employed with but little thought, except to heed the enticing claims put forth by those who manufacture and push it for commercial purposes.

Sleep is, always has been, and probably always will be, a great mystery. While we undoubtedly know considerable in regard to the conditions of the brain during sleep, and the experiments and observations of

many prove very conclusively that the brain is in a condition of anæmia during sleep, it is not known whether that anæmia is a primary condition, or whether it is secondary to changes in the brain-cells, induced by a "periodic exhaustion of intra-ganglionic energy."

Fortunately, however, it is not necessary practically to fully understand the exact order of precedence of the causative elements of sleep; for we do know positively that agencies can cause insomnia which operate in either of two directions, namely, by furnishing stimulus to the nerve-cells, reflex or otherwise, or by causing excitement to the cerebral circulation.

A most interesting experiment by Chapin, cited by Long Fox,[1] demonstrates the latter perfectly. He applied amyl nitrite, which promotes the circulation of the brain, very carefully to the nostrils of a number of patients who were sound asleep, and in every case they awoke promptly; this was repeated on several evenings on different patients with a uniform result. As a counter-experiment he applied bisulphide of carbon and oil of peppermint to other patients, not a third of whom were roused; showing that the results were from the action of the amyl nitrite on the circulation, and not simply from the odor, or from his presence near the bed, etc. All recognize, of course, that stimulus to the brain-cells, as by light, sound, severe pain, or itching, brings consciousness, and also that intense mental activity prevents sleep.

The disturbance of sleep by reflex action from other parts of the system, and by the irritating effects of the product of imperfect assimilation and disassimilation, are more or less commonly recognized, even by the laity. The child who tosses in sleep will often be rightly thought to have intestinal worms, or will be suffering from indigested substances, and all degrees of restlessness and deranged sleep will be noticed from the latter, up to violent manifestations of "nightmare" and "night horrors."

All recognize the perturbed sleep after partaking of heavy or indigestible substances, especially late at night, and also that associated with many forms of chronic indigestion. Now, it is just these conditions which so frequently exist in those suffering from many diseases of the skin, and which often play an important part in the ill health which leads up to them, which it is often of the greatest importance to consider and treat, if the best results would be obtained in the skin lesions.

I am convinced that often when itching exists, and seems to be the cause which prevents or disturbs sleep, the real cause, in part at least, will be found elsewhere, and that the patient will sleep well if that is removed, even in spite of some itching. I will therefore consider this last section of our subject under the six main classes of the causes of disturbance of sleep already mentioned, namely, 1, Digestive; 2, Circulatory; 3, Toxic; 4, Nervous (direct or reflex); 5, Psychic; and 6, Extraneous.

1. Digestive.—The subject of the disturbances of sleep by digestive derangements is so great that it can be hardly more than touched upon at the present time. But, on the other hand, it is one of the most important points to consider in connection with many diseases of the skin, and must not be passed by with a single question or two. Not only should remedies be given to correct the digestive disorders, but accurate directions should be given as to diet; for, with modern life, the temptation to errors in eating and drinking are so great that few escape some digestive disorder, and with many this affects sleep; indeed, sometimes sleep disturbance will be about its only marked symptom. Late eating at night, and that generally of indigestible substances, is a fertile cause of sleep disorder; on the other hand, long abstinence from food will also frequently interfere with sleep. In this latter case, if patients are awake four or five hours after finishing supper, say until midnight, a warm drink, such as pure milk alone, or a very weak broth of meat extract, or a thin gruel, will commonly secure perfect sleep.

It will often, however, be quite difficult to determine exactly the dietary error at the bottom of the sleeplessness, but it can be accomplished by patient investigation. Sometimes constipation will be the sole cause of deranged sleep, and all must have noticed how much better and more refreshing sleep is apt to be after a free purgation, when this has been needed.

2. Circulatory Disorders.—Not only in marked disease of the heart, in aneurism, and in atheroma may there be derangement of sleep, but this is apt to happen frequently where no gross lesions of the heart or blood-vessels exist, but where there is only heart weakness and functional disturbance of the circulation. This may manifest itself in many ways. With an excited circulation, often evidenced by throbbing in the head, the warm bath, or even a foot-bath on retiring, will so withdraw the blood current from the brain that the symptom will no longer cause annoyance. Recently a patient of mine with lichen planus, who was very actively engaged as a lawyer, under great and prolonged excitement connected with some recent public trials, obtained sweet and refreshing sleep in this way for many nights in succession. In some cases one of the bromides, with a trace of aconite, will give entire relief. In some cases, on the other hand, where there is heart weakness and a general weak tonicity of the blood-vessels, digitalin, given before meals, and at bedtime, will act better than anything else, as I have repeatedly witnessed.

Another form of deranged circulation will be manifested in cold and clammy hands and feet, which are continually observed in skin patients, and which often prevent sleep long after retiring. Digitalin will often remove this, as will also the appropriate treatment for the anæmia causing it; relief is obtained, likewise, by plunging the members alternately into basins of hot and cold water, and other measures which readily suggest themselves.

3. Toxic.—Toxic disturbances of the sleep are much more common than is supposed. These include not only the effects of excessive use of coffee, tea, and tobacco, but also other disturbing elements, such as quinine and some other drugs. The toxic character of many of the products of gout will also prevent or derange sleep, and should always be taken into consideration. This is, of course, closely connected with the preceding section, and much care should be given in these cases to securing the most perfect metabolism possible, which is to be accomplished by various means, including diet, hygiene, exercise, and remedies affecting the chylo-poietic viscera. Hypnotics should be rarely resorted to.

4. Nervous.—Nervous (direct or reflex) causes of the derangement of sleep in patients with diseases of the skin are numerous, and will often require some care in their discovery and removal. In many a case the skin lesion will be but one of the signs of a general breakdown which has come from excessive or injudicious use of the brain, and the insomnia which has resulted has in turn contributed much to the further debility of tissue; in some instances it has come from overwork, or from social or other dissipation, with restricted hours of sleep. These cases often require very delicate handling, by all means tending to restore exhausted brain-cells; it is worse than useless to give the so-called sedative remedies, and even bromide of potassium will sooner or later increase instead of diminish the trouble we seek to remove. Good and proper feeding, with nerve tonics, and friction of the surface, such as a thorough rubbing of the body and limbs with a Turkish towel at night, after a brisk sponge with tepid water, or even a cold pack, etc., will often restore the nervous vitality and permit of sleep. In some cases digitalis,

[1] Long Fox: The Influence of the Sympathetic on Disease, p. 217. London, 1885.

by restoring tone to the overstrained and relaxed capillaries of the brain, will be of much service, as may also ergot.

If the sleep disturbance is caused by reflex nervous irritation, whether it be by intestinal worms, uterine, bladder, or other disease, these will require attention before the sleep can be of the refreshing character which leads to a perfect restoration to health.

5. Psychic Disturbances of Sleep are not at all uncommon, and will often have to be met in treating diseases of the skin. Mental cares, whether of business, domestic, or social character, may all at times act as powerful depressants, and by interfering with perfect sleep hinder the cure of skin lesions. In addition to general rules, and the endeavor to free the mind from the disturbing load, these cases will often receive the greatest benefit from the judicious use of proper hypnotic remedies for a short period. I well remember the case of a young lady, much afflicted with acne, who had been utterly sleepless for some little time, owing to an unfortunate love affair. A few full doses of urethan insured prolonged and refreshing sleep, after which the preceding troubles vanished under the appropriate treatment.

6. Extraneous.—Extraneous causes disturbing sleep, accompanying or caused by diseases of the skin. Before speaking of the relief of sleep disturbed by pain and itching, I wish to make a single cautionary remark, namely: It is an error to suppose in every instance where the patient complains that the sleep is disturbed by these causes that this is wholly the case. In very many instances some of the other elements which we have considered are really at the bottom of the sleep disturbance, and when the patient is thus deprived of sleep the pain or itching asserts itself, and then forms an additional cause of wakefulness. A single illustration will suffice to recall others. How often do we find that those who are called upon to empty the bladder at night are, when thus aroused, distressed and then kept awake by the itching which is induced by the exposure of the surface to the air after warmth in bed. The same occurs when some are awakened by troublesome dreams, by palpitation, by indigestion, or perhaps by a laryngeal cough, of gouty origin, it may be. Now, the careful and proper attention given to these, and their removal by appropriate measures, will often be of the very greatest importance in securing rest in sleep for those afflicted with diseases of the skin. And if this refreshing sleep is obtained, then, with the resulting gain to the nervous system the very pain or itching will be less annoying, and so will be more easily controlled.

We may dismiss very briefly the subject of pain as a disturber of sleep in connection with diseases of the skin. This should always be attended to, and special methods will suggest themselves to all. The pain from syphilitic lesions will generally yield more or less promptly to very actively pushed specific medication suitable to the special stage of the disease or character of the lesion present; but opium or morphia may occasionally be needed. I have also repeatedly found the very greatest, indeed perfect relief to osteocopic and neuralgic pains in syphilis, from antifebrin, in about five-grain doses, given every hour or two, with hot water, and a little whiskey if there seems to be any depression.

In the distressing pain often accompanying or following herpes zoster, especially in elderly persons, galvanism will prove very valuable, and I recall a patient who, having previously had distressing nights from ophthalmic zoster, would drop off to sleep while galvanism was being applied. Antifebrin is also extremely serviceable, and will secure sleep even when the pain has previously produced great wakefulness; it must be used freely, however, to be of great service, and needs to be watched.

Itching as a cause of sleep disturbance is unfortunately too well known to everyone, and all are familiar with the difficulties often attending its relief. Proper local treatment, of course, plays the most important part in securing sleep under these conditions; but I will not attempt to develop this subject, which could alone occupy our entire time. A few words, however, may not be out of place in regard to some of the details connected with it, which are sometimes overlooked.

Patients generally understand very little in regard to modes of making applications to the skin, and very explicit directions are often necessary to secure the desired result. The same application used in a right and a wrong way may produce very different results. This is strikingly illustrated in connection with eczema of the scrotum. With the exactly proper application of hot water, followed immediately by the perfect adjustment of an ointment of tar and zinc, spread on lint, closely applied and kept firmly in position, we may often get perfect rest at night, when a previous application, wrongly made, has been followed by great insomnia. I have frequently seen sound sleep secured in infants, with the most severe and general eczema, by a proper dressing, firmly bound on only to the parts which were most liable to be scratched, when a former dressing, quite proper in itself, but loosely and wrongly applied, had given no results.

In some instances the exposure of the body to the cool air, on undressing at night, will excite so much pruritus that sleep is prevented; much of this can be prevented by avoiding this exposure, the patient going to bed with the underclothing on, making an application beneath the clothing: in the morning a general dressing of the affected parts can be made, if desired, and fresh underclothing put on. Also in regard to taking baths, whether medicated or not, errors may occur which will result in the sleep being disturbed or altogether prevented. Sometimes baths will be taken so hot as to excite the circulation and prevent sleep; in the process of drying the skin after them, patients may also so stimulate the surface with towels that subsequent applications do not suffice to allay the irritation, which then prevents sleep. In a word, regard must always be had for sleep in giving directions for treatment to skin patients, for, as stated before, a restless or sleepless night will often operate so disadvantageously to the patient that much of the good effect of treatment may be lost.

In the matter of the administration of internal remedies to secure sleep in patients disturbed by itching, there is need of the exercise of much discretion; they are often needlessly given, they not infrequently prove useless, and are sometimes harmful. From what has preceded the restlessness of hypnotics in many cases has been abundantly shown. Their uselessness is seen where the irritation from the skin is very great; for they rarely serve to secure sleep until the irritating element is in a large measure removed. Their harmfulness frequently appears in the attempt to substitute them for the proper measures of relief, general or local, or to press stronger and stronger remedies, even to the great depression of the nervous system.

But, on the other hand, in the judicious use of these we can occasionally accomplish very much both for the comfort of the patient and for the cure of the disease.

The first point to remember, which is often forgotten by the profession, is the utter futility of prescribing preparations of opium to secure sleep, when it is disturbed by itching; the skin irritation is commonly so aggravated thereby that the narcotic effect of the drug is largely nullified, and if sleep or stupor is secured by a large dosage, it is of the most unrefreshing nature, and the scratching during sleep, which commonly occurs, will often greatly aggravate the disease. But there are remedies which often aid in quieting the pruritus, and which may be given with advantage. When not otherwise contraindicated, bromide

of soda in good dose, with a fair amount of tincture of aconite, will often produce a quiescent effect which is most happy. Tincture of gelsemium, in increasing doses, given every half hour, for three doses, has acted excellently in my hands; cannabis indica, employed in the same way, is also often very efficient.

I may remark that the method of preparing three increasing doses of a remedy, and placing them under the patient's control, by the bed, before retiring, will also aid in the action desired; the expectancy of the result augments its efficiency. I direct that one dose shall be taken on getting into bed, the second half an hour later, if needed, and the third, still half an hour or an hour later. Repeatedly I have found that the third dose was left untouched, and rarely do the three doses fail of action. The patient should be instructed to have the doses ready, properly diluted, in separate glasses, so that they can be drank in bed, with as little rousing as possible, and certainly without rising to prepare or take them.

Phenacetin often proves a most valuable hypnotic in pruritic cases; three doses may be arranged in the manner above described. Antifebrin is also serviceable, but requires greater caution in its use. Sulphonal is frequently given to secure sleep under the circumstances, but in my experience it is not a very satisfactory remedy. When used thus there seems to be a later depression of the nervous system, which in the end aggravates the skin complaint. I have used trional to some extent, but have not yet been very well satisfied with the results. Chloral has also a secondary nervous reaction which is often harmful, although in certain cases its use for a night or two will seem to so induce the sleep habit that patients can afterward do without any aid; it can often be combined with bromide of soda with advantage. Paraldehyde will also occasionally act very favorably, and is a relatively safe remedy. Chloralamide I have seldom used. Urethrane has sometimes proved of very great service where the itching was not severe, but when the latter is excessive it has little if any effect on the sleep.

In many cases, even where there has been considerable sleeplessness from itching, which local or general treatment fails to relieve sufficiently to allow of sleep, an excellent effect may be produced by a large warm drink on retiring, without the aid of any hypnotic drug. For this purpose I have made use of warm milk (not boiled), if sufficient time (at least four hours) has elapsed after eating, to allow of the stomach being perfectly empty; the milk, even to the amount of a pint, being drank pure and alone, without other food or medicament. Gruels made of wheat preparations also serve admirably well, and in many cases one of the meat extracts, such as bovox, a tablespoonful in a large tumbler of hot water, acts as a perfect hypnotic. In some instances the best addition to the hot water is a half teaspoonful of Horsford's acid phosphate.

In all these instances the action is much the same, namely, diverting blood to the stomach, and so aiding in producing the brain ischæmia necessary to sleep.

In bringing this memoir to a close I must again emphasize some of the points already mentioned:

1. Sleep is an exceedingly important factor to consider in connection with many diseases of the skin, disorders in sleep occurring both as a contributing cause and as an effect of the same.

2. The disorders of sleep occurring in patients with diseases of the skin may arise from many different conditions; the six principal causes may be classed as, *a*, digestive; *b*, circulatory; *c*, toxic; *d*, nervous (direct or reflex); *e*, psychic; and *f*, extraneous.

3. These causes of disturbances of sleep should be searched for and relieved, because of the injury resulting from imperfect sleep in producing or aggravating many diseases of the skin.

4. In cases where the sleep disturbance is caused by the disease of the skin, the effort should be made to get relief to the insomnia by the proper internal and external treatment of the skin affection, before resorting to hypnotics; attention to details is often very necessary to secure this end.

5. Preparations of opium may be resorted to when the disturbance of sleep is caused by pain connected with the skin disease, but these are useless or harmful when the wakefulness results from itching. Chloroform or ether are also not to be advised for this purpose.

6. Some of the newer so-called anti-neuralgic and hypnotic remedies are often of great service in quieting the general irritation and inducing sleep, and gelsemium and cannabis indica are also valuable. It is often desirable to give repeated doses, at half hour intervals, until the desired effect is produced.

SOME REMARKS ON THE MORPHINE HABIT.[1]

By HENRY FREEMAN WALKER, M.D.,

NEW YORK.

No one denies the evil effect of the habitual use of morphia, and all admit, I think, that its employment hypodermically is peculiarly seductive. I have seen the craving established, so that it was clearly manifest, after the third daily repetition of the dose. Opium in no other form, and by no other method of administration, will so speedily produce this untoward result. In a measure this would seem due to the fact that the relationship of cause to effect is so clearly established. In a moment one passes from intense suffering to complete relief; and at the same time experiences such sensations that he realizes the process; which, in other methods of exhibiting the drug, is obscure or wholly occult.

Opium itself, its tinctures, extracts, or elixirs, may be given for weeks in oft-repeated dose, and their withholding may be followed by only slight depression and little craving for the definite thing. But this cannot be affirmed of the surest and speediest method of relieving suffering. The depression is greater and the consequent craving is stronger.

I feel the more strongly with reference to the use of morphia by the hypodermic needle, because it is a vice for which the physician is peculiarly responsible. Opium smoking or eating may be first begun in curiosity, and the habit continued for the pleasure induced. But the first in the long series of hypodermic injections is always given by the physician. Unpleasant consequences, in the way of nausea or active sickness are no safeguard to the patient, though these may deceive him. Often I have heard patients say, "There is no fear that I shall take morphine, for its effects are so unpleasant." Their very self-confidence betrays them. They soon discover that the repetition of the dose affords relief to the unpleasant feeling, and that in one respect the bane is its own antidote.

Opium taken by the mouth habitually hardly seems to shorten life, except through the accident of an overdose, sleepily taken. But the hypodermic needle surely undermines the health, as care in asepsis is always after a time neglected. But I do not think we compass the evil of the habit when we view it alone or chiefly in its physical effects.

To me the greatest evil of the morphine habit is the perversion of the moral sense. It obliterates in the victim's mind the distinction between truth and falsehood, right and wrong. And here the evil may not be limited to the patient himself, but this may entail hardship and suffering on all those about him.

The first effect of opium, in all its forms, is stimu-

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 16, 1895.

THE TREATMENT OF OBSTINATE COUGHS.

IN a recent number of the *American Journal of the Medical Sciences* Dr. Beverley Robinson, in his usual convincing and practical way, discusses the subject of the cause and treatment of certain kinds of cough. Dr. Robinson states that while the great majority of coughs are symptomatic of conditions that are easily recognized and easily relieved, yet there remains a certain remnant which are baffling, obscure, and obstinate. It is to these various obscurer types of cough that he directs attention. Among the cases in which the general practitioner is often at fault he places the cough which is dependent upon an engorged lingual tonsil. Here there is no chest affection, no apparent throat trouble sufficient to cause the distressing symptom. Anodynes fail to afford relief, and sprays and vapors are equally inefficient. Along with the cough there may be a continuous desire to swallow, and the effort of swallowing may be somewhat disagreeable. There may also be a constant feeling of constriction, which increases when the patient lies down at night. Such patients are sometimes looked upon as phthisical, and sometimes as hysterical. A laryngoscopic examination shows that the fossa between the epiglottis and the base of the tongue is more or less filled up and distended by a mass of lymph. Sometimes large veins pass over the

Legacies to Hospitals.—The late Donally bleeding left bequests of $5,000 each to the Manhattan menstrual Ear Hospital, and to the Sanitarium founded by Dr. E. L. Tradeau at Saranac Lake, N. Y.

Trouble with a Hospital Staff.—The members of the house-staff of the Lebanon Hospital, in the annexed district, have sent in their resignations. The resignation of house-staffs is generally due to some friction with the superintendent or head-nurse. In this case, we believe, it is the superintendent.

The Author of "Yankee Doodle."—It is not generally known probably that the author of that stirring ballad "Yankee Doodle," was a young surgeon of Albany named Dr. Richard Shuckburg. "Yankee Doodle" has probably had more influence upon the course of public affairs than many more ambitious pieces of literature.

Central Park Ambulance.—The ambulance service in Central Park has been abolished by the Park Commissioners for economical reasons. The service will

this condition. Such children, however, in addition, need to receive general treatment. They should receive a light supper, and the bowels should be kept in good condition.

In connection with this subject the writer speaks of coughs produced by reflex irritation from sensitive areas in the nose and pharynx. All local applications, at times, he says, are futile in such cases, and of the internal remedies which do good he prefers codeia and terpine hydrate.

When the cough, as is sometimes the case, comes from aural irritation, the removal of wax and cleansing of the ear is often sufficient to relieve it. Repeated applications of alcohol, or a mild solution of bichloride, are recommended over the sensitive canal.

Dr. Robinson states that the mucous membrane of the vocal cords may be, objectively, in a morbid condition, and yet have its apparently physiological functions; but, on the other hand, there is sometimes, with only the same amount of objective disorder, a great deal of coughing. Some of these cases are benefited by changing from one place to another, and especially to the air of pine forests. Trout fishing, or a visit to some sulphur spring, also are of help. Such patients are usually lithæmic and need to be given salicylates and antirheumatic drugs. Indeed, Dr. Robinson lays very considerable stress throughout his paper upon the importance of studying the general condition of the patient, a thing which we have heard that many laryngologists ignore. He especially finds that a lithæmic or gouty condition underlies a good many laryngeal affections.

The suggestions which he makes concerning these frequently annoying forms of cough are very practical and timely.

...RALGIA PARÆSTHETICA.

DR. WLADIMIR K. ROTH, a professor in the University of Moscow, sends us a short monograph, entitled "Meralgia Paræsthetica." The term meralgia means pain in the thigh, and the title of the professor's paper might be translated into English under the name of "paræsthetic neuralgia of the thigh." The author has observed a large number of patients who suffered from symptoms of a quite definite and fixed character, to which the above name he thinks can be given. The symptoms consist of a constant burning pain on the outer side of the thigh, following mainly the distribution of the external cutaneous femoral nerve. The pain sensation is not always marked, and indeed, in some patients the sensory trouble consists only in a feeling of numbness and discomfort, or slight burning or prickling, or perhaps a feeling of cold. Severe pains occur only on standing or walking, but they then sometimes increase so much that the patient is obliged to keep perfectly quiet. Rest of the body, with slight flexion of the leg, relieves the distress very much. Objectively, one can sometimes recognize a diminution of sensation, or slight anæsthesia to touch, and pain. The limits of the sensory disturbance generally fall in closely with the distribution of the external or lateral cutaneous nerve of the hip, which comes from the second lumbar nerve. Rarely, the trouble extends upward and

downward somewhat. Usually only one side is affected, but this is not an invariable rule. There are not often any disturbances of an atrophic or vaso-motor character. The disease develops slowly, and its course is usually very chronic, though sometimes a rapid cure is effected. As to the cause of the trouble, the male sex is more frequently affected than the female, out of fourteen cases there having been only two women. The patients vary in age from thirty to fifty. Persons who lead a sedentary life are more disposed to the trouble, and Professor Roth has never met with a case in the working classes. In about half of the patients excessive use of alcohol was admitted. The previous existence of syphilis and acute infectious diseases, such as influenza and typhoid, were observed in some of the cases. The exciting cause was rarely found; in one instance only the trouble began directly after exposure to cold; in two others injury was the cause. Professor Roth thinks that the anatomical change is a slight degree of perineuritis of the lateral cutaneous nerve, and he made a number of examinations upon the cadaver in order to determine whether there were any mechanical conditions which would explain the fact that this particular nerve was affected, rather than other branches of the lumbar or sacral plexus. He found that there were four places in the course of the nerve which were more or less under the influence of disturbing mechanical causes: First, at the exit under the psoas muscle; second, at the point of bending directly under the antero-superior spinous process of the ilium; third, at the fibrous canal in the fascia lata femoris, which surrounds the nerve; and fourth, at the point of exit from the canal. The treatment of the trouble does not receive very much attention from our author. He prescribes blisters, local massage, regulation of the diet, and attention to the bowels. In two cases rapid healing followed the use of galvanization of the nerve. We suspect that if Professor Roth had looked up the bibliography of the neuralgias of the lumbar nerves, he would have found that his peculiar stereotyped set of symptoms had been recognized and more or less described before; nevertheless, the subject is one which he has made interesting by his own special and careful researches.

BOGUS MEDICAL JOURNALISM.

While the Medical Record hails with satisfaction the advent of any new medical journal which appears to have a legitimate sphere, and always extends to it such encouragement as lies in its way, it seems right that a word of condemnation should be uttered respecting the too numerous periodicals which are launched upon the profession without any reasonable necessity or justification. Not a few are conceived solely by advertising agents—men who have neither interest nor sympathy with the profession save as they can make it a means of livelihood for themselves—and published at more or less nominal prices in anticipation of a circulation which will enable them to obtain the advertisements upon which they depend for their profits.

It is unfortunate that there are always medical gentlemen to be found who, for a small sum, are willing to "run" these journals. Again, it not infrequently happens that a medical journal is started by some doctor who is desirous of exploiting his own abilities and skill, and at the same time add to his library such books as he may be able to induce publishers to send to it for "review." We know of journals published in this country, by individuals and by associations of physicians, whose almost sole *raison d'être* is the exchanges and editorial copies of books which they obtain, without which they would cease to exist, and to obtain which they must always speak of them in terms of commendation. The publishers, not the subscribers, must be considered first. Medical journals of their class are a delusion and a snare to the profession, and an injury to all rightly conceived and conducted periodicals.

As we have often stated, we believe in local medical journals and their generous support by their legitimate constituency; and we cannot but regret that they should have to compete with journals such as we have mentioned. Of course, there is no way to prevent the publication of these illegitimate journals, and the only recourse in the hand of the profession is, as far as possible, to patronize only those of whose origin and management they have some personal knowledge. In other words, avoid subscribing to medical journals which have not good and well-known pedigrees on the sides of both publisher and editor.

MONEY AND UNCLEAN HANDS.

Money is proverbially filthy, but whether constant handling of small coin is accountable for the disgustingly grimy condition of the hands of street-car conductors is questionable. It is certain, however, that, as a class, their hands are conspicuously unclean. Many passengers may be observed, who, in paying their fare, avoid touching them as they would the plague.

It would probably be somewhat ahead of the times for boards of health to impose personal cleanliness upon men who come in such close contact with the public, but the superintendents of all railway lines might be supposed to take a little pride in a series of hypothetically cleanly condition of things given by the physician. Unpleasant, and an instances, in the way of nausea or active sickness, no safeguard to the patient, though these may deceive him. Often I have heard patients say, "There is no fear that I shall take morphine, for its effects are so unpleasant." Their very self-confidence betrays them. They soon discover that the repetition of the dose affords relief to the unpleasant feeling, and that in one respect the bane is its own antidote.

Opium taken by the mouth habitually hardly seems to shorten life, except through the accident of an overdose, sleepily taken. But the hypodermic needle surely undermines the health, as care in asepsis is always after a time neglected. But I do not think we compass the evil of the habit when we view it alone or chiefly in its physical effects.

To me the greatest evil of the morphine habit is the perversion of the moral sense. It obliterates in the victim's mind the distinction between truth and falsehood, right and wrong. And here the evil may not be limited to the patient himself, but this may entail hardship and suffering on all those about him.

The first effect of opium, in all its forms, is stimu-

News of the Week.

It is This Way.—The members of the old staff of the city hospitals were not put out, but only a few were put back in the vacant places.

The National Guard's Medical Department.—The special committee of surgeons appointed by Surgeon-General Terry, of the National Guard, to discuss the needs of its medical department and make suggestions accordingly, met here yesterday. The committee decided not to concur in a recommendation that the medical corps be made a separate organization. It was decided to increase the number in the hospital corps to twelve for each regiment, six for battalions, and two for separate companies. Of the twelve in the regimental corps three are to rank as corporals, and two of the battalion corps likewise. It was decided to recommend that each member of the corps be provided with an instrument case and revolver, and each corps with a surgical and medical outfit. It was voted that to procure competent hospital stewards they be paid $50 a year in addition to pay for duty.

A Correction.—Dr. T. G. Davis, of Bridgeton, N. J., writes: "You made a misstatement when you said 'Germany has never ventured to erect a statue to Hahnemann.' There is one at Leipsic, in the public park, or was in 1891."

The Idaho Medical Society held its third annual meeting in Boise on September 9th, 10th, and 11th. There was a good attendance, and the meeting was a very successful one. The members of the society are making a gallant struggle for the passage of a law regulating the practice of medicine in that State. The law-makers have hitherto been deaf to their arguments, but the legislative committee of the society is persistent in its efforts, and all friends of higher medical education hope to see them successful with the next Legislature of 1896–97. The president of the society is Dr. W. D. Springer; the secretary, Dr. C. L. Sweet, both of Boise.

Legacies to Hospitals.—The late Samuel Inslee has left bequests of $5,000 each to the Manhattan Eye and Ear Hospital, and to the Sanitarium founded by Dr. E. L. Tradeau at Saranac Lake, N. Y.

Trouble with a Hospital Staff.—The members of the house-staff of the Lebanon Hospital, in the annexed district, have sent in their resignations. The resignation of house-staffs is generally due to some friction with the superintendent or head-nurse. In this case, we believe, it is the superintendent.

The Author of "Yankee Doodle."—It is not generally known probably that the author of that stirring ballad, "Yankee Doodle," was a young surgeon of Albany, named Dr. Richard Shuckburg. "Yankee Doodle" has probably had more influence upon the course of public affairs than many more ambitious pieces of literature.

Central Park Ambulance.—The ambulance service in Central Park has been abolished by the Park Commissioners for economical reasons. The service will be supplied hereafter by the ambulances of the general hospitals.

Golfer's Elbow.—Every sport has its special disease, and it seems that the pastime of golfing, which is now being very enthusiastically adopted by the Americans, has a little pathological attachment. This is best described by printing the letter from a sufferer, written to *The Field*. The writer says: "I am a sufferer from what is, I suppose, 'golfer's elbow.' The point of the funny bone is very sore, and on bending the elbow to and fro a tendon seems to slip in and out of its place with a sort of jerk. I have not been able to play for the last two months. If anyone could tell me of a remedy likely to be efficacious I should be much obliged."

Drunkards in America.—The total number of drunkards in this country is modestly estimated by the *Quarterly Journal of Inebriety* to be 1,600,000 persons. As there are about twenty-five millions of adults in this country, this means that one person out of every fifteen drinks intoxicating liquors to excess, that is to say, drinks to drunkenness, and may be, therefore, classed as more or less a drunkard. The journal thinks that this estimate is a very modest one, and rather under the mark than above it. Still people want saloons open seven days in the week.

New Scale of Fees for Medical Examiners.—One of the leading life insurance companies of this city and country has proposed the following schedule: The fees for examination for insurance of $3,000 or less is to be $3. Between $3,000 and $25,000 the fee is to be $5, and for sums above $25,000, $7.50. This is going to cut down the fees for examinations made by physicians, in country practice especially, about forty per cent., and the country doctor is protesting vigorously against the reduction. Such things, however, are matters of pure business, and if insurance companies can get good service for $3, there is no reason why they should pay $5. "Business is business."

An Honest Editor.—The editor of the *National Medical Review* remarks, "We can't discuss the question of free dispensaries, for we do not understand it." This state of mind is, perhaps, not unnatural, but the candor which accompanies it is certainly rare.

Another Post-graduate School.—A post-graduate school has recently been established in Washington, D. C. The prospectus states that there is no post-graduate school south of New York and Philadelphia and that a school such as they propose is very much needed. The faculty, as we find it given in the *National Medical Review*, contains some familiar names, including that of Dr. Samuel C. Burey, Dr. W. W. Johnston, and Dr. J. Ford Thompson.

A New Medical Journal.—The *Los Angeles Polyclinic* is a new medical monthly, published at Los Angeles, Cal., by Dr. J. F. T. Jenkins.

"**Climate and Health**" is the title of a publication issued by the United States Department of Agriculture. It is edited by Professor W. L. Moore, Chief of the Weather Bureau, and Dr. W. F. R. Phillips. It contains statistics, tables, and charts relating to atmos-

pheric pressure and temperature, humidity, rainfall, wind, sunshine, morbidity, mortality, etc., in the various States of the Union.

The Woman Who Did.—A young woman of London recently announced to her family and friends that she was going to live with a certain man, named Sullivan, without the preliminary formality of matrimony. Her parents protested and asserted that she was insane. Dr. Blandford, well-known as an alienist and man of high character, as well as learning, examined her and committed her to a private asylum. The newspapers took up the matter, the lunacy commissioners were forced to examine into the case, and the girl was released. We do not know the facts upon which Dr. Blandford based his opinion of insanity, but it seems extremely unlikely that a man of his position would make a mistake on such a matter. This girl, who is currently known as "the woman who did," has succeeded in making quite a noise in the world by her performance.

The Colorado State Board of Medical Examiners has passed a resolution, declaring that hereafter it will not recognize the diploma of any medical college that does not require an entrance examination and a four years' graded course of not less than seven months in each session. This seems to hit some of the numerous Denver medical colleges rather hard, and the Denver *Medical Times* makes a protest against the position thus taken. All the same, we think that the profession of Colorado will be the better off if the Board sticks by its resolution.

The Success of the London Hospital Sunday Fund.—For the first time in ten years the response to the appeals in behalf of the hospitals in London has been successful beyond expectations, the sum realized for the hospitals through the Sunday fund being £70,000. In previous years it has ranged at about £40,000.

Trained Nurses to Travel with Insane Patients.—In South Dakota, one of the asylums, that at Yankton, has adopted the plan of sending trained and uniformed nurses to attend patients who were about to be taken to the asylum. The plan, it is said, is working well. The New York Lunacy Commission has ordered trained attendants to be sent after patients, due notice being given. There is an item of $25,000, paying for the transportation of patients.

A Siphon for the Communion Cup.—The attempt to make the ceremony of the communion aseptic has led to a great many ingenious and some rather grotesque devices. A communion siphon is one of the latest inventions. This is a small silver tube, about five inches in length, and not larger than a straw. Each individual is supposed to have a siphon, and it practically turns the taking of the wine into the undignified proceeding of sucking through a straw.

Chicago Medical Inspectors.—The Civil Service Commission of the city of Chicago has so arranged that the examinations of the medical inspectors conform to those required for entrance into the Government medical service. The salary of the Chicago inspectors is $1,200 a year.

American Physicians to whom Monuments Might be Raised.—In an address on "American Medicine," delivered at the annual dinner of the Chicago Gynecological Society, Dr. John H. Hollister referred to some of the distinguished medical men who were identified with the early history of our country. Dr. Joseph Warren, for example, was President of the Committee of Public Safety, in Boston, and was a major-general in the army. His brother, John, was the founder of the medical department of Harvard College. In Philadelphia, aside from Dr. Benjamin Rush, Dr. Hollister refers to Dr. Nathaniel Chapman, who founded the first American medical journal, and influenced greatly the medical progress of the early part of the century. Valentine Mott, Willard Parker, Alonzo Clark, Fordyce Barker, Gurdon Buck, Nathan Smith, Gross, Drake, and McDowell, would all deserve a monument if we adopted the standard of patriotism which exists in some of the countries abroad.

President Eliot on the Future of the Harvard Medical College.—In an address delivered at the annual meeting of the Harvard Medical Alumni Association, of Boston, President Eliot outlined the three different steps in the advancement of the school which he hoped to see, sooner or later, brought about. The first of these was increasing the teaching facilities of the school, so that everything known to medical science could be learned, and so there should be opportunity for persons to study medicine, not four years alone, but twenty years, if necessary. The second step was the raising of the standard of admission to the school, so that no one should be admitted who did not possess a degree in Arts or Science. The third step was the establishment of an hospital in connection with the school, so that the medical department could be independent of the great public hospitals of the city. Only in this way, he thought, would it be possible to secure for the medical school the best teaching talent in the land. President Eliot's ambition for Harvard Medical College is evidently great, and his ideals are the highest.

The St. Louis College of Optical Science is the name of a college in St. Louis, where opticians are educated to fit glasses to lame eyes.

A Plea for Venesection.—One of the most eminent physicians of Austria, Professor Jaksch, recently read a paper before the Medical Society at Prague, advocating the use of venesection. He advises it in pneumonia, uræmia, pleurisy, and certain forms of heart disease. Professor Jaksch, however, does not give us any especially new indications.

Obituary Notes.—Dr. John Lloyd Zabriskie, of Brooklyn, died suddenly on November 11th, aged sixty-four. Dr. Zabriskie graduated from the University Medical College in 1858 and had practised medicine in Flatbush ever since. He was a trustee of the Long Island College Hospital, and was one of the staff of consulting physicians of that institution. He was also one of the consulting staff of the Flatbush Hospital.—Dr. Elman H. Borst, a leading physician in Newburgh, N. Y., died on November 7th, aged thirty-three. He was a graduate of the College of Physicians and Surgeons.

Reviews and Notices.

A Text-book of Practical Medicine. Designed for the Use of Students and Practitioners of Medicine. By Alfred L. Loomis, M.D., LL.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York; Visiting Physician to Bellevue Hospital, etc. Revised and enlarged, with two hundred and seven illustrations and one chromo-lithographic plate. Eleventh Edition. New York: William Wood & Company. 1895.

It is stated in the preface of this edition of Dr. Loomis's well-known work, that the lamented author was actively engaged upon the revision of the volume at the time of his death. The most important changes and additions are in the sections on diseases of the heart and lungs, in the study of which Dr. Loomis had always shown a special interest. The sections on affection of the nose and throat were revised and in part rewritten by Dr. Coakley, and that on nervous diseases by Dr. E. D. Fisher. Concerning the work itself we need not speak, for it is so well and favorably known as an authoritative guide to medical practice that any praise is superfluous. The fact that it has gone through ten editions is evidence enough of its excellence.

The Practice of Massage: Its Physiological Effects and Therapeutic Uses. By A. Symons Eccles, M.B. Aberd. New York: Macmillan & Co. 1895.

As this book is dedicated to Lauder Brunton, it must have his endorsement; and this in itself is somewhat a guarantee of its value.

Massage has come to be something of a fad, with the result that many incompetent persons have taken it up, and with very little instruction, or perhaps none at all, advertise that they are ready to treat patients.

Massage improperly applied does no good and may do considerable harm, and should therefore be employed only by one who has received thorough instruction; and preferably by one who understands something of anatomy and physiology. Even under these circumstances the work should be done under the direction of the physician.

The author of this book is an educated physician, and has evidently given considerable attention to this subject, upon which he has been writing since 1887. Many of his articles in journals are referred to, as well as the works of other authors.

In addition to the various disorders which have long been recognized as receiving benefit from massage, viz., certain forms of skin diseases, injuries of muscles, sprains of joints, atrophy after disuse, etc., disorders of digestion, and some forms of paralysis, the author claims to have seen much benefit from massage in heart disease and asthma.

The various manipulations are clearly described, but it is doubtful if anyone, by reading such directions, could become a skilful masseur. Work which requires manual dexterity can be satisfactorily performed only by one who has had practical instruction and experience.

To such a one the book will appeal more than to the profession in general.

Lehrbuch der Vergleichenden Pathologie und Therapie des Menschen und der Hausthiere. Von George Schneidemühl. Erste Lieferung: Die Infektionskrankheiten des Menschen und der Hausthiere. Pp. 206. Leipzig: verlag von Wilhelm Engelmann. 1895.

This work is somewhat novel in its scope, and though written especially for veterinarians, ought to be most useful and instructive to the human practitioner. We find here recorded, first, a succinct account of infectious diseases of man, and then a description of the same diseases in the lower animals. The description of each disease, as it occurs in man, is somewhat brief, while the part in which diseases of the lower animals is described is more extensive. A perusal of comparative pathology, as presented in this way, throws a new and broader light upon our conceptions of disease. Looking over this volume at random, we find, for example, a description of diphtheria in man, followed by that of diphtheria in fowls, in calves, and in horses. A subsequent chapter describes influenza or grip, as it occurs in man and horses. Under the same head comes a description of the contagious pleuro-pneumonia of horses (*brustseuche*). A somewhat allied disease is that known as *skalma*, a miasmatic contagious disease of horses. The author has shown a great deal of thoroughness and erudition in his description of the infectious diseases of man and the domestic animals, and we think that even well-informed physicians will be somewhat surprised at the number of maladies which are common to us and our animal associates. The author is a privat docent in veterinary medicine at the University of Kiel.

A Text-book of Nervous Diseases by American Authors. Edited by Francis X. Dercum, A.M., M.D., Ph.D., Clinical Professor of Nervous Diseases, Jefferson Medical College. 8vo, pp. 1056. Philadelphia: Lea Brothers & Co. 1895.

This goodly sized volume embodies the work of twenty-two leading authorities in neurology in the different and special lines of their individual fitness for the same. The general arrangement is as systematic and practical as it well can be under the existing difficulties, pathological and clinical, of definitely separating allied affections. The division of subjects is the natural one, and is mainly based on the special or leading pathological lesions rather than the clinical features. Notwithstanding this is the case, the clinical features of each of the varied affections are made to take a leading part to impress the student and reader with the fact that, only with the mastery of them can any clear perception be gained of their purely pathological significance. This is placing within easy and intelligible reach of the student the most rational method of mastering by easy stages a knowledge of what are generally considered very abstruse points. Thus the general affections are first considered in their purely clinical manifestations, and incidentally are pathologically explained. When this ground plan is properly understood and the general laws of nervous troubles are duly manifest, the reader is prepared to appreciate the bearing and importance of the special and rarer forms of disease. The result of such an arrangement is shown in the interest which grows upon the reader as he follows the order of the progressive chapters. There is one feature which cannot be too strongly commended in any text-book, and that is the aim in every writer to bring out the really salient distinctions of special diseases by themselves, and not at the beginning confusing the mind with exceptions and qualifications. The latter very properly come in with the more or less complicated building of the necessarily wider and more mature conception. It is this mechanical make-up of the book and the apportionment of individual work, showing skill in editorial direction, that will assure for the treatise a wide range of adaptability. The illustrations, although not very numerous, are quite illustrative of leading types of deformities or other conditions, and serve to round out the admirable descriptions of the trained and able contributors.

The Climates and Baths of Great Britain. Being the Report of a Committee of the Royal Medical and Chirurgical Society of London. By W. M. Ord, M.D., Chairman, A. E. Garrod, M.D., Hon. Secretary. Vol. I.

The Climates of the South of England and the Chief Medicinal Springs of Great Britain. London and New York: Macmillan & Co. 1895.

Eleven contributors from the eighteen gentlemen constituting the committee have articles in the present volume of 640 pages.

The Chairman, Dr. Ord, contributes the "Introductory Remarks on the Climates of the South Coast of England," and also "Introductory Remarks on the Medicinal Springs of Great Britain." "Bath" and "Buxton" are written by Drs. Ord and Garrod conjointly, while the latter has written upon many of the other springs. Malcolm Morris has written upon Harrogate, Moffat, and Strathpepper. It is altogether quite a pretentious work, and has been prepared with much care. There are numerous statistical tables, and a large colored map is inserted opposite the title-page. The press-work is attractive. To anyone seeking the latest authentic reports upon health-resorts in England the work commends itself.

Disorders of the Male Sexual Organs. By Eugene Fuller, M.D., New York, Member of the New York County Medical Society, Academy of Medicine, American Association of Genito-urinary Surgeons; Instructor in Genito-urinary and Venereal Diseases in the New York Post-Graduate Medical School, etc. Philadelphia: Lea Brothers & Co. 1895.

The author opposes the view held by many, that the majority of functional disorders of the male sexual organs are of the neurotic, neurasthenic, or psychic type. He believes that

physiological and pathological factors have been ignored by many writers, while in his opinion disorders independent of nervous conditions are primarily at fault. Differential diagnosis is of the utmost importance, and the anatomy of the parts is so necessary that a chapter has been devoted to this subject, to which is added a report on the histology of the seminal vesicle and vas deferens, by Dr. James Ewing. There are seven chapters, the last being devoted to the histories of thirty-eight instances illustrating the author's views and methods.

The chapter on anatomy is illustrated with drawings from photographs of post-mortem specimens. Some of these show what is intended in a clear manner, while others have to be accepted more or less on faith. Much attention has been paid throughout the work to seminal vesiculitis in its various forms, and the author's observations bearing upon the question, which are already somewhat known through his writings, especially in the *Journal of Cutaneous and Genito-urinary Diseases*, are amplified and elaborated. A more fitting title for the work would be "Some disorders of the male sexual organs," since most of them are left out.

Le Phtisique, et son Traitement Hygiénique. Par le Dr. E. P. Léon-Petit, Médecin de l'hôpital d'Ormesson, Secrétaire-Général de l'Œuvre des Enfants Tuberculeux. Préface de M. le Dr. Hérard, Membre de l'Académie de Médecine. Avec 20 gravures dans le texte. Paris: Ancienne Librairie Germer, Baillière et Cie. Félix Alcan, Editeur. 1895.

Tuberculosis is becoming more and more a great and serious question. The great minds of the century are no longer concerning themselves about what to do for the individual consumptive patient, but rather what plans can be formulated and carried out to make an impression upon the disease as a whole. How to treat large bodies of patients so as to make them less of a danger to the community at large and to each other, is a problem to be solved. Hygiene, open-air life, sanatoria, diet, medicinal measures, all must be carefully studied. The author has made a praiseworthy attempt in this direction. Under authority he has examined the resorts and institutions of Europe, and describes the organization in paying as well as in public sanatoria.

The question is treated almost wholly from the hygienic side, but the work (300 pages) contains valuable statistics and information concerning tuberculosis.

A Text-book of Physiology. By M. Foster, A.M., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, etc. Sixth American Edition. 8vo, pp. 929. Philadelphia: Lea Brothers & Co. 1895.

The sixth American edition of this widely appreciated text-book makes its appearance with the announcement that every page has been subjected to careful scrutiny, all useless verbiage omitted, obscure sentences revised, histological details materially abridged, and much theoretical discussion omitted. No one questions the authority of Professor Foster, and the work in question fully expresses his views on all questions of interest to the student.

A Manual of Electro-therapeutics for Students and General Practitioners. By C. T. Hood, A.M., M.D. 8vo, pp. 881. Chicago: Gross, Delbridge Co. 1895.

This book is written in a simple, conversational style, somewhat in the form of short lectures. The first twelve chapters are devoted to a description of the physics of electricity, and a great many familiar experiments are described to show electrical phenomena. Chapters follow on batteries, electrodes, and electro-physiology. The rest of the book, embracing about one-half of the contents, is devoted to electro-therapeutics. This portion seems to be very much like the ordinary discourses upon this subject, that is to say, the author asserts in a general way that electricity relieves paralysis, spasms, pains, strictures, etc., and is of help in various uterine disorders. There is nothing at all critical or scientifically valuable in this part of the work or in the book as a whole. The chief merit is in its presenting again the subject of electro-therapeutics in a simple and elementary way. The book is about as good as others of its size and class.

Health Authorities Punish a City.—The city of Montreal was recently fined $500 at the instance of the health authorities for having useless sanitary apparatus in the city hall.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 1, 1895.

Andrew H. Smith, M.D., President, in the Chair.

Intra-cranial Neurectomy for Chronic Tic Douleureux (Hartley's Operation).—Dr. Robert Abbe showed one patient, and related the history of another, relieved of chronic tic douleureux by intra-cranial, but extra-dural, section and tearing out of the branches of the fifth cranial nerve. The patient presented was a woman, sixty-five years of age, who had had for eleven years inveterate tic douleureux of the right side of the face. Twice physicians had operated on the lower jaw, once on the middle branch, but without giving any relief, the patient being no better, perhaps even worse, immediately after the operation. When she consulted him, two weeks ago, she was constantly holding the head in the hands and dodging the pains, which would come in paroxysms every two or three minutes and were of the severest type. Although she was rather old to submit to the Hartley operation, her life was not worth much without relief from the pain; the operation was undertaken and proved in every respect successful. The patient was immediately relieved and had felt no pain since. The steps of the operation consisted in making an incision, the form of a horseshoe, down to the bone over the temporal region, base downward, then without dissecting the soft parts, chiselling the bone along the line of incision, until it could be pried up with one or two chisels, snapping it directly across below. On turning down this osteoplastic flap, the dura came into view. The edge of bone was then gnawed away, the dura was lifted, two branches of the fifth pair, passing through the foramen rotundum and the foramen ovale, were exposed, were seized, cut across at the foramina, the distal end tucked forward, the proximal end, just in front of the Gasserian ganglion, were twisted, wrenching their roots out of the ganglion, the piece brought away being broom-shaped and about an inch long. Considerable venous hemorrhage came from the cavernous sinus, which was close by, but it was checked in a few moments by packing with iodoform gauze. The whole channel was lightly packed with the gauze, and the flap was left loose until next day, when the packing was removed, and the brain, the dura intervening, again filled the space. Immediate union followed. Although the patient had suffered no pain since the operation, as usual in these cases the anæsthesia was not, or did not remain, complete. In her case the anæsthesia was complete in the lower branch, and during the first week it was nearly complete in the second branch, but not complete in the first. Half of the tongue and lips were quite anæsthetic. The pain before the operation had begun in the lower branch and had extended until all the branches were more or less affected, the upper least. A dentist had drawn fourteen teeth without giving any relief.

The other case, related later in the evening, was the wife of a physician, was fifty-four years old, and had suffered from tic douleureux for twenty years, the pain being no less severe than in the other case. Two or three operations had been performed, one on the inferior dental and one on the middle branch, without giving relief. When Dr. Abbe saw her two years ago he performed Sulzer's operation, reaching the two branches of the nerve in the temporo sphenoidal fossa at their exit through the foramen rotundum and foramen ovale by making section of the zygomatic arch and dissecting the temporal muscle. The operation proved not diffi-

cult, half an inch of each nerve branch was dissected out and the wound closed. The patient was relieved of pain for two months. It then returned, and for ten months was as great as it had been before. He then, last January, performed the Hartley operation. Like the other case, this one bled very little for this operation. Relief was perfect and remained so until the patient's death, three months later, from some cause not connected with the facial trouble.

Dr. Abbe said that in a number of cases of inveterate neuralgia of the inferior dental, he had taken out an inch or an inch and a half of this nerve and given permanent relief, but some cases had returned. The same was true of the eight or nine cases in which he had performed Carnochan's operation for neuralgia of the middle branch, dividing the nerve back of Meckel's ganglion; some of the patients had been permanently relieved, others had returned. Sulzer's operation was somewhat more difficult than Carnochan's, and left more of a scar, and was not, he thought, as satisfactory as the intra-cranial operation. He had done the Sulzer operation with satisfaction in three cases, but in two there was return of the pain. The Hartley operation was the final one, and although it was more recent than the others, it bade well to give permanent relief. It was quite due Dr. Hartley that it should go by his name. Out of fifty or sixty reported cases there had been a few deaths from hemorrhage or cerebral abscess, but Dr. Abbe thought that with due care these accidents could be avoided.

Dr. Bryant asked Dr. Abbe how he knew the hemorrhage in his case came from the cavernous sinus.

Dr. Abbe replied that there were two sources of hemorrhage. The first was from the middle meningeal artery at the foramen spinosum, a jet coming out which stopped after ligation. The other was venous hemorrhage, which took place while he was isolating and evulsing the nerve, the inner side of the bundle lying close to the cavernous sinus, which, doubtless, was torn and gave rise to the hemorrhage. This was controlled by packing. He had no other proof of the origin of the hemorrhage.

Dr. Bryant thought it was an interesting fact, if proven, that the cavernous sinus could be torn, the hemorrhage checked by gauze packing, and no further trouble follow its removal next day.

Dr. Abbe remarked that a number of operators had resorted to packing, and that Dr. Keene had used a bundle as large as one's fist, showing that the brain could be considerably compressed, yet everything go well after removing the packing.

Dr. Robinson inquired whether the ordinary means for overcoming pain had been tried in these cases, and whether Dr. Abbe would resort to an operation at once.

Dr. Abbe replied that opium, sulphonal, and other agents had been used. He would not operate until the pain had become unbearable.

Some Remarks on the Morphine Habit.—Dr. H. F. Walker read a paper bearing this title (see p. 692).

Dr. George L. Peabody, referring to Dr. Walker's first case, wished to know whether the patient had had a strong enough will, on going to the country, to entirely refrain from morphine.

Dr. Walker replied that he had, but at the beginning he took a little codeia.

Dr. Peabody thought the patient had shown unusual power of will. Regarding codeia, while it was recommended as a means of weaning patients from morphine, he believed that in the form in which it usually came it was equivalent to morphine, and giving it to these patients was practically allowing them to taper off from the morphine habit. So far as he had been able to learn, the weight of evidence was in favor of rather rapid withdrawal of morphine in the treatment of those addicted to its use. He would suppose that, like with alcoholism, gradual withdrawal of the drug would not be successful.

In the second case, it seemed an unusual train of circumstances had favored the success of the treatment adopted. The patient was a doctor, he wished to be hypnotized, had faith in it, and desired to be rid of his habit. Dr. Peabody doubted the general applicability of hypnotism to the morphine habit.

Dr. Robert Abbe had been impressed with the fact emphasized by Dr. Walker—absence of moral force on the part of the morphine habitué. He thought the loss of will-power was equally striking. The few whom he had seen who wished to break themselves of the habit had followed the physician's directions to a certain point, but when it came to cutting the drug down below a certain amount their resolution always failed. He had seen two or three very earnest people try it, but after reaching a relatively small dose they seemed absolutely unable to go farther. Morphine habitués suffered from certain sensations or cravings which they called pain, but which probably were only allied to the pain sense, and these prevented them from giving the drug up entirely, although only a small dose might prove sufficient to allay these sensations. He believed there was a mental deterioration in the chronic cases which possibly might be overcome by hypnotism, but he had had no experience with it. The loss of the moral sense seemed to him a grave phase of the question. Personally he would not trust all the statements of morphine habitués.

Morphinism and Glycosuria. — Dr. Hermann M. Biggs asked an opinion, based on two cases of the morphine habit seen by him. A woman, fifty-three years of age, had begun to take morphine seven or eight years ago, for the relief of pelvic pain, and during the last three or four years had taken the drug continuously. She was taking eight grains a day when he first saw her. Within four or five days the amount was reduced considerably, and it was then that he had occasion to examine the urine carefully and found that it contained sugar. On inquiring into her previous history, it proved very suggestive of glycosuria, from which she had not entirely recovered. There had been frequent micturition, great irritation, thirst, etc. He reduced the quantity of morphine from seven or eight grains to half a grain in the course of a week, and the sugar in the urine increased considerably, until it was about four per cent. She had used in the interval some trional and bromide. She became somnolent, with muttering delirium, and her condition became so serious that he did not dare withdraw more morphine, nor did he think it desirable in view of the glycosuria. Indeed, he gradually increased the quantity to a grain a day. The patient improved slowly, and at the end of two weeks was in her normal condition, taking a grain of morphine a day. The diet was then restricted, and the glycosuria disappeared, but if a quantity of starch were eaten the sugar immediately reappeared in the urine. She had been under observation over two years, the quantity of morphine taken had remained at one grain a day, being administered by her daughter or son, and it seemed she had made no attempt to obtain morphine outside. She had, however, a craving for stimulants, and it was necessary to keep these out of her reach. Her health was very fair.

The second patient was a woman, aged about fifty, who had been addicted to the use of morphine twenty-five years. She had begun taking the drug occasionally when she was twenty-five years old for the relief of pain during the menstrual period, and for fifteen years had taken it continuously, in any form she could get it. When a year before he saw her the opium was cut off. She had been taking ten ounces of McMunn's elixir a day. For seven months before he saw her she had received no opium, but during that time she was in poor health and had had several attacks of serious illness. During the e attacks she was given alcoholic stimulants, and later, during an attack of hay fever was given cocaine in spray, and she immediately contracted

the cocaine habit. She had always had a craving for stimulants, and when Dr. Biggs first saw her she was taking a large quantity of cocaine (about twelve grains a day) and as much alcohol as she could get. On withdrawing the cocaine she passed into a condition resembling acute alcoholism—delirium, sleeplessness, hallucinations, illusions, delusions.

The question arose whether in such a case it was possible or desirable to entirely withdraw the opium and attempt to keep the patient free from narcotics. He supposed it was a sort of heresy, but he had had the feeling that where a patient had been so long addicted to the habit, had lost the power of moral and physical resistance to its influence, and yet who was in good health, as this patient was, the entire withdrawal of the drug would require constant surveillance, and would be followed by enfeeblement of health, and it had also seemed to him that if any narcotic were allowed, opium by the mouth, in restricted amount, would prove the least harmful. He asked for an expression of opinion upon that point.

Dr. A. Alexander Smith said he felt more hopeful after hearing the histories of Dr. Walker's cases than he had felt before, for he had always doubted the ultimate result in any case of confirmed opium-taking. Many years ago Dr. Sands had remarked to him, on observing a morphine habitué in the street, that he did not believe any woman who had become confirmed in the use of the drug could stop it. Dr. Smith was then inclined to doubt this statement, but many years' observation had since convinced him that it was exceedingly rare for patients to become entirely cured of this habit.

How Much Opium is Necessary to Constitute One an Habitué?—Dr. A. A. Smith said further, that he had been interested in the medico-legal aspect of these cases. "Some years ago I was asked by a friend to go to a neighboring State and testify in a suit which he had brought against his father-in-law for keeping his wife and children from him. 'What is the matter with your wife?' 'She is an opium-eater.' 'You had better let the case stand, then. If she is an opium-eater, it seems to me your father-in-law has relieved you of a very great responsibility.' 'I accept that, but I want the children.' And then he asked me what view I took with regard to the reliability of the testimony of any opium-taker, and I said I thought it was absolutely unreliable. I felt that an habitual opium-taker was an habitual liar, and when I took the witness-stand and made that statement I was berated by the opposing counsel, and was asked what I regarded as a habitual opium-taker. The judge seemed very much interested in the question of the reliability of the opium-taker, and he turned to me and said: 'Are you not making a very strong statement?' 'I hope so, for that is exactly what I intended to make, having been impressed with the utter unreliability of these people. It is not because of a vicious purpose, but rather a want of capacity to tell the truth.' I should like to ask Dr. Walker what he considers the smallest quantity of morphine which will make one a confirmed opium-taker, and render his testimony unreliable?" Dr. Walker having replied that he thought it would depend upon the case, and the effect upon the patient, Dr. Smith went on to say that his reply on that occasion was, two grains at least, and from that amount up. That it would differ according to the individual and the circumstances. On that statement his testimony was very much damaged, for in the case in court it was shown that the woman tolerated large quantities of morphine because of severe pain.

Opium and the Temperature.—Dr. F. P. Kinnicutt thought it would be a very important fact if further experience should corroborate Dr. Walker's as to the value of hypnotism in the treatment of opium habitués. He had also seen some striking examples of the perversion of the moral sense in the particular direction of inability to distinguish between truth and falsehood. The word of the opium-taker was not to be relied upon; absolutely not. Regarding the semiology, one point had been impressed upon his mind many years ago which now was probably well known to all. He was asked to see a case with an eminent physician, to determine the cause of an irregular fever from which the patient seemed to be suffering. They were baffled, but later he read of observations made in Europe on temperature of irregular type observed in opium-takers, which at once explained the case.

As to treatment: For the past ten years he had employed only one method, that of sudden withdrawal of all opium, not even permitting the patient to use codeia. While the suffering was great, yet patients who had used both methods had told him that they preferred sudden withdrawal to the prolonged suffering of gradual withdrawal. In some cases the symptoms had appeared alarming, but no untoward result had ensued. He allowed the patients alcohol in any form, in any quantity, and also trional, sulphonal, or bromide, during the treatment. Regarding the ultimate prognosis he must say that he had not very great hope. Out of a considerable number of patients treated by him, only one had left off the drug for a long period. In the one case there had been freedom for ten years. Of course he was speaking of the habit of months' and years' duration.

Prefers Gradual Withdrawal of Opium.—Dr. Beverley Robinson said he agreed in the main with the previous speakers, but he did not think it wise to suddenly withdraw all opium from one who had long been in the habit of taking a large quantity. It caused unnecessary distress. Nor did he think other stimulants would take its place satisfactorily. Regarding the question of prescribing opium, he thought that sometimes it could not be avoided. That day he had used morphine in a case of headache in a woman who had consulted many prominent practitioners in the city without obtaining relief. There were certain mental troubles calling for it, and a neurologist had given it occasionally to one of his patients suffering from melancholia. Druggists sometimes prescribed the drug, or repeated prescriptions containing it without instruction from the doctor. He thought our prescriptions for opium should be allowed to go only to druggists whom we knew to be too conscientious to repeat them unless so directed.

Dr. Peabody said, in relation to giving morphine subcutaneously for the relief of headache, that about five years ago he was asked by a woman to see her husband, a doctor, who had been in receipt of a very large income from his practice, but who had suddenly gone abroad for many months and had only recently returned. The doctor patient quieted his suspicions by immediately telling him that morphine was the cause of all his trouble. He asked Dr. Peabody if he remembered who had given him his first dose of morphine, and stated that it was Dr. Peabody himself, who, seventeen years before, had administered a hypodermic injection for the relief of headache. The patient had continued its use ever since, although there had been intervals.

Dr. Peabody thought we ought not to administer morphine to people troubled with headache.

Dr. Kinnicutt said he fully agreed with Dr. Peabody. Women came to us with sick headache, and it did sometimes seem that morphine was the only drug which would give them relief, but he was positively of the opinion that it should not be used in those cases. A migraine was likely to last a number of years, and if morphine were once used it would likely be continued.

Dr. Peabody added that his patient died a most miserable death as a result of a combination of morphine and cocaine habit. Neurotic people, suffering from chronic neuralgia, were the very ones to whom morphine should not be given.

Dr. Robinson said it must be assumed that those physicians who sometimes gave morphine exercised some precaution and solicitude. They did not put the drug into the patient's hands and walk away. There were some cases which could not be afforded relief in any other way, so that all one could do was either to administer morphine, or walk out of the room and leave the patients to suffer for hours with extreme headache. He was not talking to the general practitioner, but to members of the Practitioners' Society.

Why Opium Habitués Prevaricate.—The President, Dr. Andrew H. Smith, could see no reason why opium should tend any more toward destruction of the moral sense than alcohol. The only difference was, he thought, that the person taking alcohol usually found no necessity for concealing it, while one taking opium always did so stealthily. At first he lied only with regard to this habit, but by degrees he became accustomed to prevaricate. He thought it was wrong to try to corner such patients and convict them of their habit against their statement, for it only precipitated the habit of untruthfulness.

Regarding gradual withdrawal of opium, the usual method was to reduce the quantity by, say, one drop a dose. This meant a reduction perhaps of one-tenth the first day, one-ninth the next, one-eighth the next, and so on, the increase becoming rapid and distressful to the patient. The President had found a better method to consist in filling up the bottle, if a liquid preparation were taken, by adding water or alcohol after each use. By this method the reduction was by a smaller percentage each subsequent dose, but the amount of opium taken finally became infinitesimal. He found in practice two classes of opium habitués. The first class took the drug for the relief of pain or some form of suffering, and for that reason had not the fortitude to lay it aside. The second class, much less numerous, could lay it aside, but continued to take it because of the mental excitement which it caused. The latter were the most intractable. He had known such persons to drop opium for a long time, until all necessity for it must have been lost, and then, when the favorable opportunity came, they deliberately returned to its pleasant sensations.

The President said he had not been able to detect opium in the urine unless it were taken in considerable quantity. He asked for the experience of others in that direction. He supposed all knew that a single dose might send the temperature up, but he did not know whether, after continued use of the drug, the system ceased to respond in this way.

As to depriving the patient of the drug suddenly and entirely, he recalled the case of a physician, an intelligent man, who had been under the care of many doctors at different times. At one time his life seemed to be a complete wreck. Finally it was found that by allowing him a certain amount of morphine every day it would not incapacitate him, and he could attend to a large consultation practice. There was no reason why this moderate amount of morphine, which was essential to him as his daily food, should be cut off. He knew one woman who had become a wretched creature through the use of morphine, mentally, morally, and physically. Under some influence she gave up the drug, regained her health and beauty, and happiness was restored to her family. After a number of years, within the last year or two, she had gone back to opium, and was again becoming a wreck. It was difficult to understand why a person, after such an experience, and after so long a respite, should fall a victim to the drug again.

Regarding habitual headaches, they were difficult to meet at times, and often it seemed cruel to withhold a single injection of morphine which was capable of giving relief. He could hardly bring himself to say that it was wrong to use the drug in such cases when the intervals were long and the danger of establishing the morphine habit was not so great. In one case the woman had suffered about once a month for years, and he was in the habit of giving her relief with a single hypodermic injection of morphine. Finally, he induced her to consent to an operation for very slight strabismus, and from that time the headaches had ceased, and she had received no more morphine.

Dr. Walker closed the discussion.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 1, 1895.

Edward D. Fisher, M.D., President, in the Chair.

Neuritis of the Brachial Plexus, as a Sequel of Pneumonia.—Dr. W. M. Leszynsky presented a man, thirty-six years of age, who five months ago had suffered from an attack of neuritis involving the brachial plexus upon both sides. This condition had developed during convalescence from acute pneumonia. There was no history of traumatism or exposure to cold, nor was there any evidence of alcoholism, syphilis, or rheumatism. He looked upon the pneumonic infection as the direct cause of the neuritis. The speaker said that at present there was a pronounced and typical paralysis of the left serratus magnus, and also some atrophy of the deltoid and supra-spinatus. Upon the right side there was well-marked atrophy of the deltoid, with absolute anæsthesia in the cutaneous distribution of the circumflex nerve, and complete loss of faradic irritability. There was also some atrophy of the supra-spinatus.

Hereditary Cerebellar Ataxia.—Dr. Joseph Collins presented a patient illustrating so-called hereditary cerebellar ataxia. The patient, a boy eleven years of age, was the second of two children. Both his parents were still living, and aside from a marked tubercular history on the paternal side of the family, no hereditary taint could be traced. The child had never had spasms, and had passed through the ordinary infectious diseases of childhood. He began to talk and walk, and the teeth developed, at the customary time. The mother said he had never been able to walk or talk like other children. He was always "stiff in his joints," "easy to fall," etc.; he never climbed and played like other children, though he tried to do so. When four years of age it was noticed that he was becoming very near-sighted, and glasses were applied and had been worn since that time. In February, 1894, after returning from an outing with his father, he vomited a large quantity of liquid, and later clotted blood. A few days before this he had had a fall down a flight of stairs, and to this fall the parents attributed his illness. He had been attending school since his fifth year, and had been repeatedly sent home on account of inability to make any advance. A year ago he had been returned from school permanently. For a year or more there had been periods when his mother said he could not use the left side of the body, and at such times the arm and leg had become very steady, and his speech more unintelligible. Great difficulty had been experienced in keeping him warm, and especially in the winter. The speaker said that mentally the boy was peevish, irritable, and irascible. He was affectionate, fond of animals and pictures, and while he could be led, he could not be dominated. When seen on July 21, 1895, it was noted that he was tall for his years; face looked very old; the skin looked and felt dry and the flesh pultaceous; no enlargement of the thyroid gland; right side of face more innervated than left; very slight grip in hands; knee-jerks exaggerated, especially on the right; elbow-jerk lively; moderate ankle clonus; gait shambling and reeling; head bent forward; walks as if intoxicated; stands fairly well with feet wide apart; no Romberg; genital or-

gans extremely undeveloped. His manner of rising from the recumbent posture resembled that of one suffering from progressive muscular dystrophy, except that he did not "crawl up the legs." There was no real nystagmus, but the fixation power of the eyes was not good, and the eyeballs twitched, and there was slight weakness of the external ocular muscles. There was progressive myopia, but Dr. W. A. Holden, who examined the eyes, stated that in the background no real abnormality could be stated. His speech was ataxic, explosive, and thick, and sometimes quite jerky. It was almost impossible for him to go up and down stairs. Ataxia of the upper extremities very marked. Mentally, he was very defective, particularly his associative faculties.

The speaker said that this case, although not a pure one, would tend to corroborate the view taken of these cases by Nonno, to whom more than to anyone else credit was due for calling intelligent attention to them. Marie, who discussed Nonno's cases, and some others, had suggested the name heredo-ataxic cerebelleuse. He took for granted a factor which apparently was not necessarily constant, viz., heredity, unless we use the terms hereditary and familiary interchangeably. The sister of this boy, who died in her second year, was affected in the same way, for the parents give a very clear description of her condition. Another element stated by Marie to be constant was optic atrophy, yet in some cases recently reported, and in Fraser's case, the first to be substantiated by autopsy, this symptom was absent. The condition has been more commonly observed in patients older than the one just presented. In fact adolescence is the period in which it is usually recognized. It was hardly necessary to refer to the apparent relationship between Friedrich's disease and this condition.

Cystic Tumor of the Brain.—Dr. L. Stieglitz presented a young woman whom he had exhibited to the Society in January, 1893, after she had been operated upon in June, 1892, for a cystic tumor of the brain, situated in the right arm centre.[1] The cystic tumor was subcortical, about one inch and a half deep, and its walls had been found perfectly smooth. About an ounce of straw-colored serous fluid had escaped from the cyst at the operation. In discussing the case at the time, it was clearly shown that the cyst could not have been of vascular or of parasitic origin, and the conclusion had been arrived at, that a glioma was at the bottom of the trouble, and on that account a recurrence of the growth had been feared. During the following two years the patient had done very well, and had recovered the use of her arm sufficiently to attend to her housework, but had been subject to more or less frequent focal epileptic seizures involving the left hand, or the entire left arm and side of the face. During this period she had also had about five general convulsions which had set in with the same focal symptoms. In March of this year, the patient had begun to complain of headaches, the power in her left hand had again perceptibly diminished, and the focal seizures had occurred more frequently than ever, from one to three times a day. Dr. Koller, who had examined her eyes frequently, found a beginning cloudiness and swelling of the disk for the first time. A recurrence of the original neoplasm, or a refilling of the old cyst, was suspected, and Dr. Gerster performed a second operation upon the patient in April of this year. Upon exposure of the brain, a very small maroon-colored mass about the size of a filbert was found at the point where the cyst had been. This mass was removed, and as it evidently infiltrated the surrounding brain-tissue, a broad ring of the latter was excised. The patient made a good recovery. She had two severe general convulsions when the dressings were first removed, but had been free from all seizures ever since, a period of six months. Her arm was at first completely paralyzed, but she had now recovered its use to a certain extent, the only marked paralysis left pertaining to the index-finger, which could not be fully extended, and to the thumb, which could be flexed, extended, abducted, and adducted only very imperfectly. Tactile sensibility was less acute in the paralyzed limb than on the other side. There was a very marked disturbance of the muscular sense, the patient being very uncertain about passive movements in her finger-joints, especially in those of the thumb and index-finger. The deep reflexes of the arm and knee-jerk were greatly exaggerated on the affected side. Curiously enough, they were also distinctly exaggerated on the healthy side, though to a far less degree. The microscopic examination of the excised tumor was very interesting. The old cyst wall was found collapsed; originating from a point in this wall a small spindle-cell sarcoma was found. This could be seen in the specimen. Sections through the ring of brain-tissue removed showed the new growth to be of a very malignant and complex type. From its character at different points it would have to be termed a melano-glio-angio-spindle-cell-fibro-sarcoma. The brain-tissue was infiltrated, and no doubt sooner or later the patient would have a recurrence of the growth.

The case showed that cystic tumors of the brain were not as innocent in character as many would believe, and on that account the excision of the cyst-wall would be advisable in all cases of this kind. If this were not possible at the first operation, it could be easily done at a subsequent operation, a few months later, when the wall would be found compressed into a small, solid mass.

Dr. B. Sachs expressed the belief that the original cyst might very well have been of hemorrhagic origin.

The President said that the clinical history of the case prior to the first operation would throw light upon that question.

Dr. Stieglitz said that in order to save time he had omitted the details of the original history. The patient had been perfectly well up to December, 1891, when she had been suddenly taken with twitching in her right thumb and fore-finger. The twitching had spread rapidly up the arm to the face, and had ended in a general convulsion. In December the patient had had three or four more general convulsions of the same character, but none after this time. She had been subject, however, to frequent focal seizures confined to the right hand. When first seen in December there had been no loss of power in the arm. The weakness in the arm had developed the following March, and had gradually increased, until in June, the time of the first operation, it had become very marked. In spite of the absence of all general cerebral symptoms, the diagnosis of progressive, destructive focal process, probably a tumor, had been made. The slow and late development of the paralysis after the onset of the symptoms of cortical irritation positively excluded any vascular lesion.

Amyotrophic Lateral Sclerosis.—Dr. William Hirsch presented a case of amyotrophic lateral sclerosis, which had developed in a patient who had formerly had anterior poliomyelitis. M. D——, forty-five years of age, gave a negative history as regards syphilis and heredity. About three years ago he noticed a stiffness and weakness in his left leg, which gradually became worse. After some time, the right leg also became affected. He soon became unable to use his legs in working his sewing-machine (being a tailor), and his gait became so much impaired that he was not able to stand or walk for any length of time. When he came under treatment, four weeks ago, he had complained of nothing else, and there were no sensory symptoms or disturbance of bladder or rectum. The examination showed an atrophy of some of the muscles of the trunk and the upper extremities. The right deltoid, the su-

[1] American Journal of the Medical Sciences, June, 1893.

pra-spinatus, and especially the thenar eminence on the right hand, showed a fairly marked atrophy. There was fibrillation in the muscles of the trunk and shoulder, increased by tapping them with a percussion hammer. There was also diminished electric excitability, and in some muscles the reaction of degeneration was present. There was no atrophy in the muscles of the lower extremities, and the electric reaction was perfectly normal in these parts. The tendon reflexes of the lower extremities were considerably increased, the knee-jerks were extremely exaggerated, and there was bilateral ankle clonus. The last very frequently came on spontaneously, to the great annoyance of the patient. Sensation was perfectly normal in all parts of the body, and the senses of pain and temperature were unimpaired. There were no abnormal conditions in the function of the cranial nerves, with the exception that the tongue was slightly atrophied, and there was a marked masseter reflex. Speech was in no way affected. There was no nystagmus, and the ophthalmoscopic examination showed perfectly normal conditions.

This was evidently a typical case of amyotrophic lateral sclerosis, and the man was brought here because of a possible relation between the present disease and an old affection.

An examination of the case at present showed a very marked atrophy of the muscles of the left shoulder and upper arm, but the patient did not think it worthy of mention, as he said it had existed as long as he could remember. This appearance together with the history show that he had had in childhood an attack of infantile paralysis. This brought up the interesting question, Does there exist any relation between the present disease and the anterior poliomyelitis, and if so, what is the nature of this relation? Dr. Hirsch said that Ballet and Dutil were the first to enter upon a discussion of this subject. They pointed out that an infantile spinal paralysis might give rise in later life to various affections of the spinal cord, but that they were all limited to the gray matter of the anterior horns. The irritation of the cord by the old lesions enfeebled, they said, the medulla and made it a *locus minoris resistentiæ*, which on any occasion might become subject to further disease. Charcot expressed the view that there existed in some individuals a certain disposition, a kind of hereditary vulnerability of the ganglion cells of the anterior horns, which at one period of life might give rise to an acute poliomyelitic anterior, and at another, to a progressive muscular atrophy, so that in fact both diseases would form different periods of one and the same pathological process. In some cases of infantile spinal paralysis, Charcot said, the old scar which was produced by the inflammatory process in the gray matter of the anterior horns, formed a latent, but permanent, inflammatory focus, which at any time might light up afresh and cause a new set of symptoms. A similar view, the speaker said, was held by Strumpell, who, on the theory of the infectious origin of poliomyelitis anterior, compared the scar in the anterior horns to an old tubercular focus which was capable of setting up a new inflammation at any time. So far as he knew, the case presented differed from all others recorded in literature, in that the later disease was not limited to the anterior horns of the gray substance, but that other parts of the cord were also involved, *i.e.*, both lateral pyramidal tracts. He would not attempt to decide upon which of the theories applied to this case, but it could be proved with absolute certainty, by the history of the clinical symptoms, that the pathological process of the present disease started from the place where the old scar of the poliomyelitis anterior was located. This lesion lay apparently in the left horn of the cervical region of the cord. As the man first noticed weakness and stiffness of the left leg, the process must have approached first the left pyramidal tract, which lay next to the scar. Then, after the affection of the right horn, which showed itself in atrophy of the muscles of the right upper extremity, the pathological process spread over to the right pyramidal tract, causing a spastic condition in the right leg. Whatever the theory regarding the nature of the relation between the two diseases, there could be no doubt that there existed such a relation between infantile spinal paralysis and various spinal diseases of later life. Further observation and study of similar cases might throw more light upon this subject, as well as upon the etiology and nature of the diseases in question.

A Report of a Series of Cases of Multiple Neuritis in Infants in the City of Bridgeport, Conn.—Dr. Græme M. Hammond read a paper in which he reported a series of cases of multiple neuritis in infants in the city of Bridgeport, Conn. There were ten cases in all, ranging from four and a half months to four and a half years in age. In all but two cases there were distinct premonitory symptoms of headache, vomiting, and fever. Following this there was a gradual and progressive paralysis, usually beginning in the foot and extending to the upper extremities, and in some instances involving the muscles of the trunk, and in two cases the muscles of deglutition. Accompanying the paralysis there was pain, both spontaneous and on passive motion, and the nerve-trunks were very sensitive to pressure. The area of pain and tenderness accompanied the extension of the paralysis. The reflexes were abolished, and the electrical reactions of degeneration were well marked. Two of the cases exhibited symptoms of spinal meningitis in addition to the neuritis. One case, the youngest, aged four and a half months, died after an illness lasting one month. The muscles of deglutition became paralyzed, and the child died from exhaustion. In the other cases recovery began in from four to six weeks, but was not completed until from three to four months. No similar cases were discovered in neighboring towns. After referring to the epidemics of anterior poliomyelitis which have in the past been reported, both in Europe and in America, the reader concluded by accepting the theory of their microbic origin, and expressed his belief that these cases of neuritis were due to a similar cause.

The author expressed his indebtedness to Dr. John C. Lynch, Dr. Samuel M. Garlick, and Dr. J. W. Wright, of Bridgeport, for the reports of cases, and for their courtesy in affording him the opportunities for personal examinations.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 9, 1895.

George P. Biggs, M.D., President, in the Chair.

Diseased Placenta.—Dr. Mary Putnam-Jacobi presented an extremely diseased placenta, together with the liver, heart, lungs, and kidneys of the child. As the child had been born only two days before, no opportunity had been given for a microscopical examination. It was the mother's third child, and the first one born at term. All three children had died with exactly the same symptoms. The mother had been married about twelve years, and had been apparently healthy at the time of her marriage. For the first two or three years afterward she had been under treatment for sterility. No obvious uterine disease had been discovered. Afterward, she had had two early miscarriages. When about three months pregnant, a watery discharge from the uterus began, and became more and more abundant until, at about the seventh month, labor had come on spontaneously. The child lived two hours. About three years later she again became pregnant, and again, at about the third month, there was a similar discharge of water. As a result of keeping absolutely quiet the discharge was diminished, but by the sixth month it had become very profuse, and

the uterus almost empty of fluid. This gave rise to strong uterine contractions, several times a day. She was kept under opiates with the hope of postponing labor until the period of viability. This was done, for labor occurred when she was seven months and one week pregnant. The child was placed in an incubator and did well for a short time. It then began to breathe with great rapidity, and after a few minutes of this excessively rapid respiration it died. Last January this woman again became pregnant. She was at once placed on milk diet, and medication with iodide of potassium and bichloride of mercury. This time the child was carried to within four days of full term; then there was spontaneous labor, and after four or five hours a child weighing about four pounds was delivered. The child was cyanosed and extremely feeble. Just before labor the fœtal pulse had been very strong, and 140 per minute. The child was wrapped in cotton and kept warm by artificial heat. For one hour after its birth the fontanelle beat forcibly. Seven hours after birth the respirations suddenly rose to 70, and a few minutes later the heart stopped beating. An autopsy was made two or three hours later, and the pleural cavities were found distended with fluid which, on the right side was sanguinolent, but on the left side clear. The fluid in the pericardium was also very abundant. There was no fluid in the peritoneal cavity. The lungs had evidently expanded, as they floated perfectly on water, but they were found to be intensely congested throughout. There was no evidence of there having been any intra-uterine respiration. The greatest congestion was located in the upper lobe of the right lung, and in the lower lobe of the same lung. The right heart was completely empty, while the left ventricle was distended with a large quantity of dark coagula, and these extended into the left auricle. It would appear, therefore, that the arrest of the heart began, not in the lungs, in which case the damming up of the circulation should have been in the right heart, but in the left heart, and hence, as the left ventricle was unable to empty itself, there was a damming up of the blood toward the auricle and the lungs. On this theory it was inferred that the congestion of the lung might be the immediate consequence of a failure of the left ventricle to contract. The liver was of normal size, and in the fresh state looked quite normal. Without a microscopical examination, the speaker said, she could not state at all positively regarding the condition of the kidneys. The placenta was excessively small, and there was an entire absence of the normal lobulation of the placenta. From the gross appearance, the maternal side of the placenta seemed healthy, but on the fœtal side the placenta was almost completely converted into a tough, thick mass. The manner in which the blood-vessels entered the placenta would seem to indicate some form of degeneration, either fibroid or amyloid, which had caused contraction of the tissue around it. The exact form of degeneration could not be stated without microscopical examination. The placenta probably represented that type formerly called "fatty placenta," but now known to be a condition in which the blood-vessels have become degenerated. The existence of hydro-thorax and hydro-pericarditis in this case was interesting from several points of view. In the first place, there was nothing in the child typical of "general dropsy of the fœtus." Ballantine, an authority on this subject of general dropsy, says that this condition hardly ever occurs in women having renal disease. This mother, ever since the first pregnancy, had presented more or less pronounced indications of chronic interstitial nephritis. At that time there had been no albuminuria, and the urea had been sufficient in quantity. The discharge of amniotic fluid the speaker was inclined to attribute rather to a disease of the chorion primarily, because the patient had had a slight endometritis. In the interval between the first and second pregnancies the symptoms of nephritis had become more pronounced—there had been a marked diminution in the urotoxic coefficient. Normally, from thirty to sixty cubic centimetres of urine were necessary to poison a single kilogramme of rabbit, while in this patient from seventy-three to eighty cubic centimetres had been required. In the second pregnancy this diminution of toxicity persisted, and she also began to exhibit a slight dilatation of the heart. She had, during the pregnancy, two or three distinct attacks of transient aphasia and hemiplegia. There was no albuminuria, but after the birth of the child marked œdema of the lower extremities and albuminuria were present for a short time. During the last pregnancy a tricuspid insufficiency developed, there was some œdema, the albuminuria was marked about one month before confinement, and there were one or two uræmic attacks before confinement.

Dr. Jacobi closed by propounding the following questions: Is not the degeneration of the placenta an expression of the poisoning of the maternal blood? Was the hydro-thorax and hydro-pericarditis the direct expression of this poisoning derived from the maternal blood, or was there any renal disease inherited by the fœtus, and there being an obstruction of the peripheric circulation, the heart was unable to overcome it, and heart failure resulted? Or, was it an expression simply of asthenia from the cachexia? Could this abundant effusion into the cavity have occurred during the seven hours of extra-uterine life, or did it occur before birth?

Dr. H. S. Stearns, in answer to the query regarding the rapidity with which an effusion might occur, referred to the rapidity with which the pleural cavity filled up in cases of empyema. He had at the present time under observation a case which would discharge about ten ounces in twenty-four hours.

Dr. Donald M. Barstow thought it unlikely that the lungs would have expanded so well had this effusion existed before birth. He recalled several autopsies in which there had been apparently a very rapid effusion of fluid into the pleural cavity just before death.

Dr. Warren Coleman said that he had seen at autopsy, on the preceding day, a case which had been previously carefully examined physically by a competent physician, and no fluid detected, yet at autopsy a considerable quantity of perfectly clear liquid was found in both pleural cavities. In this case, the actual cause of death was thrombosis of both pulmonary arteries. To be sure, there was in this instance a decided obstruction to the circulation, but in the case now under discussion, the marked congestion of the lungs might be considered as an obstruction to the circulation.

The President said that it was very common, at autopsies on very young infants, to be unable to determine satisfactorily from the pathological findings the cause of death. It was particularly difficult to discern slight changes in the kidneys of such infants, at least without microscopical examination. He had also frequently observed at autopsy a considerable quantity of fluid in the pericardial and pleural cavities, in cases in which careful physical examination just before death had failed to show the existence of such an effusion.

Rupture of the Liver.—Dr. Donald M. Barstow presented a liver removed from a man who had been brought into the Hudson Street Hospital on June 2d. About half an hour previously a rope had been twisted around him, thus squeezing the body forcibly. He was in a condition of collapse at the time of admission, apparently from internal hemorrhage. Before infusion could be performed, the man died. At autopsy, made about three hours after death, abrasions were found on the two sides, on the lower part of the thorax, marking the location of the rope. Curiously enough, the ribs did not appear to have been at all injured. The heart and lungs were normal. About four quarts of blood

were removed from the peritoneal cavity. The only injury was in the liver, the tissue of which had been completely ruptured between the lobes.

Dr. Coleman asked the experience of the President as to the seat of rupture with reference to the point at which the external violence had been applied—was the rupture at this point or on the opposite side?

The President said that he had not observed that these injuries followed any definite rule of this kind. He could, however, recall seeing the rupture at some distant point from the spot at which the violence was applied.

Dr. Coleman said that he had seen on the preceding day an autopsy on a man who had fallen off a fire-escape. The external marks of violence extended from the ensiform cartilage to the umbilicus. The cause of death was found to be a very similar rupture of the liver. All the organs were markedly anæmic, and the abdominal cavity was filled with blood. In this instance it seemed as if the blow had thrown the liver back, and that the tension thus produced in the suspensory ligament had resulted in the rupture at this point. There was no other internal injury.

"**Dissecting Aneurism of the Aorta, Rupturing into the Pericardium.**"—Dr. Warren Coleman reported a case of this kind. The subject was a muscular, well-developed man, forty-seven years of age, a meat-carver by occupation, found dead in his room. As he lived alone, no history could be obtained, and all that could be learned was that he had failed to report for work one morning, and on investigation he had been found dead. When the sternal plate had been removed, the pericardium was found full of blood, and in addition a distinct swelling at the ascending portion of the aortic arch was noted. Suspecting rupture of the heart, or an aneurism at the arch, the thoracic viscera were removed, including the thoracic portion of the aorta, and then the parts were carefully dissected. The examination of the heart excluded rupture, and the calibre of the aorta was normal, at least as far as the diaphragm. The outer portion of the aortic wall, however, had been dissected off throughout almost the whole of its circumference, and from the diaphragm to the heart, by an effusion of blood which, upon reaching the pericardium, had broken into it at the reduplication of the membrane upon the aorta. The blood had not suffused itself between the aorta and pulmonary artery, but had passed down on the right, or outer side of the arch. The inner surface of the thoracic portion of the aorta was normal except for a few atheromatous patches, none of which had ruptured. Aneurism of the abdominal aorta was then sought for as a source of the blood, and the abdominal viscera carefully removed. But the aorta was of normal size down to the bifurcation, as were the common and external and internal iliac arteries. The aorta and the iliacs were removed as far as Poupart's ligament, especial care being taken not to wound the vessel wall. The separation of the coats of the vessel extended to the bifurcation of the aorta, and thence down the left common iliac to its division into external and internal. Upon opening the vessels, extensive atheromatous patches were discovered in the region of the cœliac axis, and above it to the diaphragm, while below the patches were few and discrete. None of these patches had ruptured. Atheromatous changes were found also around the mouths of the lumbar branches of the aorta. With a probe sufficiently large and blunt to prevent an accidental puncture, these branches were tested, and it was found that three had been torn just at their junction with the aorta, and that a communication existed between the lumen of the aorta and the space in its wall. The torn vessels were in the region of the cœliac axis, the portion of the aorta showing the most extensive atheromatous changes The fact that more than one of the lumbar arteries was ruptured, of course, cast some doubt, the speaker said, on his interpretation of the case: but admitting the method pursued to have been defective, it did not seem likely that each of the three arteries would have been cut just at its junction with the aorta. Cutting them from within would have been impossible, as an enterotome was used in opening the aorta, and an accidental cut from without might be excluded also, for the wound did not involve the outer portion of the aortic wall, but extended only to the space formed by the effusion of blood. The explanation offered by Dr. Coleman was, partial rupture of the aortic wall at the mouth of perhaps one of the lumbar arteries, the other two being torn subsequently as the result of violent physical exertion, or a blow on the abdomen followed by an effusion of blood both below and above, until the rupture into the pericardial sac occurred. It was impossible, owing to the absence of a history, to determine the length of time between the rupture of the artery and the occurrence of death. As nearly as could be ascertained, this interval was not greater than forty-eight hours, and perhaps less than thirty-four hours. The rupture of more than one of the lumbar arteries must have increased the amount of blood extravasated, and have hastened the onset of death.

The speaker said that dissecting aneurisms were rare as compared with the other varieties. They were seldom recognized during life. The duration of life after the rupture of the artery varied greatly in different cases. Holmes states that "when the coverings of the blood are strong, and the fluid finds a ready passage back into the artery, life may be prolonged for a considerable period; in fact, the symptoms referred to the disease have been observed to last for years." The blood, however, instead of re-entering the artery, might suffuse itself into the surrounding tissues, or pass upward along the course of the vessel until it finally ruptured into the pericardium. Holmes says: "The position of the original rent seems always to be in the aorta, and generally in the arch, quite close to its origin; though it has been known to be situated in the abdominal aorta, even as low as its bifurcation. The position of the secondary rupture of the inner coats, by which the blood passes back into the cavity of the vessel, varies much. A case is mentioned in which the separation extended into the popliteal artery; and in another case, in which the primary rent was in the transverse arch, the secondary opening was in the subclavian. Death occurs soon in all cases where the blood passes out of the artery, either into the pericardium or into the surrounding tissues: and in most of those in which the blood makes its way back into the artery. The patient is usually advanced in life, very probably a female, and suffering from hypertrophy or other disease of the heart."

Abdominal Aneurisms.—Dr. George P. Biggs presented an abdominal aneurism removed from a male, aged thirty-one, an ice-man by occupation. He had been admitted to the New York Hospital on September 16th, and had died the same night. It was said that a week before admission he had begun to have constant pain in the left shoulder, and three days before admission, pain in his right shoulder and neck, and occasionally across the chest. For these three days he had been unable to retain any food. He had been accustomed at his work to carry very heavy blocks of ice. On the day before admission he had had severe headache and pain in the back. At autopsy a number of old cicatrices were found on the legs, suggestive of specific disease. The peritoneal cavity contained 1,500 c.c. of blood: the left pleural cavity contained 200 c.c., and the right pleural cavity, 400 c.c. of blood; there were a few old tubercular lesions in both lungs. In the abdominal aorta was a sacculated aneurism. It was just below the diaphragm on the anterior aspect of the artery, and just above the superior mesenteric artery. The aneurism pressed forward just about the cardiac end of the stomach, and near the cardiac orifice. The opening from the artery to the aneurism was circular,

and 1½ ctm. in diameter. The aneurismal sac was 10 ctm. in diameter, and was filled with coagulated blood and thick layers of fibrin. In the adventitia of the aorta there was an extensive dissection of blood for some distance below the point of the aneurism, and upward about the œsophagus and aorta to the middle of the transverse portion of the arch. No distinct point of rupture into the left pleural cavity was found, but on the right side there was a distinct rent through the pleura near the root of the lung. It was about half an inch in length. There was also a large rupture at the peritoneum. In addition to these lesions, there were chronic diffuse nephritis and a fairly well-marked cirrhosis of the liver. The interesting feature was the multiple points of extravasation of blood.

Dr. Biggs then presented another aneurism. He said that in an autopsy occurring within a few days of the preceding one, another abdominal aneurism had been found—or rather, three aortic aneurisms in the one case. The specimen presented had been removed from a man, aged forty-five, an engineer by occupation. He had been found by an ambulance surgeon in the street, where he had suddenly fallen while walking. It was said that consciousness had been lost for a short period after the fall. When first seen he was complaining of severe pain in the right hypochondriac region. For two or three days previously he had not been feeling very well. From the location and character of the pain, together with the statement that these pains had been experienced several times before, the ambulance surgeon thought the man was suffering from biliary colic. Examination at the hospital showed the whole right side of the thorax to be extremely tender. Dyspnœa was quite marked, but was thought to be due to the pain caused by respiratory movements. He died quite suddenly during the night on which he was admitted, and after the expectoration of a few ounces of fluid blood. At autopsy there was such extreme emaciation present that the case appeared on inspection to be one of phthisis. The diaphragm on the left side was at the level of the fifth space in the mammary line, whereas on the right side it was very much depressed, having a convex instead of a concave under-surface, and being on a level with the sixth space on the mammary line, and extending nearly down to the free border of the ribs in the axillary line. The left pleura presented only a few old adhesions. The right pleural cavity contained 400 c.c. of coagulated and fluid blood in about equal quantity. The heart was normal in size, the ventricles were contracted, the muscle was apparently normal. There were slight atheromatous changes in the mitral and aortic valves. Both primary bronchi contained a small quantity of coagulated blood, and the small bronchi in the lung contained also a considerable quantity of blood. The left lung appeared normal. The pleura over the posterior and outer surfaces of the right lower lobe was completely dissected up from the lung by extensive hemorrhage. No distinct point of rupture into the bronchi could be detected, but it was thought that the small quantity of blood in the bronchi came from multiple extravasations into the pulmonary tissue. The spleen and kidneys were normal. The liver was distinctly cirrhotic, but not of the syphilitic form. The aorta was the seat of advanced atheromatous changes throughout. It presented three aneurismal dilatations; the first one, situated in the upper part of the descending portion of the aortic arch, was about the size of a hen's egg. It projected forward, and was adherent to the apex of the left lung. The mouth of the aneurism was 3½ ctm. in diameter, and the wall 1½ to 2 mm. in thickness. The inner surface was not lined with fibrin. The second aneurism was found in the thoracic portion of the aorta, opposite the root of the lung. It projected backward, and had eroded superficially the soft tissues over the seventh, eighth, and ninth dorsal vertebræ. Its diameter was 7 ctm., and the opening into the lumen of the aorta was of about the same size. The wall was only 1 mm. in thickness in certain portions. It was not lined by fibrin. There was a large, ragged rupture 2 ctm. in diameter at the root of the right lung, and blood escaped through this rupture between the visceral pleura and the lung. The third aneurism was located in the abdominal aorta, just above the origin of the renal arteries. It had a diameter of 4 ctm., and an opening of about the same size. The superior mesenteric artery and the cœliac axis arose from the interior of the aneurism. The former was of large size, while the latter was completely occluded just at the origin of the vessel from the aneurismal sac. The occlusion seemed to be due to the contraction of new fibrous tissue in the wall around the lumen. The manner in which the blood-supply was kept up under these circumstances could not be determined, as the specimen had not been carefully dissected, and this point was not discovered until the following day.

Dr. Coleman said that in view of the occlusion of the cœliac axis, he would like to know the exact condition of the stomach and spleen.

Dr. Biggs replied that both these organs were normal, although it was difficult to understand how that could be.

The Society then went into executive session.

Clinical Department.

ACUTE ŒDEMA OF THE LARYNX.

By E. B. BAYLIES, M.D.,

DAYTON, O.

Dr. F. E. Hopkins, in reporting an interesting case of this distressing affection in the issue of the Medical Record dated October 19th, goes exhaustively into the subject of etiology, but seems to have forgotten that malaria has shown one of its many ways of attacking mortals by appearing in this form.

Dr. Jacob D. Arnold, in his article on acute laryngitis contributed to Burnett's "System of Diseases of the Ear, Nose, and Throat," pages 312 and 313, describes what he terms miasmatic epiglottitis, and cites cases in point.

The following case is reported on account of its uniqueness in demonstrating the possibility of malaria causing œdema of the glottis, as well as showing how readily it can be controlled by the proper remedies.

A. B——, aged thirty, a letter carrier, presented himself at the office on June 4th last, relating a history of having been under the care of a homœopathic physician for about a week, on account of difficulty in breathing and swallowing, the diagnosis having been tonsillitis.

At this time breathing was moderately difficult, and deglutition was not exceedingly painful.

Examination revealed a reddened pharynx, but no evidence of the enlargement of the tonsils.

A laryngoscopic examination brought to view a typical case of œdema of the larynx, though the tissues were not so much swollen as to prevent a very fair view of the cords.

After cocainizing the parts, a thorough application of zinc chloride two per cent. solution was made, and the patient sent home, to report next day, taking, in the meantime, lozenges composed of mild astringents, to be dissolved in the mouth at stated intervals and swallowed. No report was heard from him the next day, but the day following a call to come in haste was received. On arriving at the house it was seen that all the symptoms were very much aggravated, though the patient said that the day before he had concluded that entire recovery had taken place. The treatment was as before, with the addition of cold applications to the

throat, and proper medication for an elevation of temperature to 101° F., which was found. Toward evening the symptoms abated, and the night and following day were spent in comparative comfort. The fifth day of his being under my care was the worst of the series. The temperature was above 101° F., and all the symptoms were more grave. The voice was husky, and in fact it began to look as if more radical measures would have to be employed if life was to be saved.

The peculiarity of the action of the disease had impressed me with the fact that perhaps it was of malarial origin, and I began the exhibition of quinine as soon as the fever subsided. Five grains that night, ten the next morning and night, with five on the morning of the seventh day, had a happy effect, the attack on that occasion being very mild. A continuation of the treatment as outlined above prevented any further trouble and restored the man to health.

This cannot be called a malarious country, but if the action of remedies has anything to do with determining the nature of diseases, my case was surely one produced by miasmatic influences.

A YOUNG MOTHER.

By C. W. GLEAVES, M.D.,

WYTHEVILLE, VA.

I WISH to report the case of the youngest mother in Virginia. Annie H—— was born in Bland County July 15, 1885, and September 10, 1895, she was delivered of a well-formed child weighing five pounds. She was only ten years and nearly two months old. The girl has no developments of a woman, although she has menstruated regularly since she was five years old.

The labor was a short and uneventful one, and two hours afterward the child-mother wanted to get up and dress, and would have done so had she been permitted.

There were no developments of the mammæ, or secretion of milk; the baby was nourished through its short existence (as it only lived a week) by its grandmother, who had a child only a few months old. The parents of this child, Mr. and Mrs. J. P. H.——, are prosperous, intelligent, and worthy people, and there is no doubt of their child's age.

The child is now well, and plays about with the other children as if nothing unusual had happened.

CANCER OF THE PROSTATE GLAND.

By ERLY H. MADISON, M.D.,

OKAMEL, N. Y.

WILLIAM D——, aged sixty-seven, carpenter by trade; health, previous to last illness, was always good. Gave the following history:

In the winter of 1890 he received an injury in the region of the prostate gland, caused by being thrown on the pommel of a saddle while riding horseback. This injury caused him trouble for some little time, but he finally recovered, as he thought, perfectly.

In the winter of 1894 he complained of uneasiness and pain in the neck of the bladder and in the region of the prostate, accompanied by a frequent desire to urinate; also pain upon defecation. These symptoms gradually increased in severity until about May 1, 1895, when he was confined to the house, with complete retention of the urine and great pain at stool. About this time he had an attack of localized peritonitis on the left side, which readily yielded to treatment.

The most prominent symptoms in this case were frequent desire to urinate, pain upon defecation, and intense pain in the region of the bladder and prostate gland, emaciation, and loss of appetite.

Cancer of the prostate gland was diagnosed. About January 10, 1895, I called Dr. A. H. Lyman, of Fillmore, N. Y., in consultation, who confirmed my diagnosis and who watched the case with me during the remainder of his illness. The symptoms already described steadily increased until death, July 3, 1895.

Post-mortem showed a scirrhus of the prostate gland about as large as a hen's egg, nodular and very hard. The peritoneum was also infiltrated with cancerous masses. There was also a small secondary cancer of the liver, some portions of which had undergone calcareous degeneration. The bladder contained about one ounce of purulent liquid, evidently partly urine, partly pus. The mucous membrane at the base of the organ, while extremely red, could hardly be said to be ulcerated. A more correct description of it would be conveyed by the term granular inflammation. The rectal wall was infiltrated by the growth and was adherent to the tumor, although rectal symptoms were surprisingly few and slight, being practically limited to pain on defecation.

The peculiar characteristics of this case are: 1. The rarity of the disease. I have been able to find only three cases reported, two by Sir Henry Thompson. Dr. Samuel D. Gross says he never saw in all his practice a scirrhus of the prostate, the only form he ever saw being colloid. 2. The obscurity of the symptoms, making diagnosis extremely difficult. 3 The amount of opiate required to control the pain. The last three weeks of his illness I gave him four grains of morphine, hypodermically, every four hours, and this amount did not produce complete narcosis, the effect lasting only from two to three hours. A hypodermic needle was used on this case something over one thousand times.

Such cases as this are extremely suggestive in the light of present pathological knowledge. Here was a growth no larger than a hen's egg which had not ulcerated and which caused no pressure symptom whatever excepting inability to urinate. The urine, to within a few days of death, remained entirely normal as far as chemical analysis showed. The microscope only showed a small amount of mucus from the bladder. There was never any rectal discharge, and the post-mortem showed no breaking down of the tumor. And still the growth caused death.

Death from malignant disease is generally attributed to sepsis from absorption from ulcerated surfaces and to hemorrhage. But such cases as this seem to point to a specific cancer poison, to a specific cancer germ which, though it now eludes the microscope, still probably exists and will some day be discovered.

Quackery in Bavaria.—Official statistics which have recently been published show that the total number of persons practising the healing art without a legal qualification in Bavaria, at the end of 1894, was 1,168 as against 1,152 in the previous year. Of the number 866 were men and 302 were women. With the exception of 17 Austrians, 2 Americans, 1 Italian, and 1 Swiss, the whole of this noble army of quacks was a home product. As regards the special form of quackery, the statistics show some curious features. Thus, 12 philanthropists devote themselves to freeing their fellow-creatures from tapeworms; 12 practise "electrohomœopathy," whatever that may be; while 84 are set down as apostles of homœopathy, pure and simple; 129 offer to sufferers—for a consideration—"secret remedies and sympathy," and 3 deal in uroscopy.—*British Medical Journal.*

Phœnix, Ariz., is progressive. It has recently organized an Anti-Noise League. When the league is in good running order we hope it will send missionaries to New York and other suffering places.

Surgical Suggestions.

Caries of Vertebræ.—Fontan describes a new operation for reaching the bodies of the vertebræ; he makes an incision one centimetre from the middle line, splits the common mass of muscles in order to come upon the apophyseal tubercle; then outside this he plunges in his finger, in order to recognize the costal apophysis which lies at a deeper level. Then with a chisel he cuts this at its base, seizes it, and excises it completely. From here he follows the vertebral column from behind forward with the raspatory, keeping close to the bone under the periosteum, until he reaches the seat of the caries.—M. Fontan.

Diphtheritic Conjunctivitis.—The only local treatment was by washing with warm water and with a solution of boric acid, and the serum was administered in doses of from ten to thirty cubic centimetres, according to severity and to the age of the patient. In two of the cases single doses of ten cubic centimetres were sufficient.—Morax.

Appendicitis.—I have been led to feel that when the symptoms indicate appendicitis, the combination of a rapid pulse and respiration, going with a temperature normal, or nearly so, points to the necessity for prompt operation.—Dawbarn.

Bone-grafting.—Dead bone seems to answer the same purpose as the living, if it fills the defect properly, the formation of bone in each case taking place throughout the implanted portions of bone. With decalcified bone the case is different; the deposition of bone takes place only on the surfaces of the fragments. Bone in which the animal matter has been destroyed by heat answers the same purpose. The beneficial influence seems to depend upon the presence of the calcium salts. The author states that calcined bone placed in the soft parts, or even in the abdominal cavity, is followed by bone-formation.—Barth.

Vaginal Secretion of New-born Infants.—For twelve hours after birth the vulva and vagina are sterile. From this time until the third day germs are occasionally found, and after the third day they are present in most cases. In four per cent. of cases staphylococci were discovered, while in 14.6 per cent. streptococci were isolated.—Vahle.

Is it Peritoneum or Transversalis Fascia?—Regarding the recognition of peritoneum as distinguished from transversalis fascia, these membranes cannot always be distinguished by a differing appearance. I have often seen transversalis fascia that did not look fibrillated, and was just as shining as the peritoneum. Possibly it may be worth while, for others than the members of this Society, to refer to a valuable point which many years ago I obtained from Dr. McBurney, and have never seen in print, namely, that after cutting the deepest muscle, its cut edge be lifted and its deep surface examined. If, now, that surface be found bare, then the transversalis fascia has not yet been cut. But if that under-surface of the deepest muscle be found covered with a fascia, however thin, that is the transversalis fascia, which has already been cut, and then the next membrane attacked will of course be the peritoneum.—Dawbarn.

Cancer.—He believes that both on *a priori* grounds and on the existing evidence the germ-theory of cancer should be rejected unhesitatingly, and thinks that "the microbe of cancer has not yet been discovered, because in all probability it does not exist." As to contagion, there is not a single authentic instance of the transmission of cancer from one individual to another, and the alleged successes in the attempts to transmit it to lower animals should, he thinks, be accepted only in a tentative sense.—Williams.

Correlated Variability.—It is a very remarkable fact that in every female all the secondary male characters, and in every male all the secondary female characters, exist in a latent state, ready to be evolved under certain conditions. It seems perfectly warrantable to assume that the normal condition of the mammæ in each sex is determined by correlation with the essential sexual organs. When the latter are destroyed the correlated integrated force determining mammary development also fails, so that the latent tendency to develop the opposite sexual characters then becomes manifest.—Williams.

Foul and Sloughy Wounds.—In the treatment of this sloughing surface sterile gauze soaked in oil of turpentine was freely employed and changed daily, the skin being thickly dusted with compound talcum or bismuth subnitrate, to avoid turpentine blistering. This treatment was not much complained of, and was ideal in its results. Indeed, in foul and sloughy wounds, everywhere, the writer knows of no plan of equal value with this, which he first saw suggested many years ago by Dr. Banks, the Liverpool surgeon.—Dawbarn.

Lithotomy.— The supra-pubic method seems so thoroughly to have established itself among surgeons that one may easily look forward to its being the operation of the future.—Heath.

Flat Foot.—1. The feet of the infant at birth are not flat; the tracing at that time resembles the adult normal foot. 2. A body of fat develops under the arch which gives the appearance of flat foot for some years, and at four or five years of age this is absorbed. 3. The smoke tracing is not a perfect method of studying abnormality of the arch of the foot, because it fails to detect the slighter cases or to record pronation. 4. The element of pronation is more constant than breaking down of the arch of the foot, and may be entirely separated from it. 5. The condition of pronated foot without breaking down of the arch of the foot, should be recognized and not confused with flat foot. 6. The treatment of pronate and flat-foot is the same, and consists in the use of proper boots, the application of a pad or plate, the stretching of the gastrocnemius muscle where it is shortened, and in the routine use of massage if obtainable, and always of exercises to develop the muscles which hold up the arch.—Hovett and Dane.

Ectopic Pregnancy.—The etiology of ectopic pregnancy is still shrouded in doubt, but after examining a large number of cases and the prior history of these patients, I am led to the opinion that the true cause is a former salpingitis, which has either destroyed or impaired the integrity of the ciliated epithelium of the Fallopian tube to that extent, that the ovum is impeded in its passage through the tube, together with the impairment of the peristaltic action of the tube through the same inflammatory process.—Sheldon.

Acetanilid as an Antiseptic.—The action of acetanilid upon wounds, especially granulations, when used in full strength, is to produce intense dryness, blueness, and to check at once and prevent the formation of pus. Upon extensive granulating surfaces and chronic ulcers a slight burning sensation is at first perceived, which is rapidly succeeded by a sedative or anæsthetic effect. If used in sufficient quantity, a thin scab of acetanilid, combined with the wound secretions, forms, under which healing rapidly progresses. If a very large surface is exposed to the action of the undiluted drug, toxic symptoms promptly supervene in susceptible individuals.—Morton.

Therapeutic Hints.

Alcohol in Fevers.—1. If the tongue becomes dry, discontinue; if moister, the drug is doing good. 2. If the pulse becomes quicker harm is being done, and the contrary if slower. 3. If the skin becomes moister the antipyretic effect of alcohol is obtained, and again good is being done. 4. If the breathing becomes easier continue the drug.—ARMSTRONG.

Alcoholic Intolerance.—The fact that many persons use spirits to excess at intervals, or in moderation for a lifetime, and from superficial observation are apparently no worse, is both misleading and dangerous. In one case it conveys the impression that spirits are harmless in small quantities, and occasional excesses are of little injury from which restoration quickly follows. In the second case the danger of repeated pathologic disturbances are masked until organic changes take place, and most serious results follow, that are not apparent except in other departures from health.—CROTHERS.

Cimex Lectularius and Phthisis.—Parisian scientific circles are exercised over the discovery that bedbugs are active agents in the transmission of the bacillus of tuberculosis from one person to another.

Adenoid Growths.—The reflex spasms of the larynx and a condition closely resembling that of croup is frequently caused by reflex nerve-irritation from the pressure of such growths; and general convulsions, attacks of asthma, or deafness, are all well-known complications resulting from the same nervous irritation.

Local Tuberculosis.—The caustic action of iodine is limited and prolonged when the metalloid is introduced in the powdered form into a tubercular focus, and it is still more prolonged when the sublimed crystals are put in even to completely fill the cavity. Iodine seems to have an elective action on tuberculous tissues. It acts deeply, and is painless when applied to tubercular nodules, but it is painful and merely superficial in its action when applied to healthy tissue.—GUERMONPREZ.

Arsenic in Skin Diseases.—The diseases for which arsenic seems to be especially useful are few. At the top of the list stands psoriasis, then chronic eczema, and the lichens, with some of the hydroa type. Some cases of psoriasis are benefited.

Removal of Tattoo Marks.—After asepsis of region the tattoo is remade with a solution of thirty parts of zinc chloride in forty parts of sterilized water; with due precautions no great inflammatory reaction takes place. After a few days a crust forms, which falls off from the fifth to the tenth day.—BRAULT.

The Contagion of Scarlet Fever.—Dr. Edward G. Gilbert writes to the *British Medical Journal* that in a considerable practice for the last twenty years he has acted on the conviction that in a desquamating skin after scarlet fever there is no danger to others; and that if the throat and nose are quite sound again, isolation of the patient is not necessary for more than a month. Acting on this theory, he has uniformly succeeded in preventing the spread of the disease, although often children with free desquamation still going on have mixed and played freely with others who have never had the disease. During the period of isolation he has the skin smeared daily with a weak solution of carbolic acid in oil, and during the last week of it the patients have three good scrubbings with hot water and soap, immediately after the last of which they are sent from their rooms, leaving all their belongings behind them.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

KING'S COLLEGE—DR. BEALE'S ADDRESS—ORIGIN OF LIFE—SIR CRICHTON BROWNE'S ADDRESS—MIND AND MATTER—HARVEIAN ORATION AT THE COLLEGE OF PHYSICIANS—SOCIETIES—MEDICO-CHIRURGICAL NEW ENTRIES.

LONDON, October 25, 1895.

KING'S COLLEGE is a Church institution, and all its professors are accordingly required to accept the articles of the Episcopal Established Church. In consequence of this, opposition was raised to a grant from the public funds, and the late government withdrew the grant unless the College would give up its sectarian demand. The College refused, and the new government has restored the grant. Whatever may be said in favor of tests in the theological faculty, there are departments of knowledge in which sectarianism might well be excluded. King's was founded avowedly as a Church school, to counteract the influence of University College, which was established on non-sectarian lines. No doubt there would be legal difficulties in the way of altering the constitution of either.

The professor of medicine at King's and physician to the hospital is Lionel Beale, F.R.S., whose researches on bioplasm, a word of his coining, must be as familiar to your readers as his great authority on microscopical researches. At his opening lecture he took the opportunity of declaring his continued conviction that the materialists' views of the origin of life, of late years so ardently advocated by a small section of scientific men, are contrary to all living nature, and to make them popular it was necessary to invent a new nature—a nature which has been shown to be impossible. Then he remarked that lately a change has come over these advocates, and not a few have begun to doubt whether the purely physical doctrine of life is supported by facts. Even the president of the Chemical Section at the late Scientific Congress pleaded "for a little more vitality," and Dr. Beale naturally joins in the plea, as he has for years been the prominent supporter of the view that a vital, guiding, arranging, regulating, constructing power is working in everything that has life. It is some five and thirty years since Dr. Beale laid down the distinction between forming and formed material. He has taught that every form of living, growing matter is absolutely distinct from every kind of formed material produced by it, and that the influence on the non-living pabulum is peculiar and belongs to all living matter, but to this only, and is not comparable with or allied to, any other property, power, or action. Many new facts have been discovered about living matter, but observation and experiment go to show that all its powers have been derived from pre-existing living matter and may be transmitted without loss, though sometimes with temporary modifications. We have been told again and again that we are on the eve of finding out how life works, but Dr. Beale says we are further off than ever from this discovery, and asks whether, in the whole range of knowledge, one fact can be pointed out as comparable with vital characteristics; whether anyone of the powers of living matter has received anything like adequate explanation; and whether there is anything in the non-living world comparable with the ordinary changes that have taken place in every living particle that has ever existed. Dr. Beale then observed that, in the wonderful operations of living matter, we must look for the foundations of physiological, pathological, and medical science, and indeed, of that of the whole living world as distinguished from the lifeless cosmos. Here, too, we must look for origin of the changes characteristic of the living state, and

account must be taken of these vital phenomena in discussions about consciousness, thought, and will, and the life that has been, is, and is to be.

Approaching the subject from a somewhat different stand-point, but travelling to the same goal, Sir J. Crichton Browne, in his presidential address at the Medical Society, on Monday last, treated of relations of mind to matter. Admitting that, as often asserted, there is an inbred predisposition to adopt materialistic constructions of the external world, and that if it be so it would be, it follows, as Arthur Balfour argues, that such belief is necessary, he remarked that the tendency may have been strengthened by medical studies, so that some had come to regard thought as a cerebral secretion. No doubt a few medical writers have used language of this kind, which Sir Crichton proceeded to controvert—maintaining that investigations would be more fruitful if unhampered by this false hypothesis. He held it necessary to again and again insist on the truth that mental activity cannot be referred to any physical agency, and that ingenious analogies with heat, light, and electricity, though useful for illustrative purposes, can never bridge the gulf between mind and matter. Mind and matter, he declared, were two distinct essences, irreconcilable in their nature, but accordant in their operations. One kind of motion may be transformed into another, but under no condition can mind pass into a thought, or a thought into motion. Even a neural process and a mental process have nothing in common. The discoveries in the histology of the brain have not brought us a hair's-breadth nearer a solution of the mystery of mind. But mental changes are definitely linked with changes of body, and to account for this Sir C. Browne supposed a parallelism of two causal series running side by side, but never interfering with each other. This is somewhat akin to Leibnitz's pre-established harmony, which likened mind and body to two clocks, side by side, keeping exact time. A psycho-physical parallelism is thus assumed as an ultimate scientific fact, and the two sets of sequences must await a higher synthesis to unite them. That higher synthesis is an ideal to which perhaps we cannot attain with our present faculties, though it would introduce us to a coherent theory of the universe.

But this psycho-physical parallelism, though close and exact as far as it goes, is very limited in extent. Vital phenomena are insignificant if compared with the forces of the material universe, and of these vital phenomena there are only a few in which we discern mental processes. The whole mass of organic life, animal and vegetable, is but a film of exquisite tenuity spread over patches of the material surface like the bloom on a ripe plum. Brain substance in this film is only an infinitesimal sprinkling like grains of gold in the earth's crust, and of this brain substance only a tithe, the gray matter of the cerebral hemispheres, is concerned with man's mental life. The parallelism is only between mind and the highest level of nervous evolution, and does not apply to the elaborate products of mental life. In other respects obvious limitations were pointed out. What we perceive is but a fraction of physical events beyond our cognizance. The spectrum is only a measure of the degree in which we are not color-blind. Stone-deafness, except for a paltry eleven and a half octaves, is universal in our species, and there are in nature vibrations laden with tastes, smells, and tactile impressions that cannot reach us. So limited after all is the parallelism, that we might perhaps rather liken mind and matter to two vast spheres that only impinge on each other at one point. Sir Crichton repudiated therefore some of the localizationists as quite as ridiculous as their predecessors, the phrenologists. In breaking up the faculties into constituent ideas and distributing them among morphological units of the brain, they have overlooked the complex processes involved in the formation of an idea. There is no mental atom indivisible, unalterable, and eternal. A single rod or cone of the retina cannot be the seat of a visual image, and no more can a single cell of the visual area be the seat of a visual idea. The young medical psychologist who piqued himself on having discovered a delusion cell was only the victim of a profound delusion.

While I was writing my last week's letter, the Royal College of Physicians was commemorating Harvey and its other benefactors by the Harveian oration, which was delivered this year by Dr. W. S. Church and was, I am assured, a good specimen of these discourses. This is the two hundred and thirty-ninth celebration, or nearly so, for I believe there have been a few intermissions of the annual function, which is not to be wondered at in so long a period. Of course, one does not expect anything new about Harvey by this time, but a fresh aspect is sometimes given at these orations to some facts in connection with him or his work. On this occasion, I learn, his views on "innate heart" were prominently considered. At the conclusion of the oration the Baly medal was presented to Dr. Gaskell. This medal was founded in 1866 in memory of Dr. Baly, physician to the Queen and translator of Muller's Physiology.

At the Medico-Chirurgical it was considered "a graceful act" to present to the country doctors who had contributed valuable information to the Report on Health-Resorts, a copy of the part of the report containing their contributions. A very graceful act! If the report is worth anything I should have supposed each contributor, not being paid, would have expected a complete copy. Considering how soon the volume will be almost unsalable, I should think the society might distribute copies to those who have assisted.

There was a paper on "Posture in Relation to Operations and Anæsthesia," but the debate on it was adjourned, so I defer any remarks.

There has been a meeting of one or other society or else a lecture every day this week, and to night the Clinical Society is to have the president's address and several papers. You will see, therefore, that there is plenty going on to occupy those who can or will spare time for attendance, and this society's work is well worth the fatigue it entails, for even at the dullest meetings there is generally something to be picked up, and of course always the opportunity of meeting friends; though it must be confessed that sometimes "the bores" have long innings.

The new entries at the London schools are not quite so discouraging as was feared.

The death of another surgeon-general is announced, that of Dr. Shelton, of paralysis, in his seventy-fourth year. Death has been very busy of late among the retired army surgeons.

MATERNAL IMPRESSIONS.

To the Editor of the Medical Record.

Sir: The case of supernumerary thumbs, recently reported in your columns, recalls a case in which my informant believed that a child was born with cleft palate, because the pregnant mother had been surprised at seeing her roommate remove from her mouth a set of artificial teeth.

As counter-evidence allow me to contribute the following: Mrs. S——, who had recently lost an only child, a daughter, aged ten, to whom she had been devotedly attached, and for whom she "mourned, and mourned, and mourned," became pregnant. Living in the neighborhood was an intimate friend who had an idiot child. During the whole of the pregnancy Mrs. S—— was profoundly impressed with the idea that the coming babe would be a girl, and she an idiot; but at the proper time she was delivered of a well-nourished boy, and he as intelligent "as they make them."

My experience leads me to the following conclusions: If maternal impressions could produce the effect some claim, 1, the majority of conceptions would abort soon after the mother discovered she was pregnant; and, 2, the minority would be "marked" or crippled, mentally or physically.

FREDERICK H. S. AMES, M.D.

DENVER, COL.

WHERE THE PRINCIPAL BLAME SHOULD REST.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read your recent editorials concerning the "reform" in the charity hospitals, secured through the summary removal of men who, for years, had given their time and talents toward the succor of the poor, and the substitution of supposedly equally competent men prepared to similarly serve the worthy poor. You have laid stress on the gross outrage thus inflicted on a deserving body of professional men, and you have paid your respects in an honest, upright, manly way to the so-called "reform" Commissioners who, on the surface, have dictated this act. You have also incidentally noticed the statement that certain of these Commissioners claim that everyone is satisfied except the "soreheads" who have been removed.

Since I may properly figure as not being a "sorehead," having voluntarily resigned last spring after duty properly done — otherwise the Commissioners presumably could not have appointed me — I feel safe in calling your attention to a fact you seem to have overlooked, which is, that the obloquy and the shame—everlasting shame—of this wholesale and uncalled-for removal belongs to, and shall rest with, the small number of medical men who instigated and advised the act, rather than with the Commissioners, who were simply tools. This fact it behoves the medical profession to ponder over and to remember. Respectfully,

EGBERT H. GRANDIN, M.D.,

Consulting Obstetric Surgeon (Emeritus) New York Maternity Hospital.

THE QUESTION OF AN INTERNATIONAL LANGUAGE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your correspondent, Dr. W. T. Greene, of Belvedere, Kent, England, simply ignores the question at issue. In my first paper on Greek, read before the Academy of Medicine, I said: "The rivalry of nations is against the employment—as an international language—of one of those principally spoken in the civilized world, such as English, French, or German. In addition, these languages are insufficient for the expression of new ideas and for the composition of words. Even as it is now, the English, French, and German have one thing in common, they borrow from one and the same language, which has many claims to be preferred to every other in the selection of a universal language for scholars. In choosing Greek no mutual rivalry need be taken into consideration. . . . While an universal language sufficient to satisfy the intellectual want of every people and of every time can be as little imagined as the equality of all mankind, still such an uniformity is possible in a restricted part of human society, viz., in that aristocracy formed by art and science. It is not the masses who need such an universal language, but the men of science."

Dr. Greene himself confirms my views in saying, "I dare say the Frenchman and the German would squirm at the idea [to have English the universal language]. Let them." Now, this settles it; as long as the Frenchman and the German squirm, English will simply be an impossibility as an international language.

Dr. Greene is perhaps not aware that of hundreds of German physicians there is hardly one who speaks English; in France it is certainly not better. It is amusing, however, to read in his letter that the French and the Germans have annexed many English words. The German would say, "Umgekehrt wird ein Schuh draus." I think I understand German and French both pretty well, but I know only one English word which all Germans and Frenchmen employ, namely, the word "beefsteak."

Far be it from me to say one word in disparagement of the English language, the English or the American people; on the contrary, I fully admire both language and nations. In one of my pamphlets on Greek I even have quoted the enthusiastic praises of the greatest German linguist, Jacob Grimm, which he has given to the English language. English is certainly, as Dr. Greene says, a good and a practical language; but, as I have said already, it is, as little as the German or the French, the language to be selected for international communications of scholars.

There can be no doubt that the study of the classic languages, and of the Greek more especially, is indispensable to the formation of a truly cultured mind. It has been said that no truly liberal education is possible without the study of Greek. It is impossible to imagine a polished gentleman devoid of knowledge of it. Especially an Englishman, in order to understand his own language, must necessarily know Latin and Greek.

I am sure Dr. Greene will not dispute these facts, and since Greek has to be on the school plan, since every true scholar is obliged to know it, I only ask for a consideration of the living Greek, and that it be taught in a rational way in our schools.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 9, 1895.

	Cases.	Deaths.
Tuberculosis	111	115
Typhoid fever	39	15
Scarlet fever	55	5
Cerebro-spinal meningitis	2	3
Measles	112	9
Diphtheria	188	41
Whooping-cough		5

The Dangers of Long Journeys.—Huchard calls special attention to arterial cardiopathy and interstitial nephritis. Some years ago, he says, a man fifty years old, who had arterial cardiopathy, showed slight symptoms of renal insufficiency, with hyposystole, although there were no traces of albumin in the urine. The patient intended to make a long journey by rail, and M. Peter, who saw him in consultation with M. Huchard, made no objection to this. They were very much astonished, says the author, to hear that, two days after his arrival at Nice, he had been taken with dangerous symptoms of acute uræmia and had died in less than a week. In the same year another patient, suffering with the same trouble, died after a journey of twenty-six hours by rail. M. Huchard has also seen the same symptoms supervene in identical conditions, but without a fatal termination. The trembling motion of the train, says M. Huchard, which so quickly produces symptoms of renal congestion and genito urinary excitation, leads to the transformation, in arterial cardiopathy, and especially interstitial nephritis, of incomplete renal impermeability to a complete impermeability, from which sometimes arise the fulminant symptoms of uræmia. M. Huchard thinks that patients who suffer

with arterial cardiopathy or with interstitial nephritis, with slight symptoms of renal insufficiency, should avoid long journeys by rail. If, however, a long journey has to be taken, it should be done in easy stages, with intervals of several days for rest. The following examples, says M. Huchard, demonstrate the unfavorable influence of long journeys on patients suffering with these troubles: A patient who had come under Prout's observation suffered very much from cold and sea-sickness during a tiresome voyage, and died the following morning. Charcot mentions the case of a woman who, before leaving Paris for Switzerland, made a number of calls on foot and returned home completely exhausted. The following morning she became comatose, and death occurred very rapidly. Foster cites an observation of a man who took a very long walk in order to reach his home. He complained of feeling very tired, and on the next day symptoms of diabetic poisoning set in and he died on the third day. M. Huchard himself has observed a diabetic who suffered with arterial cardiopathy. This patient went to Paris, where he spent some time in taking long walks about the city. Eight days afterward he became comatose, and death rapidly supervened. Here, says M. Huchard, the aggravation of the disease cannot always be attributable to renal congestion, nor can the long journeys by rail be given as the pathogenic cause of the symptoms. It is known that the muscles, which are alkaline in a state of repose, become acid after repeated and energetic contractions, for a muscle that is tired is a muscle poisoned by acids, and especially by lactic acid. Now, fatigue, long walks, and violent exercise act in the same way as diabetic poisoning, which is nothing but an acid poisoning.—*New York Medical Journal.*

The Ductless Glands.—The equivocal position of the ductless glands in the animal economy, and the interesting nature of the facts that have recently been ascertained in regard to them, give a special interest to a recent address by Professor Schäfer. The functions of the spleen, thyroid, thymus, and supra-renal capsules have long been shrouded in obscurity, and many points in their life-history still remain to be elucidated. (*The Lancet.*) The similarity of the structure of these bodies to that of glands, but unprovided with ducts, their large volume, and the evident activity of the processes that take place in their interior, as indicated by their large vascular and nervous supply, which militates against the supposition that they are useless or that they are mere degenerate remains of once more important organs; and, on the other hand, the possibility of removing the whole or the greater part of their substance without apparent injury to the health of the animal—all these and many other facts combine to render them a physiological puzzle. For many years past, however, the conviction has been growing in the minds of physiologists that their true function consisted in the separation of certain materials from the blood, acting in the same fashion as the salivary glands or pancreas, but that these secretions, instead of being discharged from the surface of the body, as is the sweat, or into the alimentary canal, are reabsorbed into the blood, and fulfil certain definite purposes in the economy. Hence the term applied to them by Professor Schäfer, of internal secretions. In one sense every part of the body, be it nerve or muscle, bone or fat, modifies the blood in a similar manner, by abstracting from the blood the materials of its own nutrition and restoring to that fluid the products of its disintegration. In the cases of the liver and pancreas the internal secretion is more important than the external, since the secretion of the former of these glands, at least, may be permanently diverted by a fistula without interference with the vital functions, while removal of the whole gland is invariably fatal. As our knowledge of the liver and its functions has extended we begin to see the reason of this. The liver visibly secretes bile which may be abstracted before entering the alimentary canal without harm, but it also forms urea and glycogen, and it is the accumulation and decomposition of these products that cause death when the whole gland is removed. Analogous experiments on the pancreas enable similar deductions to be drawn. The pancreatic juice can be diverted by a fistula from the intestine, and the major part of the gland can be cut away without harm, but if the whole be removed death results from diabetes. The internal secretion of the gland is more important than the secretion it discharges by its ducts. After discussing the relations of the thymus and thyroid bodies Professor Schäfer dwelt at length on the supra-renal capsules, on which he, with the assistance of Dr. Oliver and Mr. Moore, has been working for some years. He sums up his results, which show conclusively that the medullary portion of the adrenals contains a dialysable organic principle, soluble in water and not destroyed by boiling for a short time, which produces a powerful physiological action upon both striated and unstriated muscular tissue, especially affecting the skeletal muscles and the muscles of the blood-vascular system, causing these contractions to be greatly prolonged, and in this respect resembling the action of veratria. It also has some exciting influence on the cardio-inhibitory centres in the medulla oblongata, causing the heart to slow down; but after section of the vagi it exercises an opposite effect, increasing the force and frequency of the heart's action, and thus leading to a great rise in the blood-pressure, which is enormously increased by its power of inducing contraction of the muscular tissue of the arterioles.

Pastor Kneipp's Medical Practice.—The *Westminster Gazette*, of recent date, contains an account of the way in which Father Kneipp, of cold-water fame, treats his patients at Woerishofen. He could give points, as regards rapidity of diagnosis, to many a dispensary doctor in New York, for the average time which he devotes to each patient is about twenty-four seconds. When receiving patients on a busy day the pastor sits at a long table in a large, plainly furnished room, smoking a huge cigar. He dictates his "prescriptions" to an assistant in a solemn tone, as if he were presiding at a religious ceremonial. Men, women, and children of every station in life file past him. In an hour and a quarter he gets through one hundred and eighty without difficulty. There is no examination, and few questions are asked. Indeed, there is little necessity, for cold-water baths and bandages and walks on wet grass with bare feet exhaust the worthy pastor's pharmacopœia. There is one exception—an ointment composed of honey and medicinal herbs for those who suffer from diseases of the eye. But then the ointment is a sovereign one for everything, and so Pastor Kneipp manages to break the record as an oculist as well.

Experimenting upon Criminals.—The Governor of the Punjab, in India, has ordered that half the prisoners in the jails there be kept on fresh water, and half on boiled, records being kept to see whether the boiled water has any effect in the way of preventing ordinary sickness.

Deaths from Lightning.—During the five years, 1890–1894, lightning caused the death of one thousand one hundred and twenty persons in the United States. The greatest number occurred during June and July, and all, with but few exceptions, between the months of April and September.

A Quartette in Himself.—According to a newspaper paragraph, now going the rounds, Dr. Stuart, of Sydney, N. S. W., has invented an artificial larynx, which has been successfully applied, the mechanism of which can be so regulated as to make the voice bass, soprano, tenor or contralto, at will.

SOME OBSERVATIONS UPON THE EFFECTS OF HORSE-SERUM INJECTIONS.[1]

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

THE special appeal that serum therapy makes to all thoughtful physicians is the fact of its not being empiric, but based upon a long and laborious study conducted on scientific principles. At last we seem to have reached a therapy that is directly founded upon a knowledge of the natural history of the disease it is intended to combat. The products of the diseased process in one animal may be employed to check the ravages of the same disease in another animal. Experimenters have not been slow in following up this new field, and protective or curative inoculations of serum have been tried in many diseases. Diphtheria, cholera, hydrophobia, influenza, pneumonia, small-pox, tetanus, tuberculosis, typhoid fever, and syphilis may be mentioned as diseases in which serum therapy has been proposed, and, in some, given a more or less extensive trial. The serum from various animals has been tried. Thus, Tommasoli treated six syphilitic patients with intra-muscular injections of sheep blood-serum, and the same author used dog-serum upon five cases of lupus. Kollman tried sheep, calf, dog, and rabbit serum in syphilis, some of the patients remaining under treatment for eight and a half months. In all the studies that have been made, comparatively little attention seems to have been given to the action of blood-serum itself upon the economy, entirely apart from any curative effects upon certain diseases or the development of antitoxins. The new works on serum-therapy do not, as a rule, mention any dangers, or contain any warnings as to the limit of its use. In the absence of such caution, last winter the writer experimented with horse-serum injections in a number of children suffering from syphilis and allied diseases. The treatment was continued for about two weeks, and all the cases did badly. It then occurred to me that, in serum, we are dealing with a physiological fluid of great potency and that damage might result from its careless or too prolonged use. A glance at the physiologies shows that serum is described as a transparent, yellowish, alkaline fluid, with a specific gravity of from 1.025 to 1.032, being the liquid part of the blood or of the plasma which remains after the separation of the clot. Serum differs from plasma in that it contains no fibrinogen; it contains paraglobulin and serum-albumin in the same proportion as does the plasma. Thus it appears that these fluids are, above all, highly albuminous solutions, containing nearly as much proteid as is contained in ordinary white of egg.[2]

With reference to the effect of serum, as such, upon other bodies, little is said. Landois and Sterling state that the blood-serum of some mammals dissolves the blood-corpuscles of other mammals. Thus, dog serum and frog-serum dissolve the blood-corpuscles of the rabbit in a few minutes. They do not say, however, in what manner the serum is applied to the corpuscles. Hermann, under Transfusion, in the "Handbuch der Physiologie," also mentions blood-serum as a destroyer of the red blood-corpuscles. Hayem, upon the same topic, states that autopsies on animals that have received transfusion of blood from one species of animal to another, show that of the lesions resulting, those of kidney congestion and changes in the uropoetic apparatus take first rank. In order to study some of the effects of blood-serum injections various animals were subjected to injections for different lengths of time and then killed. In all of the cases, plain, sterilized horse-serum was employed. The horses had not been inoculated with any toxins, and were apparently healthy. Certain conditions of the blood were noted before and after the injections.

In 1,000 parts of serum there are :[3]

Water	about 900	
Proteids :		
α. Serum-albumin		80
β. Serum-globulin		
γ. Fibrin ferment		
Salts.		
Fats, including fatty acids, cholesterin, lecithin, and some soaps		20
Grape sugar in small amount		
Extractives—creatin, creatinin, urea, etc.		
Yellow pigment, which is independent of hæmoglobin		
Gases—small amounts of oxygen, nitrogen, and carbonic acid		
	1,000	

July 2, 1895.—Large rabbit; two months; count of the red blood-corpuscles, 8,316,666; hæmoglobin, 105; 5 c.c. serum injected. In three hours: corpuscles, 7,170,000; hæmoglobin, 90. July 10th, after daily injecting 5 c.c. serum: corpuscles, 8,246,666; hæmoglobin, 95. Autopsy: Spleen enlarged and congested; kidneys showed cloudy swelling.

July 4th.—Sheep, two years old; weight, 60 pounds; healthy; hæmoglobin, 110; 16 c.c. serum injected. In three hours: hæmoglobin, 110; 12 c.c. serum injected daily until July 16th; temperature varied from 104° F. to 105° F. (normal, about 101° F.); respiration and pulse increased, but the animal ate well; no œdema nor infiltration around points of injection. July 16th, temperature 105⅘° F.; hæmoglobin, 100. The animal was killed by being bled to death. Autopsy: Kidneys enlarged, soft, and congested, with all evidences of cloudy swelling; glomeruli prominent, with granular prominences marked over the cortex; very marked congestion at base of pyramids; infarction in one kidney; spleen enlarged.

July 5th.—Guinea-pig; corpuscles, 9,253,333; hæmoglobin, 105; 2 c.c. serum injected. In three hours: corpuscles, 8,453,333; hæmoglobin, 100. More white blood-corpuscles, and quite a number of blood plaques to be seen. July 11th, after daily injecting 2 c.c. serum: corpuscles, 7,783,000; hæmoglobin, 105. Autopsy: Spleen enlarged and congested; kidneys, congestion and cloudy swelling.

July 11th.—Large dog; hæmoglobin, 120; 8 c.c. serum injected. In three hours: hæmoglobin, 118. Daily injections were given, increasing each dose by 2 c.c. until, on July 19th, 24 c.c. was injected, and the animal killed; hæmoglobin, 118. Autopsy: Spleen enlarged, with Malpighian tufts greatly congested; kidneys, capsule adherent: cortex shows cloudy swell-

[1] Read before the New York Academy of Medicine November 7, 1895.

[2] Waller's Physiology.

[3] Kirke's Hand-book of Physiology.

ing; medullary rays very prominent; pyramids show very marked congestion.

July 18th.—Guinea-pig; corpuscles, 9,320,000; hæmoglobin, 112; 2 c.c. serum injected, and in three hours: corpuscles, 8,970,000; hæmoglobin, 110; 2 c.c. injected daily until July 25th; corpuscles, 10,983,333; hæmoglobin, 106. Autopsy: Spleen enlarged and congested, with Malpighian tufts prominent; kidneys, congestion and cloudy swelling.

August 3d.—Large rabbit; corpuscles, 7,436,666; hæmoglobin, 105; 2½ c.c. serum injected, and in three hours: corpuscles, 7,343,333; hæmoglobin, 105; 2½ c.c. injected daily until August 9th; corpuscles, 6,983,333; hæmoglobin, 105. Autopsy: Spleen enlarged and congested; kidneys, cloudy swelling.

In the remaining experiments only three injections were given, in place of the repeated injections of the first experiments. The speedy recuperative powers of the blood are well known, hence the tests were made a few hours after the first injection and repeated at the end of a goodly number of injections in the first experiments.

October 14th.—Small rabbit; corpuscles, 8,036,666; hæmoglobin, 98; 2 c.c. of serum were daily injected on October 14th, 15th, and 16th.

October 17th—Corpuscles, 6,656,666; hæmoglobin, 95. Autopsy: Spleen not enlarged. Microscopical examination of frozen sections of the kidneys showed cloudy swelling and numerous small areas of fatty degeneration.

October 21st.—White rabbit, 1 pound, 5½ ounces in weight; corpuscles, 11,716,666; hæmoglobin, 85; 1½ c.c. serum injected on October 21st, 22d, and 23d. October 24th, weight, 1 pound, 6 ounces; corpuscles, 10,196,666; hæmoglobin, 85. Autopsy: Microscopical examination of kidneys showed cloudy swelling and a few small areas of fatty degeneration; spleen not enlarged.

October 21st.—White rabbit, weight, 1 pound 5½ ounces; control, uninjected; corpuscles, 12,040,000; hæmoglobin, 90. Kept under same conditions as former rabbit.

October 24th:—Corpuscles, 11,023,333; hæmoglobin, 85; weight 1 pound 6½ ounces. Autopsy: Kidneys normal; microscopical examination.

October 30th.—Rabbit, 1 pound 15 ounces; corpuscles, 9,686,666; hæmoglobin, 95; 1½ c.c. serum injected on October 30th, 31st, and November 1st. November 2d: Urine had specific gravity, 1.015, with a trace of albumin. Under the microscope, a large number of abnormal blood-corpuscles and a few fine granular cells; corpuscles, 8,083,533; hæmoglobin, 85; weight, 1 pound, 15 ounces. Autopsy: Kidneys showed cloudy swelling and some fatty degeneration.

October 30th.—Rabbit, 1 pound 7½ ounces; control, uninjected; corpuscles, 9,206,666; hæmoglobin, 105. November 2d: Microscopical examination of the urine showed a number of abnormal corpuscles and one fine granular cast; no albumin; corpuscles 7,233,333; hæmoglobin, 105. Autopsy: Microscopical examination showed cloudy swelling of the kidneys and some fatty degeneration.

November 4th.—One per cent. of egg albumin was mixed with a six-tenths per cent. salt solution; 2 c.c. of this was injected into a guinea-pig on November 4th, 5th, and 6th. November 7th the urine contained a faint trace of albumin, a few abnormal blood-corpuscles, and two or three fine granular cells; no casts. Autopsy: Kidney, slight amount of cloudy swelling; liver, marked cloudy swelling and fatty infiltration.

As a control, another guinea-pig was injected on November 4th, 5th, and 6th with 2 c.c. of a simple six-tenths per cent. salt solution. November 7th: Urine, specific gravity, 1.018, and trace of albumin; a large number of abnormal blood-corpuscles and several fine granular cells. Autopsy: Kidney, simple cloudy swelling; no fat; liver, cloudy swelling and fatty infiltration.

In attempting to draw conclusions from experiments upon animals, especially rabbits and guinea pigs, two considerations must be borne in mind. The worry and annoyance to which they are subjected by repeated handling and opening of vessels, with a certain loss of blood, has an unfavorable effect upon their health. Again, these animals that have been kept cooped up for experiments are often in an unsound condition to begin with. Thus, two of my controls had about as bad a state of the kidneys as the animals experimented on. In Dr. Vissman's experiments with rabbits, however, the injection of antitoxin serum invariably produced nephritis, which was not found in the controls. In summing up the experiments here narrated, they are to a certain extent inconclusive, except that the injections of the serum do not appear to have produced any very marked effect in these animals, save upon the kidneys. Serum injections, as ordinarily employed in therapeutics, probably have little effect upon the blood-corpuscles. The kidneys are the vulnerable point, and must always be carefully watched when injections are employed. Another possible danger is noted in the June number of the London *Veterinary Journal*. It is here stated that M. Nocard recently reported to the Society of Biology of Paris the results of some experiments that he has been conducting, from which it appears that the blood sometimes contains microbes, although no germs could be found by microscopic study of the blood. Cultures made from the serum of blood, collected with such precautions as to prevent the possibility of infection, indicate that microbes are sometimes present, and especially during digestion. The latter has led M. Nocard to believe that microbes find their way into the blood through the intestinal wall. Examinations made upon dogs recently fed, and upon fasting dogs, have shown that the blood of fasting dogs is always sterile.

In conclusion, the final verdict upon serum injections and serum therapy must rest upon clinical, rather than laboratory, evidence. Studies in the laboratory thus far made, warn us to use this powerful agent carefully. If prolonged and careful clinical observations made under varying conditions and by different observers prove its utility, serum therapy, in spite of possible dangers, will have a brilliant future. Research in the line of separating the antitoxins, so that they may be given in an innocuous vehicle, or highly concentrating them in small quantities of serum, seems to be the next step desirable. I am indebted to Dr. Gill for supplying me with serum, and to Drs. Brooks, Wyman, Lewright, and Wilson for aid in the experiments.

When May Gonorrhœics Marry?—The question when may syphilitics marry has been often discussed and answered. The inquiry now is turned toward the victims of chronic gonorrhœa. Dr. Lowenhardt asserts that the prospective bridegroom should be subjected to repeated examinations in order to determine the presence or not of the gonococcus. A slight secretion is not sufficient for this purpose, but the urethral mucosa must be irritated in such a manner as to place it in analogous condition (excess in *baccho et venere*) to those which light up an indolent case. The best means to obtain this result is to inject a few drops of a one-fifth per cent. solution of silver nitrate. If, then, the secretion contains no gonococci, but is strictly made up of epithelial cells, marriage can be permitted. The presence of numerous pus corpuscles necessitates renewed examinations and treatment of this pseudo-gonorrhœa. Lowenhardt insists upon the fact that the gonococcus is alone responsible for the virulence of the exudate and the serious results that follow inoculation with it in the genital apparatus of women.

Antitoxin Treatment of Syphilis.—Dr. Vievorovsky has been employing antitoxin serum in the treatment of syphilis, in the Moscow Military Hospital, and claims to have observed most satisfactory results.

ERYSIPELAS IN ITS ETIOLOGICAL RELATION TO PRECEDING SKIN LESION, AND ITS LOCAL TREATMENT.[1]

By CHARLES W. ALLEN, M.D.,

NEW YORK.

LATE SURGEON TO THE CITY HOSPITAL, AND DERMATOLOGIST TO RANDALL'S ISLAND HOSPITALS.

GENTLEMEN: In the preparation of the following brief paper I have been influenced:

1. By the belief that originating, as erysipelas so often does, in some skin affection or lesion of the integument, and being in itself so pre-eminently a skin disease, its study should receive greater consideration from dermatologists than has often been accorded it in the past.

2. By the fact that certain suggestions as to treatment, made in a paper read by me at our Fifteenth Annual Meeting, have in a further test given results which warrant their being reported.

3. By the statement from no less an authority than one of our honorary members, Professor Kaposi (English translation of last edition of his "Handbook," p. 289), that the plan of surrounding the parts with adhesive plaster has not acted as a preventive of the spread of erysipelas.

In defence of my first reason I may state that in Mr. Crocker's excellent "Handbook" of recent date, the subject of erysipelas is omitted. Jamieson likewise excludes it from his work on skin diseases. Other authors show the same inclination to ignore this disease in their dermatological writings. It was only recently, and on my motion, that the erysipelas wards of the New York City Hospital were made a part of the dermatological service—a change which I feel sure has proven advantageous to all concerned. It seems to me that if there is any one disease which should be in every way disconnected from the surgeon and his work, it is erysipelas; and this is equally true of the gynecologist and obstetrician. There is still much to be learned about erysipelas in its migrating and erratic forms, and as a recurrent affection in such dermatological conditions as are presented by elephantiasis. It should also receive further study as a causative agent in the production of pseudo-elephantiasis, and it is probable that much could still be found out about the relation which true erysipelas bears to certain attacks of pseudo-erysipelas observed after vaccination. In the realm of diagnosis as well, the specialist for the skin should find an interest and a field of usefulness, for it must be the experience of all that numerous affections of inflammatory nature—dermatitis, poison ivy, and drug eruptions, certain erythemas, and even occasional rarer forms of eczema, have at times been wrongly diagnosticated as erysipelas by the unwary.

The etiological relationship of erysipelas to dermatoses and to certain lesions of the skin, is likewise of interest, and I have been impressed with the frequency with which some cutaneous *porte d'entrée* for the infection can be discovered if sufficient attention is given to the examination. Thus in 100 cases, which include 50 reported to this Association four years ago, just one-half were clearly traceable to pre-existing skin lesion. Of these, vaccination furnished 12 instances; varicella, 5; ulcer, 5; impetigo, 4; ulceration of the skin following circumcision, 4; syphilis of the scalp, 3; ecthyma, 2; ulcerating nævus, 2; fissure, 2; dermic abscess, 2; elephantiasis, 2; pediculosis, 1; pustular eruption upon the legs, 1; excoriation, 1; eczema, 1; dermatitis from kerosene, 1; dermatitis calorica, 1; rosacea, 1; total, 50.

Of the remaining 50 cases, in 29 the origin is either not accounted for or is not put down in the notes. Throat disease is made accountable for 9 instances; trauma has 5 to its credit: catarrh, 3: lachrymal fistula, 2: salivation, 1: and ulcerating tooth, 1.

The frequency with which soreness of the throat precedes the earliest manifestations of erysipelas upon the skin surface, has led me to look upon the former region, and especially that of the tonsil, as one furnishing in many instances the conditions necessary for the entrance of streptococci. I have already stated my belief that in the proximity of the faucial and nasal mucous membranes, and their liability to present denuded, excoriated, or granulating surfaces, and especially in the peculiar anatomical conformation of the tonsil itself, is to be found the explanation of the relatively great frequency of erysipelas of the face.

This frequency is indicated in the following table, which, so far as the facial cases are concerned, agrees closely with the statistics given by various authors, as well as with my own made up from a large number of cases. Of these fifty cases now to be considered:

25	involved the face	(fifty per cent.).
12	"	" arm.
8	"	" leg.
3	"	" genitals.
1	"	" hand.
1	"	" scalp.

The treatment of erysipelas has been an ever-changing one, but in recent years it must be admitted that the modifications of the methods have been influenced by Fehleisen's discovery. The reason that so many different drugs have had their warm advocates at various times, lies partly in the fact that scarcely any one remedy had been found which exerted a decided influence upon the course of the affection, and partly in the self limited nature of the disease, which, in most instances, tends to spontaneous resolution in about a fortnight, when uncomplicated, and occurring in middle life.

The claim of any plan of management must therefore be based upon its powers to jugulate the process, or to confine it to a period of a few days. The statement sometimes made by authors, that there is no treatment which arrests the march of erysipelas, will not stand at the present day, nor can I accept the statement of those who would include the plan of adhesive bandaging among the useless devices for checking its spread.

The plan of treatment which I have for the most part employed during the past few years, aims to accomplish its purpose, first by preventing extension of the disease process into new territory; and then to restore the skin to its normal state by making compression, excluding the atmospheric oxygen, and exerting an antiseptic and reducing action upon the already inflamed and infiltrated area. While perfectly well aware that there is nothing new either in the theory or in the employment of the particular agents for the practical accomplishment of the desired end, still I have been forced to the belief that in the following procedure, which I have termed the "combined method," we possess an effectual means of preventing the extensive invasion of new territory, as well as of cutting short the existing process in a very large proportion of cases.

The plan consists simply in the application of bands of rubber adhesive plaster, as advocated by Wölfler, in such a way as to entirely shut in the region implicated, and then in covering over the whole of the enclosed area, including the apparently healthy skin, with ichthyol in collodion varying in strength from ten to fifty per cent. The bands, one inch wide for a child and one and a half inch for an adult, are applied in such a manner about the limb, trunk, or head, that a decided pressure is exerted upon the skin against the underlying bony or softer parts. The bands are applied at a distance of from one to three inches from the visible margin of the advancing patch, varying with the region, rapidity of the advance, and degree of intensity of the inflammation. The theory of action is that the lymphatic vessels and channels, in which the streptococci

[1] Read at the Nineteenth Annual Meeting of the Medical Association, Montreal, September 17, 1895.

are believed to circulate, are compressed in such a way as to prevent the penetration of the latter to the parts beyond. Upon a limb I apply the bands, if possible, both above and below the patch of erysipelas; upon the trunk I surround the part, laying the bands in a direction where the best points for counter pressure are to be found; upon the head I apply them tightly about the forehead, and, if required, across the vertex or any portion of the scalp after a swath of hair has been cut close for its reception.

In my former paper I advised the application of the method to head cases, and my subsequent experience has shown that it acts here quite as well as elsewhere. A lotion or ointment of ichthyol, or possibly the substitution of some other local dressing, is here advisable, though, upon the face, I have found little opposition to the disfiguring nature of the paint. Ichthyol has been experimentally shown to possess decided antibacterial properties, and to be fatal to erysipelas cocci in cultures even in weak solution. Its action as a reducing agent is also known. When these qualities are combined with those which collodion furnishes for making compression and excluding air from a part, we possess a local dressing which is not alone theoretically admirable, but one which has been practically demonstrated to possess decided merit.

The results of treatment by the combination of the adhesive strips and the ichthyol varnish, so applied as to include the still healthy-appearing skin, making one continuous occlusive dressing, have been very satisfactory. My notes were not made at the time with the view of incorporating them in a paper, and are fragmentary and lacking in detail. It is shown by them, however, that at least 30 cases were treated by the restricting band; 22 of them in conjunction with the ichthyol varnish; 2 with solutions of ichthyol; 2 with aristol in collodion; and in 4 the form of local dressing is not recorded.

In 11 instances ichthyol varnish was alone applied without the band, or at least no mention is made of the latter; 6 received ichthyol ointment or solution, and in the 3 others the treatment employed is not in evidence.

In the 30 cases treated by the combined method, 14 are recorded as showing no extension beyond the barriers. In 9 the result is not put down. In 3 extension of the erysipelas beyond the band is noted. In 3 the result is marked "recovery;" 1 of them being entered as "prompt," 1 as "well in three days," and 1 "in a few days." In 1 the patch ceased spreading before the margin reached the band. In 1 a recurrence is noted after some days, and this in turn was recovered from in eight days. In 2 of the 11 cases treated without the band no spreading occurred beyond the limits of the ichthyol varnish.

The dates do not show, as a rule, just how long the cases were treated before being considered well, but many were seen only a few times, and several were practically well after one application of the ichthyol. It was frequently observed that the painful sensations subsided, the fever fell, and general improvement in the patient's condition set in promptly after the dressings had been applied. In scarcely any of the cases was internal treatment employed, and then drugs were given only symptomatically. Alcoholic stimulation was, however, usually advised. With few exceptions the cases were seen quite early in the course of the disease, usually upon the first day. They were mostly treated at their homes, but some, especially those following vaccination in children, at the dispensary. Under such conditions I think the results of treatment can be better judged than in hospital cases, which, as a rule, enter the wards only after the disease has existed for some time, and probably without any preceding treatment to speak of.

Local foci of pus, or sources of purulent secretion, must always be sought out and, by the use of peroxide of hydrogen or other agent, eliminated so far as possible from the problem while the attempts are being made to check the advance. Open surfaces must be included in the antiseptic dressings. In a number of instances where the erysipelas originated in skin lesions, the happiest results have followed their inclusion in the ichthyol applied. This benefit was especially noticeable in the vaccination ulcer. An important point, which has already been pointed out, is the necessity of leaving the plaster bands a long time *in situ*, and in applying a second, when the erysipelas has passed the first, of not removing the first at once. There seems often to be an intensity of the inflammation either at the margin of the band or sometimes beneath it, and bullæ are often large in this situation. After recovery, too, there should be no haste in removing the dressings.

The advantages of this treatment over the Kraske-Riedel scarification method, which often necessitates the use of an anæsthetic, rises to the importance of a surgical operation, and, after all, frequently fails of its object, need scarcely be dwelt upon.

Even if the process most often oversteps the bounds, as many authors claim, this is no argument against the method; for even if a much smaller proportion are cut short than is indicated by my results, there is no plan which offers as much. In cases originating in patients the subjects of grave disorder, and where the lesions occur in remote regions simultaneously, or where rapid migration is observed, it is probable that the infection is more deeply seated, perhaps in the blood, and in such cases our method must of necessity fail. In the present series I have applied it in none such.

126 East Sixtieth Street.

ON FUNCTIONAL DISORDERS OF THE STOMACH ACCOMPANIED WITH HYPERSECRETION.[1]

1. Hyperchlorhydria.
2. Gastro-succorrhœa Continua Periodica.
3. Gastro-succorrhœa Continua Chronica.

By MAX EINHORN, M.D.,

NEW YORK.

I. **Hyperchlorhydria.** — By the term "Hyperchlorhydria" ("Hyperacidity," "Hypersecretion") is designated a condition in which the stomach secretes a juice that is more acid than normally and richer in the ferments. While the quantity of the juice is very often likewise increased, its secretion, however, takes place only during the digestive period.

Although disturbances of digestion associated with an hyperacid gastric juice were vaguely known to the old writers (Pemberton, Copland, and others), it is only in recent years that these forms have been thoroughly studied and placed on an exact scientific basis. Formerly it was thought that in most disturbances of the stomach the gastric secretion was deficient. Nowadays, since the publications of Riegel, Reichmann, Jaworsky, Glusinsky, Ewald, and others, we know that in almost one-half of all the patients suffering with digestive disorders, the gastric juice is rather increased.

According to my own experience, the gastric disorders accompanied with hyperchlorhydria form more than one-half of the number of patients troubled with digestive affections. With reference to this point the following table may be of interest. Among 564 patients whose gastric contents I have analyzed during the years 1889–95, 286 showed a hyperacid state of the gastric juice. In all these patients the degree of acidity one hour after the test-breakfast was above 60, and in more than half of them above 80.

[1] Read before the New York State Medical Association, October 16, 1895.

Table of Private Patients whose Gastric Contents have been Analyzed during 1889–95.

Number of patients with hypochlorhydria, 187.	in 89 : HCl = 0,	acidity = 2 to 40
	in 31 : HCl = 0,	acidity = 40 to 80
	in 67 : HCl + ,	acidity = 15 to 40
Number of patients with eu-chlorhydria, 91.	in 91 : HCl + ,	acidity = 40 to 60
Number of patients with hyperchlorhydria, 286.	in 286 : HCl + ,	acidity = 60 to 140

Total number of patients, 564.

Whether hyperacidity should be considered as a disease *sui generis* or not, is difficult to decide. Hyperacidity certainly describes only one symptom, showing that the secretory function is increased without pointing to any definite anatomical lesion; but this symptom may be of the greatest importance, and very often covers the whole ground upon which is based the subjective suffering of the patient and the rational treatment at our command. That is the reason why we think it best to discuss hyperchlorhydria as a separate disease.

Does hyperchlorhydria always give rise to digestive disturbances and other symptoms? In order to answer this question it will be best to determine more exactly where hyperchlorhydria begins, *i.e.*, to what degree of acidity we may apply this term. According to the experience of Ewald and others, to which I add my own, the degree of acidity of the gastric contents, about one hour after Ewald's test-breakfast varies, as a rule, in healthy people between 40 and 60. A degree of acidity of 70 and above is therefore considered as hyperacidity. The above question will now be put in the following way: Must people with an acidity of their gastric contents of 70 and above, always present morbid phenomena? To this I must answer in the negative. From a very large experience I must assert that we occasionally meet with persons whose degree of acidity of the gastric contents is as high as 100, and even more, without producing any disturbance whatever. This condition need not even be a transient one, but may last for years and still cause no discomfort. This, however, is not the rule, and the greater number of persons with an hyperacid juice are not free from disturbances, and rather present a very characteristic train of symptoms. We speak of a pathological hyperchlorhydria whenever this condition is associated with subjective complaints.

Etiology.—Hyperchlorhydria is, as we have just stated, of very frequent occurrence. It is met with chiefly in adults, although neither the young nor the old are exempt. In the majority of cases the origin may be traced to either a psychological cause, such as grief or worry, or to mental overwork. It is, as a rule, more frequent among the wealthier and more educated class of people, as lawyers, bankers, etc., although hyperchlorhydria may be met with also among the poor. But in addition to this so-called reflex action of the brain as an etiological factor of the disease, there may also be direct causes; thus, for instance, the habit of taking highly spiced dishes, much ice-water, and strong alcoholic drinks is liable to produce this trouble.

Symptomatology.—The development of this disorder is usually gradual. The patient at first begins to feel uneasy about two or three hours after dinner. Afterward this uneasy feeling changes into a somewhat painful sensation experienced in the gastric region, and instead of appearing after dinner, it occurs about two hours after each meal. The pain lasts for about an hour or two, or even three, and then disappears. Very often pyrosis accompanies the pain, and occasionally regurgitation or water-brash takes place. The patients, as a rule, can ease their pain by taking some nourishment, especially one that is rich in albumin; thus the white of an egg, milk, meat is capable of dispersing the pain. It also disappears after the ingestion of some alkali, as Vichy water, or bicarbonate of soda. The appetite is ordinarily not diminished, but frequently rather increased. Thirst is generally enhanced. The bowels in most cases are constipated.

The composition of food is frequently of significance with reference to the character of the pains, which are less intense in people partaking of large quantities of meat and eggs, while they are much more severe in persons living chiefly on vegetable diet.

Besides the attacks of pain, patients affected with hyperchlorhydria very often suffer from severe headache, or attacks of dizziness, which may appear either independently or accompanied by gastric pains. The patients, as a rule, do not lose in weight except in some rare instances, in which a faulty and insufficient diet has been instituted for quite a long time.

Objective Symptoms.—On palpation the gastric region is frequently found tender to pressure, although not actually painful, this tenderness not being limited to one circumscribed spot, but to a larger area covering the greater part of the gastric region. The contours and the size of the stomach are frequently found enlarged, although this condition is by no means characteristic of the affection in question. A splashing sound can be produced after the ingestion of water into the stomach, or after meals, but not in the fasting condition.

On examination of the stomach with a tube in the fasting condition it is found to be empty, or only a few c.c. (5–10) of gastric juice can be obtained. One hour after Ewald's test-breakfast, or two to four hours after Leube-Riegel's test-dinner, the gastric contents contain an abundance of hydrochloric acid and of the ferments, the acidity being, as a rule, much higher than normally (twice or three times as high). A disk of egg-albumin becomes digested in the filtrate of the contents in a very short time (sometimes in half an hour). The gastric contents obtained three to four hours after the test-dinner show microscopically that the meat has been perfectly digested, while starchy substances are yet either unchanged or very little altered. The filtrate of the gastric contents, either after the test-dinner or after the breakfast, will reveal the presence of either starch or large quantities of erythro-dextrine. The addition of a few drops of Lugol's solution to the filtrate will produce either a blue color or an intense dark red.

The high degree of acidity is most commonly caused by free hydrochloric acid. The difference between the amount of free hydrochloric acid (as determined by Mintz's method) and the total acidity is not great, the figure very frequently being from 10 to 20.

The motor faculty of the stomach is usually not impaired; in a few instances it is rather increased. Thus, two hours after the test-breakfast, or six to seven hours after the test-dinner, the stomach is found to be either empty, or contains but very little food. The salol-test likewise shows salicyluric acid in the urine as early as an hour after the ingestion of the salol.

The degree of acidity of the urine is frequently diminished during the digestive period. This, however, is not always the case, for occasionally the degree of acidity of the urine and of the gastric contents may be found increased at the same time.

Course of the Disease.—At the beginning hyperchlorhydria is most frequently intermittent. The patient may suffer from this affection for several days, weeks, or even months, becoming free from this ailment for periods of time which vary from several weeks to months, or even years. After this interval the trouble recurs, either spontaneously without any apparent cause, or is evoked by a severe mental shock or worry. Later, the periods of hyperchlorhydria become longer, and at last this condition may become permanent.

Prognosis.—The prognosis in hyperchlorhydria is, as a rule, quite good, except in some cases of a very protracted and severe nature, in which the prognosis regarding the complete disappearance of this condition is bad, although even then there is no danger of a fatal issue.

Diagnosis.—The diagnosis of hyperchlorhydria is made either by the subjective symptoms alone, or in connection with the results of chemical examination of the gastric contents. The subjective symptoms characteristic of hyperchlorhydria are: 1. Pains, appearing constantly about two to three hours after meals. The relief from the pains felt immediately after the ingestion of an alkali, or a little while after the partaking of some food, especially albuminous. 2. Appetite and thirst are either in a healthy condition or increased. 3. No marked cachexia. 4. Constipation.

Although all the symptoms mentioned make the diagnosis of hyperchlorhydria probable, it can be made with certainty only after a repeated examination of the gastric juices. 1. On examination of the stomach in the fasting condition the organ is either found empty, or contains only a few c.c. of juice. 2. One hour after Ewald's test-breakfast the degree of acidity is found highly increased, due to the great amount of free hydrochloric acid.

Differential Diagnosis.—In making the diagnosis of hyperchlorhydria we shall have to exclude all conditions which are liable to give similar symptoms—thus, for instance, gastric ulcer, permanent hypersecretion, and biliary colic. The characteristic symptoms of ulcer are too well known to necessitate their perusal. We shall limit ourselves to the remark that the pains of an ulcer, even if this is accompanied by hyperchlorhydria, do not disappear entirely after the ingestion of large doses of alkalies. Permanent hypersecretion is very frequently accompanied by vomiting, and the most intense attacks of gastric pain appear, as a rule, in the middle of the night or early in the morning. On examination with the tube, the stomach in the fasting condition is found to contain considerable quantities of gastric juice (80 c.c. to 100). Biliary colic, not accompanied by jaundice nor by considerable palpable swelling of the gall-bladder, may give rise to errors as to the real cause of the pain. In biliary colic, however, the pains, as a rule, appear later than in hyperchlorhydria (four to five hours after a meal), and are not eased by the ingestion of food or by alkalies. Another means of differential diagnosis is, that the pains in biliary colic most commonly extend over the right epigastric and hypochondriac regions, whereas the pains of hyperchlorhydria are felt more in the middle of the epigastrium, although sometimes radiating further to the right.

Treatment: Hygienic Regimen.—As hyperchlorhydria is most frequently caused by too much mental work, the daily life of the patient as to amount of work, bodily exercise, mental rest, and pleasure, will have to be regulated. With regard to this point the same rules will not apply to all, but it will be necessary to individualize each case for itself. Thus, business men with a great deal of responsibility resting upon them, lawyers, politicians, and physicians must be sent away from their work to some country place, so as to relieve their brains temporarily from the strain. Ladies moving in high social circles, and participating in all manners of festivities, will have to be reduced to a more quiet life. Again, there are people with large fortunes and without any occupation whatever, who become sick from paying too much attention to their own bodily functions. Here it will be necessary to occupy the mind of these patients with some kind of work.

Cold sponge-baths in the morning, bodily exercise of about eight to ten minutes during every morning, are in most instances of value. Walking once or twice a day for half an hour to an hour, horseback riding, driving, bicycle riding, should be highly recommended.

Diet.—All substances that are liable to intensely excite the glands of the stomach must be excluded from the dietary of such patients. Therefore all kinds of acids, including organic acids (citric, tartaric, acetic acid), all kinds of spices, such as pepper, mustard, horse-radish, and the like must be forbidden. The food should consist of nourishments rich in albumin, while the quantity of starchy substances should be diminished. Thus, all kinds of meat (even game), fish, oysters, eggs, milk, should be taken in large quantities. Bread and butter is permitted. Potatoes, spinach, asparagus, green peas, farina, and rice should, as a rule, be given in only small quantities. Cocoa, weak tea, weak coffee, and beer can be given in moderate quantities.

As a rule it is advisable to have the patient partake of five meals daily, three larger and two smaller. The larger meals should not deviate much from the ordinary bill of fare, while the two smaller ones should consist either of a glassful of milk or matzoon, with bread and butter, or a cup of cocoa and a few crackers, or occasionally a cup of bouillon with an egg beaten up in it, and some bread, or half a dozen oysters, a few crackers, and a glass of beer. The patient must be impressed with the importance of masticating the food thoroughly, and eating slowly, besides resting fifteen or twenty minutes after each meal.

Medicaments.—All kinds of alkalies can be applied in the treatment of this affection. Where hyperchlorhydria is not complicated with constipation, bicarbonate of soda may be given, either alone or in combination with sugar of milk or peppermint sugar (German Pharmac.) in doses of half a teaspoonful to about one teaspoonful three times a day, two hours after meals. In cases which are accompanied by constipation, magnesia usta and some rhubarb can be added, and here I frequently prescribe the following:

℞. Magnes. ust.,
Pulv. rad. rhei ..... āā 7.5
Natr. carbon. exsiccat.,
Natr. bibarbon.,
Elaeosacch. menth. pip ..... āā 15.0
M. Exactissim, f. pulv.
D. Ad scatulam.
S.: One-half teaspoonful to a teaspoonful three times daily, two hours after meals. To be taken in plain water or in Vichy water.

Bouveret uses sodium bicarbonate in two-gramme doses, to be taken two hours after lunch and supper, and to be repeated after an hour's interval. The alkaline treatment can be continued for very long periods without any ill effects whatever. In cases in which the nervous element is more disturbed (sleeplessness, headaches, over-excitability, etc.), we should give a good dose of a bromide salt. I am in the habit of prescribing strontium bromate:

℞. Stront. bromat. puriss 12.0
Aq. menth. pip 60.0
D. S. One teaspoonful twice daily in milk, at meal-time.

Sodium bromide and ammonium bromide can be employed in the same way. The bromides should, however, be given only for a week or two, and their use then discontinued for a short time, after which they may be resumed for the same length of time. Boas advises the administration of small doses of morphia or codeine. He frequently prescribes the following:

℞. Magnes. ust 15.0
Morphii hydrochlorici 0.1
M. f. pulv. d. in scat.
D. S.—A point of a knife to a teaspoonful three times daily.

I have very seldom seen the necessity of prescribing either morphia or codeine in this affection.

Of the watering-places, Vichy and Neuenahr are to be highly recommended. For the treatment of these patients at home these mineral waters are taken most advantageously in small quantities.

Electricity.—In cases of a protracted nature, the direct application of the electric current to the inside of the stomach is frequently of the greatest benefit. In most instances the faradic current should be applied, but in cases in which the pains are very severe, galvanization should be employed.

As to the mode of application of the current, and the length of time required for this treatment, see my

papers on intra-gastric electrization. The electric current applied in this manner exerts a stimulating tonic influence, not only upon the stomach but also upon the small and large intestines. I have frequently seen cases of hyperchlorhydria, accompanied by the most obstinate constipation, perfectly cured by means of the current, even when no medicament whatever has been given.

II. Gastro-succorrhœa Continua Periodica (Reichmann), **Gastro-xynsis (Rossbach).**—By "gastro-succorrhœa continua periodica" (or "periodic continuous flow of gastric juice") is designated an affection which is characterized by a constant secretion of gastric juice giving rise to spells of vomiting and severe pains and lasting only several days.

General Remarks.—The affection is met with either in persons suffering from some organic lesion of the peripheral or central nervous system, or in persons whose nerves appear to be in a normal state. The periodic continuous flow of gastric juice was first described by Reichmann;[1] a few years later Rossbach[2] had described, under the name of gastro-xynsis, a nervous affection of the stomach, which consists in a sudden appearance of severe headaches accompanied by gastric pains, and vomiting of very acid chyme or gastric juice. In accordance with Boas, I consider gastro-xynsis and gastro-succorrhœa continua periodica, as one and the same affection, and I do not think they should be treated under different headings.

Symptomatology.—In the midst of perfect health a sensation of discomfort is experienced in the gastric region, which is associated with restlessness. Soon afterward the discomfort changes into a rather painful sensation, and a feeling of nausea appears. The patient is compelled to occupy a recumbent position. The symptoms just described continue, or rather increase in severity, and in about an hour or two the nausea ends in vomiting of a large quantity of gastric contents. The patient may now feel a little relieved for a short time, but soon the same symptoms return. The appetite is entirely lost, and instead there is extreme thirst. The more the patient drinks, the more, as a rule, he has to vomit. If he abstains from drinking the vomiting is less frequent, but persists nevertheless. Thus, as a rule, in the middle of the night or early in the morning, the patient has to vomit a large quantity of a watery liquid which is very acid in character, and either quite clear or greenish from the admixture of bile. If this liquid be examined, it will be found that free hydrochloric acid is present in large quantities, as well as the ferments (rennet and pepsine). No food particles can be discovered in the fluid. It consists of either clear gastric juice or gastric juice with admixture of a little bile. After such an attack frequently a constant desire to vomit persists, and the patient suffers from very violent and painful retching. Often, a quarter of an hour after the last paroxysm of vomiting, the patient's efforts to vomit cause a small quantity of clear yellow bile to be ejected. Even if the patient absolutely abstains from all kinds of food and drink, a few hours later a large quantity of gastric juice may again be vomited. The patient in this condition is hardly able to sleep for any length of time, as the pains awake him soon after he has fallen asleep. The abdomen, as a rule, is sunken. The patient looks extremely pale and his extremities are frequently cold. Severe headaches often accompany this train of symptoms, and constipation is almost a constant concomitant. After this condition has lasted for about two or three days, or sometimes even longer, the nauseous feeling begins to disappear, the pains subside, and the patient experiences for the first time a desire for food. He is now able to eat without vomiting, and in a day or two feels himself again. It is characteristic of this affection that the symptoms disappear almost suddenly, and that the patient, who seemed to be in a wretched state a few hours before, may now appear nearly well. After a period of perfect euphoria, varying from several weeks to a few months or a year, or even longer, a similar attack may occur. The attacks may then recur either after the same period of time, or the intermission of health may become gradually shorter, so that at last the patient has hardly recuperated from his last attack before a new one supervenes. The latter condition forms the intermediary stage between periodic and chronic gastro-succorrhœa. During the free intervals the gastric secretion takes place either in a perfectly normal manner, or hyperchlorhydria may exist. In both instances, however, the stomach remains free from secretions in its empty state.

The following case, which I observed recently, may serve as a good illustration of this affection. R. B. I. ——, aged thirty-seven, business man. During 1890 and 1891 patient had several attacks of the then prevailing grippe. In December, 1892, after the third attack of the grippe he was taken ill with a stomach trouble, the nature of which patient described as follows: "I was taken suddenly by a fit of vomiting, entirely emptying the stomach apparently, but followed by successive spells, at an interval of one to two hours, accompanied by the most intense pain. This would last from twenty-four to thirty-six hours, and sometimes forty-eight, after which the stomach would gradually quiet down so that nourishment in the form of milk—either hot milk or kumyss—could be taken in small quantities at intervals of about two hours, until a normal condition was restored, which usually took from two to three days to accomplish.

"The character of the vomit was, first, that of undigested food, followed by a strong and very acid nature of a whitish color, and finally that of a greenish color, consisting principally of bile. After each of the spells mentioned the intense pain would subside, and I would fall to sleep—to be awakened again by a recurrence of the pain—the intervals of sleep and suffering varying from an hour to three as I became better, and continuing until vomiting had ceased.

"During all these spells I was exceedingly nervous—the slightest noise or vibration causing pain and sometimes causing the vomiting. General condition after becoming able to sit up was one of extreme weakness—having lost from ten to twenty pounds, as the attacks were longer or shorter.

"During 1893 I was ill four or five times, in 1894 as often, and in 1895 four times. Weight previous to grippe averaged 135 to 138 pounds; since these attacks it has varied from 125 to 133."

Present Condition.—July 22, 1895.—Chest organs normal. The palpation of the abdomen does not reveal any pathological condition. The splashing sound can be easily produced in the gastric region, and extends downward to about two fingers' width below the navel. Knee-reflex present. Urine does not contain any sugar or albumin. Besides the above described attacks of vomiting, patient complains of a feeling of heaviness in his gastric region about one hour after meals, and of slight constipation.

July 23d.—Examination of the gastric contents one hour after Ewald's test-breakfast: HCl + Acidity = 100; free HCl = 86.

October 8th.—Patient is in bed suffering from one of the attacks mentioned; he had vomited several times during the day and is suffering from intense pain. On inspection the abdomen is slightly sunken; on palpation the whole gastric region is found extremely sensitive and painful to pressure. The hands and also the face (particularly nose and forehead) are somewhat cold; pulse, 110; temperature, 98° F. The vomited matter consists of a pretty clear fluid with an abundant admixture of mucus; no food particles can be discovered in the liquid. On chemical examination free HCl as well as pepsin and rennet are found present in large amount. Patient complains of intense thirst. Under

[2] Rossbach: Deutsch. Arch. f. klin. Med., 1885, Bd. 35.

the administration of opiates the patient grew better and was able to leave his bed after three days.

Diagnosis. — The diagnosis of gastro-succorrhœa continua periodica can be made by the above-described symptoms, in connection with the examination of the vomited matter (which is found to consist principally of clear gastric juice without admixture of much food), or the examination of the stomach in the fasting condition by means of the tube (which results in the withdrawal of a considerable quantity of clear gastric juice). Inasmuch as similar attacks of gastro-succorrhœa may occur as a consequence of either an open ulcer or a cicatrix within the stomach, the pylorus, or the duodenum, it will be necessary to exclude such organic affections before making a diagnosis of continuous periodic gastric flow, which we consider as a nervous affection. It will also be of importance to exclude organic, spinal, or cerebral troubles, which may cause a similar disorder of reflex origin.

Prognosis.—The prognosis of pure cases of gastro-succorrhœa continua periodica is, as a rule, not bad. In many instances, it is possible either to make the attacks less severe, or in some instances to effect a cure by rational treatment.

Treatment.—It will always be advisable to analyze the gastric juice of the patient during the free intervals. If hyperchlorhydria is found, this will have to be treated as such, even if there should be no subjective complaints; for hyperchlorhydria is frequently, although not always, the cause of such attacks. At any rate, a hygienic way of living should be inaugurated by the physician. I am in the habit of prescribing a good-sized dose of bromide, as soon as the patient feels an attack coming on, and find that occasionally it may be cut short from the very beginning In some instances the attack, although not interrupted in its progress, is thereby rendered less severe. When the attack has appeared the patient must be kept in bed. A hot-water bag is placed over the gastric region, and if the pains are severe an opiate, either alone or in combination with belladonna, is administered. During the first day of the attack no nourishment whatever should be given. A teaspoonful of cold water, or a small ice-pill, can be administered from time to time, especially if the patient is very thirsty and dry. The next day small quantities of milk, matzoon, or egg-water, one or two tablespoonfuls, are given every hour. On the third day the quantity of nourishment may be increased to half a cupful at a time, administered every two hours, and besides the above liquid food, the white of a hard-boiled egg, chopped up fine, may also be given (one or two eggs a day). On the fourth day meat (scraped, raw, or broiled) may be tried, and afterward the diet gradually arranged as for cases of hyperchlorhydria. The system of diet as laid down here for every day from the beginning of the attack will certainly depend upon the condition of the patient, and will have to be modified accordingly. As there is always constipation during the attack, it will be best to move the bowels on the second or third day, either by a glycerin suppository, or by a large injection of water (a quart of water and a teaspoonful of salt), or an injection of sweet oil (one pint).

III. Gastro-succorrhœa Continua Chronica ("Chronic continuous flow of gastric juice," or "Reichmann's disease"). — Under the above name Reichmann,[1] in 1882, described a pathogenic condition which is characterized by a constant secretion of gastric juice, even when there is no food whatever in the stomach. The stomach is found to contain considerable quantities of gastric juice in the morning, even in the fasting condition.

General Remarks.—In describing this new disease, Reichmann, in 1887, mentioned that he had observed sixteen cases. An exact scientific diagnosis had been made, however, only in six of them. "In the remaining cases," says Reichmann, "I was unable to find in the stomach in the morning, in the fasting condition, a large quantity of a liquid containing hydrochloric acid and pepsin, and exhibiting digestive properties, but containing also much peptone and remnants of amylaceous food."

Among the six cases which Reichmann considered as typical of gastro-succorrhœa chronica, I think that only one (Case 3) deserves this name, for the remaining five, aside from the constant secretion of gastric juice, presented other important lesions of the stomach, which in all probability were rather the cause than the effect of the constant gastric flow. In all the cases described by Reichmann (except in Case 3) the stomach in the fasting condition contained a considerable quantity of liquid, consisting of gastric juice, and containing amylaceous food remnants. When the stomach had been washed out on the previous night, and the patient had abstained from food or drink, the stomach in the morning nevertheless contained clear gastric juice. These cases are then undoubtedly cases of dilatation of the stomach, or more correctly speaking, of stenosis of the pylorus, in which hypersecretion must be considered as a concomitant factor. Reichmann, and following him, especially the French writers Bouveret,[1] Debove, and Rémond,[2] and among the Germans, Riegel,[3] have laid too little stress upon the distinction between the constant flow of gastric juice and dilatation of the stomach due to stenosis of the pylorus. On this account the picture given by these authors of the true gastro-succorrhœa chronica bears a closer resemblance in many points to that of dilatation of the stomach, than to the picture of the affection in question. Inasmuch as the treatment of cases of stenosis of the pylorus in most essential points differs from the treatment of cases of gastro-succorrhœa (I need only mention that the most rational treatment for the former is a surgical one), it is absolutely necessary to strictly differentiate between these two conditions.

About two years ago Schreiber,[4] of Koenigsberg, published an extensive paper in which he doubted the existence of the new disease, and considered all the cases described by Reichmann as cases of dilatation of the stomach with stagnation of food. Shortly afterward, two other important papers appeared with reference to this question: Riegel[5] defended Reichmann's views, while Martius[6] was inclined to favor Schreiber's opinion. Whether Schreiber's view, that the stomach normally secretes gastric juice even while in its empty state, is correct or not, is a question that is quite difficult to decide, although I am personally of the opinion that when there is no food in the stomach there is no secretion. But leaving aside this question about the physiology of the stomach, there is no doubt that, as a rule, the stomach in the fasting condition does not contain any considerable quantity of gastric juice. Whenever considerable quantities are found, the stomach must be considered as affected. In this respect I agree with Reichmann, as to the existence of a pathological continuous gastric succorrhœa, although I shall restrict this name only to cases not presenting any organic lesions of the stomach. Whenever the latter exist I deem it best to look upon the accompanying gastric succorrhœa as a consequence of the main trouble, but not as a primary affection. According to my experience, which coincides with that of Ewald, cases of genuine gastro-succorrhœa chronica are quite rare. They are less frequent than the gastro-succorrhœa periodica. During the last seven years I have met with six cases of this affection, one of which I[7] pubilshed in 1887.

Before entering into the discussion of the pathology of this disease, it might be best to briefly describe one of my recently observed typical cases of gastro-succorrhœa.

A. S——, twenty-one years of age, has suffered since early youth from digestive troubles. As far back as he can remember, he has felt hungry very soon after meals (one hour). The bowels, although regular, were occasionally very constipated. Patient was always weakly, but in the last three years had been troubled in a higher degree. He felt extremely weak, became dizzy after meals, and was overcome by a feeling of sleepiness. The bowels became constipated all the time. During the last six or seven months there was a sensation of extreme weakness in the hands and feet. The appetite was constantly increased, and a hungry feeling appeared very frequently. Since three months there had been present a burning sensation in the gastric region, which increased in severity about an hour or two after meals. From that time on, patient began to vomit frequently. The vomiting, as a rule, occurred very soon after a meal, although occasionally it took place either in the middle of the night or in the morning before breakfast. Patient had lost lately in weight (about ten pounds).

Present Condition.—Chest organs intact. On palpation, the gastric region is somewhat sensitive to pressure. There is, however, no circumscribed painful area. A splashing sound can be produced, extending to about one finger's width above the navel. Tongue is thickly coated. Color of lips and cheeks quite good, and the patient does not look emaciated. The knee-reflex is present, and the urine does not contain anything abnormal. The examination of the stomach one hour after a test-breakfast, showed the quantity of chyme to be small (about thirty cubic centimetres); hydrochloric acid + ; acidity = 100.

The examination of the stomach in the fasting condition revealed that the organ contained a considerable quantity of pure gastric juice ; 120 c.c. of a somewhat turbid liquid, not containing any food remnants whatever, were withdrawn with the tube. This fluid contained free hydrochloric acid, had an acidity of 80, gave only weak biuret reaction, while erythro-dextrine, dextrine, and sugar were totally absent. During the first three months of treatment the condition of the stomach in reference to its secretion of juice did not change in any way. Repeated examinations which had been made in the fasting condition of the patient always gave the same result: presence of about one hundred cubic centimetres or more of pure gastric juice.

The treatment consisted at first in regulation of the diet and in the administration of large doses of alkalies. Later on, washing of the stomach and spraying of the organ with a 1 to 2 pro mille solution of nitrate of silver was instituted. The latter means proved more effective than the above treatment, and after about two weeks it was noticed that the stomach in the fasting condition contained considerably smaller quantities of juice. Thus, thirty or twenty cubic centimetres of juice were frequently found. The spraying was continued for two months, after which time the stomach in the fasting condition was usually found empty. This objective improvement was connected with a subjective amelioration of all the symptoms: the vomiting ceased, the hunger was much less marked, the dizziness subsided, and the patient felt stronger and could do his work much better. The examination of the stomach one hour after the test-breakfast, however, showed that the hyperchlorhydria still persisted. In this case we frequently tried to determine the motor (or transportation) faculty of the stomach ; one and a half hour after the test-breakfast, as a rule, the stomach was found empty, showing that this faculty was rather increased. This is of interest, inasmuch as it shows that continuous hypersecretion need not be associated with sluggishness in the muscular action of the organ, a theory which is accepted by most investigators who have written on the subject.

Etiology.—Gastro-succorrhœa chronica is met with much more frequently in men than in women. In some instances there is present, besides this affection, some other functional neurotic disturbance. In three of my cases the latter was very marked. Thus one of these patients complained of a burning sensation all over his limbs, which lasted for three months and then suddenly disappeared. Like hyperchlorhydria, the gastro-succhorrhœa seems to arise from great mental worry or strain.

Symptomatology.—After a more or less prolonged period of different dyspeptic disturbances, which are similar in character to those caused by hyperchlorhydria, there appears a pronounced sensation of pain several hours after and shortly before meals. Very soon vomiting supervenes as a new symptom. At first it occurs only occasionally, but constantly grows more frequent, until at last there is either one or several vomiting spells every day. The vomiting appears most frequently soon after breakfast, sometimes also after supper. In only a few cases does it occur at night, about two or three o'clock, preceded by long and severe attacks of pain. The vomited matter is always very acid, and more or less liquid. The night vomit especially consists, as a rule, of a clear liquid containing hardly any food.

The appetite is generally increased, although there are exceptions to this rule. In some cases periods of extreme hunger alternate with periods of severe anorexia. In most cases the sensation of thirst is greatly increased. In all of my cases constipation was marked. In some there was present loss of weight, but none of my patients was emaciated in any great degree.

Diagnosis.—Although the symptoms described might suggest the presence of gastro-succorrhœa in certain cases, the exact diagnosis can be made only by a repeated examination of the stomach in the fasting condition. By inserting the tube into the stomach, and telling the patient to exert some pressure with his abdominal muscles, a more or less large quantity of liquid (60–100 c.c.) is obtained from the stomach. This contains no food particles, but exhibits all the properties of the gastric juice. It may look greenish from the admixture of bile, but this is not an important sign. The filtrate, as a rule, shows a somewhat increased degree of acidity. It never contains any starchy products (absence of erythro-dextrine, achroo-dextrine, and sugar). Microscopically no sarcinæ or other signs of decomposition are found. Frequently cell-nuclei are met with in large numbers. In examining the patient one hour after Ewald's test-breakfast the gastric contents will be found to contain more liquid than usually, and the degree of acidity will be quite high (80–100). As a rule, the degree of acidity of the gastric contents is higher than that of the gastric juice when withdrawn from the stomach in the fasting condition. In examining the filtrate of the gastric contents as regards the starchy products, it will be found that the lugol solution will produce a deep violet or even blue color, showing that the starch has not been much changed. A thin disk of a hard-boiled egg will be digested in the filtrate at blood temperature in about half an hour to an hour. The difference as to the degrees of digestion of the albuminates and starches (the former being quicker, the latter much more slowly digested) can be best studied after Leube-Riegel's test-dinner. Three to four hours after such a dinner, the obtained gastric contents contain hardly any meat particles (all being digested), whereas particles of starchy food form the principal part of the mixture. In this way the difference between the digestion of meats and starchy foods existing in this affection is seen at once.

Differential Diagnosis.—In making the diagnosis of gastro-succorrhœa, all organic lesions of the stomach (ulcer and stenosis of the pylorus), which are liable to

be accompanied with gastro-succorhœa, will have to be excluded. According to my experience, it is easy to exclude stenosis of the pylorus, but not an ulcer. In stenosis of the pylorus the stomach in the fasting condition is also found to contain a liquid, but this is mixed with food ("ischochymia"), and the filtrate always shows the presence of starch or sugar products. But the main thing is that food particles can be seen even with the naked eye, whereas the liquid found in the stomach in case of genuine gastro-succorhœa does not contain any food particles, as described above. The presence of an ulcer will be suspected if there has been a preceding hæmatemesis or melæna, or a circumscribed spot (in the gastric region) very painful to the slightest pressure. The absence of these symptoms will tend to justify the diagnosis of gastro-succorhœa.

Prognosis.—According to my experience, the prognosis of gastro-succorhœa is not bad. As a rule, most patients improve under rational treatment. Frequently, however, there are relapses. Some very obstinate cases are occasionally met with, and the trouble, although yielding somewhat to treatment, may persist for years. There is, however, no danger of a fatal issue resulting from this disease alone.

Treatment.—As we have seen, gastro-succorhœa is always associated with hyperchlorhydria. The treatment of the latter condition in reference to diet, medicaments, and mode of living, will have to be resorted to here also. With reference to diet, I have only to add that it is of great importance not to permit the patient to partake of any large quantities of liquid. In this affection more stress must be laid upon this point than in hyperchlorhydria. The treatment of gastro-succorrhœa must be directed toward decreasing the undue amount of gastric secretion.

1. Medicaments: With this end in view, Voinovitch[1] recommends the use of atropia in doses of two milligrammes daily. Bouveret prefers morphia to atropia. Following the advice of Leubuscher and Schaeffer,[2] he administered two to three centigrammes of sulphate of morphia three times daily, in subcutaneous injections. This author doubts, however, whether this treatment, which seems to be effective in the initial state of the affection, will prove useful in cases that have progressed further. The use of either atropia or morphia may be tried for a short time, but they should never be administered for a long period. The subcutaneous injections of morphia especially should be avoided, as the patient runs the risk of becoming an habitué of this drug.

2. Lavage: Reichmann, and latter Riegel, recommend the use of lavage of the stomach as the best means of improving its condition. While Riegel washes out the stomach in the evening, six to seven hours after the last meal, Reichmann and most writers administer the lavage in the fasting condition. The latter way is also employed by myself; it has the following advantages:

a. That by emptying the stomach in the fasting condition we are better enabled to judge the quantity of juice present at a time when normally there should be none.

b. That no food whatever is removed from the stomach.

Instead of lavage Boas recommends emptying the stomach by means of a tube in the fasting condition (expression method). In order to more effectually combat the undue secretion, Reichmann recommends adding nitrate of silver to the water used in washing out the stomach. After it has been washed out with plain water, 300 c.c. of a 1 to 2 per 1,000 solution of nitrate of silver are poured into the organ, and left there for about five minutes, when it is withdrawn by siphonage.

3. Spraying the stomach: Instead of the latter proceeding I have sprayed out the stomach after the washing with a 1 to 2 per 1,000 nitrate of silver solution. In two cases I found this method of treatment of great benefit.

4. Direct galvanization of the stomach: The first of my observed cases of gastro-succorrhœa chronica was a very obstinate one, and the affection did not yield much to the medicinal treatment or to the use of lavage. I empirically tried direct galvanization of the organ, and after a treatment of a few weeks the stomach began to be empty in the morning, and has remained so for several years. Since then it has been my custom to make use of this method in this affection, and I must say that the result has been very gratifying. Very often I employ both spraying with nitrate of silver and direct galvanization, applying them alternately.

EXTINCTION OF TUBERCULOSIS IN HERDS.[1]

By PROFESSOR JAMES LAW,

CORNELL UNIVERSITY, ITHACA, N. Y.

In dealing with diseases of the lower animals there are various possibilities and limitations which do not enter the field of medicine as applied to man. These must ever be borne in mind if the veterinary sanitarian would have his work prove a success. As applied to tuberculosis these considerations must largely influence us in the choice of methods, and in their application in the sanitary field. Prominent among such considerations are:

1. The facility with which the contagion may be checked by the death of all infected animals.

2. The possibility of arresting the career of contagion by breeding only from insusceptible strains of blood.

3. The impossibility of applying effective methods because of the financial ruin which would be entailed.

1. Destruction of the Infected.—Under the first head—the checking of the contagion by the killing of the infected—the principle being altogether inapplicable to dealing with man, the physician naturally thinks first of segregation, disinfection, and a police control of the sick. With the veterinarian, on the other hand, free from any sense of the sacredness of the life of the sick, the first thought is a purely economical one, namely: Will the cost of the seclusion and care of this animal, and of the probable infection of others, outvalue the prospect of its recovery, and the actual value of the animal when well again? With any virulent and dangerous disease there can only be one answer to this question, namely, that economy demands the extinction of the contagion at the expense of the first victim, before ten or a hundred more shall contract the disease. With a subject, the actual sound value of which may have been anywhere between $10 and $100, the administration of such police control as would guarantee the prevention of the extension of the infection, through man, beast, bird, or inanimate object, would, as a rule, more than use up the actual price of the first victim. Every day of delay in shutting up these living factories of contagion places a greater balance on the wrong side. The economical soundness of this position has been now so often illustrated on a large scale and in regard to so many different diseases, as rinderpest, lung plague, sheep-pox, glanders, and rabies, that for those who have made a special study of it, it has passed from the field of discussion to that of established truths.

2. Insusceptible Families.—In regard to the second question, that of propagating insusceptible families only, while it is equally, with our first proposition, impossible of adoption in the human family, as interfering

[1] Presented to the Academy of Medicine, New York, November 8, 1895.

with personal rights, it is certainly available for the lower animals over which the State can exercise the right of eminent domain and enforce a police control for the common good. In animals, as in man, there are certain families which show a strong susceptibility to given infections, and others that show an equally potent resistance, and if it can be shown that no more serious interest is threatened by such a course, it is quite within the power of the State to exclude the first-named class from reproduction, and to breed only the animals that show the comparative immunity. A principle of this kind is already in force in certain countries, in which all stallions are licensed, and those are excluded from stud uses which are calculated to deteriorate the breed of the district. The same principle is in force in the Channel Islands, where no cattle except those of the native breed are ever allowed to enter a herd.

3. Economic Limitations.—In the third place, we are confronted with the question of economic limitations. It may be said that where human health and life are concerned no question of mere economy should be allowed to enter. But the economic question may be so far-reaching that the evil to humanity would be greater in the end, and our boasted liberality for sanitary needs would itself finally defeat the much-coveted sanitary object.

Deferring for a moment the question of the immediate influence on human health, let us glance at the national wealth in farm animals. The United States own, in round numbers, $1,500,000,000 worth of farm stock, and in this are included 16,000,000 head of milch cows, and 20,000,000 head of other cattle. The cows produce yearly 5,209,125,567 gallons of milk, or 315 gallons per head. Of the other cattle, probably 5,000,000 are killed yearly for human food, representing 1,000,000 tons of beef. This cannot be materially restricted without dealing a serious blow at our national prosperity.

While it must be conceded that animals would acquire a greater power of resistance to tuberculosis if kept in the open air and in a condition more nearly approximating the natural one, yet if we let the milch cow revert to the condition of the native Texan cow, which can only scantily support its calf, and if we remand the beef animal to its native state, in which it took four years to reach maturity, in place of putting him on the market as prime beef at two years old, we render the whole cattle business unprofitable. Under such conditions our stockowners can no longer compete in the markets of the world, and this branch of live stock must be abandoned. But if abandoned, the exhaustion of our soils is a necessary consequence, and in due time agriculture, in its turn, must become unprofitable, and with its decay we shall reach the end of our whole national prosperity, built upon our abundant agricultural products.

Whatever we do with our domestic animals we dare not cause them to revert to a state of nature. This would be to throw away the achievements of the labor and the skill of centuries, and would entail the most serious retrogression of the nineteenth-century civilization. As well propose to abandon the modern triumphs in steam and electrical engineering.

The abnormal productiveness of the present farm animal is one of the most substantial foundations of modern prosperity, and it would be an economical blunder, and finally a sanitary one, to seek its abandonment or limitation. So far as we can secure an innate immunity within the productive families, our work will be sound, and so far as we can produce an acquired immunity by hygienic measures we are laboring in the right line; but the line must be drawn wherever these protective measures tend to seriously impair the capacity of the breed for profitable uses.

These considerations serve to clear up our field of veterinary sanitary police, and to narrow it to the limits which are at once the most indispensable and the most effective. One measure stands out above all others as the one which must never be lost sight of, and to which all others must be held as accessory and subservient. This measure is the extinction of the disease germ.

Feeding from Separate Troughs.—Where from any cause the immediate extinction of the germ is impracticable, an all-important precaution is to teach each animal to use its own stall only, and to have the stall so separated in front that no two cattle can feed from the same trough. For the same reason no common feeding-trough should be used in yard or field, and there may be danger in using a common drinking-trough or bucket.

Salting Troughs and Front of Stalls.— In view of the fact that tuberculosis is largely propagated by the dried-up virulent expectorations which are raised and diffused in the form of dust, the daily sprinkling with a strong brine, of the front of the stall, the manger, and the passage in front, proves an important protective measure. Condensing the moisture of the air, the salt keeps the surface constantly damp, and prevents the sputa from drying up and rising as an impalpable powder. The salt is not only harmless, but wholesome, and has, besides, a very slight bactericidal action. In a cold barn, below freezing, a weak solution of sulphuric acid may be substituted.

Open-air Life.—So far as possible a free, open-air life should be secured for the stock. In city and suburban stables the infected may reach anywhere from six to ninety per cent., whereas among 2,250,000 of our fat range cattle the tuberculous did not exceed 0.02 per cent. The comparative absence of viable bacteria in the air of the pastures, and the operation of full sunshine in devitalizing the bacillus tuberculosis in a few hours, while it may live for months in an ordinary room, are sufficiently instructive in this connection. In the Northern States, where cattle must be sheltered indoors for five or six months of the year, too great care cannot be taken to secure ample windows and sunshine, as well as free air in the stables. Darkness in the stalls reduces the quality and number of the red globules, and the vitality and power of resistance of the animal; so that it virtually burns the candle at both ends, preserving and multiplying the germ and increasing the susceptibility of the animal.

These considerations strongly condemn the city and suburban dairy. Other things being equal, the larger the city the greater the number of floating bacilli and the greater the susceptibility of the animal system. In French towns of five thousand inhabitants the ratio of tuberculous persons is only half as much as it is in towns of one hundred thousand to five hundred thousand. In German abattoirs the ratio of tuberculous cattle is about five per cent. of all slaughtered, yet Ostertag gives the ratio for old cows in the Berlin slaughter-houses as seventy-five per cent. The ratio is greater in our city and suburban dairies to-day than it was years ago, when a large proportion of the fresh cows were killed off by lung plague within three months of their purchase. There remains, however, this redeeming element, that the city dairyman finds it unprofitable to keep the same cows from year to year, and as a slow disease like tuberculosis finds insufficient time for abundant development, the result is better for the city dairy than it otherwise would be. The case is worse with a thoroughbred herd kept in the city or suburbs as long as the cows will breed, as there are here the combined evils of a generally contaminated atmosphere of indoor life in a barn too often infected, and in too many cases a bodily constitution rendered increasingly susceptible by inbreeding. Once start the infection under such conditions and the affection is liable to become concentrated by a number of successive reinfections in the same animal, so that not only are cases multiplied, but generalized cases soon come to prove the rule rather than the exception. Everything considered, the city and suburban dairies are surrounded by greater

dangers than the country ones, and this should be taken into account alike by the dairyman himself and by the sanitarian who would protect humanity against the bovine source of infection.

Precautions.—Among the further precautions which are within the control of the stockowner himself are the following:

Avoid Breeding too Young.—The immature system is easily debilitated.

Don't unduly Stimulate the Milk Secretion.—Let the diet be always sufficient to fully sustain the vital powers as well as lactation.

When the Cow goes Dry don't Allow Her to Suffer from Insufficiency nor Unsuitability of the Food.

Correct all Conditions of Ill health.—Debility is an urgent invitation to the bacillus. On the other hand, the most phenomenal powers of digestion, assimilation, and rapid growth and fattening give no guarantee of protection when the germ is implanted.

Bang tells us that the disease was virtually unknown in Danish cattle until 1840, when it was introduced in some purchases from Schleswig, and later, in 1850, by large importations of English short-horns, and now the Copenhagen abattoirs show seventeen per cent. of the cattle tuberculous, and the tuberculin test on 19,462 cattle showed 61.6 per cent. tuberculous.

Old and Unthrifty Cows should be Excluded from the Herd.—Twice to six times as many old cows as of young ones are tuberculous. The first sign of unthriftiness should be a warrant for separation from the rest of the herd, and especially in the case of the aged. Better still to use the tuberculin test to decide whether the animal should be promptly slaughtered.

Don't Buy from a Herd that has Furnished Cases of Tuberculosis in Recent Years.—Here, again, the safe course is to admit only such as have stood the test with tuberculin.

Let no Tuberculous Person Care for the Herd.—The tuberculous person is a source of greater danger to the herd than is even the tuberculous animal. The latter can be confined to one place and the virulent sputa can be prevented from drying and rising as dust, but for the attendant there is no such limitation, and his discharges are all the more dangerous. In one herd where three of the family in charge had died of tuberculosis, I found nineteen of the twenty-six cows badly affected.

By attending to such precautions, by killing all tuberculous animals and safely disposing of the carcases, and by thoroughly disinfecting all the products, the stockowner may reasonably hope to purify his herd of the infection and to keep it sound.

I have purposely omitted all reference to methods of treatment, as these, however good for a human patient whose life must be spared, necessarily entail a long-continued administration, and are attended by too great expenses and uncertainty of result to warrant their recommendation for animals when the object is to stamp out the disease.

Sanitary Police for Tuberculosis in Herds.—In considering police methods for tuberculosis in herds, our past experience in dealing with plagues of animals does not furnish an exact counterpart. The absolutely successful results in different parts of the world with rinderpest, lung plague, sheep-pox, rabies, and glanders, were obtained with diseases which confined their ravages to animals, or which, in attacking man, entailed an acute and fatal disorder, so that the agency of man in propagating the contagium could be practically eliminated. In tuberculosis, on the other hand, we confront a disease which, even in man, often follows a tardy and occult course, and which is, at all events, habitually chronic, so that the contagium must be preserved so long as the phthisical man is allowed to go at large. It is not, however, so diffusive as the contagia of rinderpest, lung plague, or sheep-pox, and hence the same absolute seclusion is not necessary to prevent its propagation.

If we could exclude dairy herds from cities and other dense aggregations of humanity, and see to it that consumptive persons were debarred from caring for, or mingling with, cattle and other susceptible animals elsewhere, we could proceed with the extinction of bovine tuberculosis with the same confident expectation of success as we have in the past undertaken the extinction of the plagues of animals already referred to.

So long, however, as such separation is unattainable, we must be content to be satisfied with less perfect results, and must stand ready to repeat the process of extinction in the same herd as often as it may become necessary. Even with this drawback, however, we can promise a practical extinction of the affection in our herds, and a reasonable guarantee of the soundness of our dairy and butcher products.

For the Speedy Extinction of Tuberculosis in Herds.—In this direction I cannot do better than to repeat my suggestion in the report of the Tuberculosis Commission for 1894: "All herds of the State would be examined and tested with tuberculin as speedily as possible, the diseased animals would be condemned, appraised, killed, and safely disposed of, the premises disinfected, other genera of animals that have lived with the diseased" (cattle) "would be examined, and, if necessary, safely disposed of, vermin would be killed, and all consumptive persons would be advised" (enjoined) "against attending on the purified herd or preparing their food. Finally, all new purchases would be kept apart from the herd until they had been tested with tuberculin. In this way every step would be so much clear gain, and what had been once accomplished could be looked upon with reasonable confidence as a permanent success."

The continued testing of new purchases and the repeated examination of the herds at long intervals would be required, as, at first, isolated cases would appear from bacilli that had lodged on the digestive or respiratory mucosæ, but which had not colonized the tissues prior to the tuberculin test, and also from other accidental outside sources. Necropsies of all animals dying or killed would also be requisite, so as to insure that no seeds of the disease should be overlooked in the herd, so as to break out later. The most serious objection to this prompt and effectual method is the lack of a sufficient appropriation. For indemnities alone, at $25 per head, four per cent. of our 2,500,000 head of cattle (100,000) would demand $2,500,000. If we add to this the cost of the inspection of the whole bovine race in the State, and of animals kept with them, of appraisements and of administration generally, we could not calculate on less than $3,000,000 as a working fund. Another drawback is the lack of professional men sufficiently acquainted with the use of tuberculin, and with the diseases of animals generally, to satisfactorily fill the *rôle* of inspectors. It would take a length of time to organize a satisfactory sanitary force for the entire State, so that, even if the money were forthcoming, the inauguration of the enterprise would be necessarily slow.

Registration of Herds and Necropsies as a Means of Tracing Tuberculosis.—A most effective but less speedy means of dealing with tuberculosis in herds would be based on an universal registration of the bovine animals. To each county or district could be assigned one or more trustworthy veterinarians who should keep an accurate record of bovine animals, and of all additions and removals, and who should examine all cattle killed or that died. On the discovery of a case of tuberculosis, the disease would be identified by the chief veterinarian, and the whole herd would be subjected to the tuberculin test, and those found tuberculous would be condemned, appraised, killed, and safely disposed of, and the premises disinfected. Similar precautions as under the speedy method would be adopted toward other domestic animals on the same place, toward ver-

min, and toward tubercular attendants, and new purchases.

In this way every tuberculous herd would be discovered and purified without serious delay, and at the same time the expensive tuberculin test would be reserved for herds in which tuberculosis was known to exist. The unfounded stock objection to the tuberculin test, that it might introduce disease, would in this way be rendered absurd even to the objector himself.

This work could probably be accomplished by one hundred inspectors at a cost of $150,000 or $200,000 a year. Indemnities also would be lessened, as many of the occult cases would be detected only at the butchers, and at least the demand for values would be more gradual and more easily met.

Abattoir Inspections to Trace Tuberculosis.—A third method of tracing tuberculosis is to provide municipal or other official abattoirs in which alone farm animals designed to be marketed as human food can be killed. This has long been in use in Europe, and must one day be adopted in America, as a purely sanitary measure, no matter how it may interfere with the vested interests and monopolies of individuals. Inspection in private abattoirs can never be made as satisfactory as in public institutions in which everything is done according to rule. Incidentally the government stamp and endorsement furnished with all sound meats would open to all competitors interstate and foreign trade, which is now the monopoly of the packers in certain large cities. Its effect in tracing the centres of animal tuberculosis may be inferred from the reports of the Berlin abattoirs, where seventy-five per cent. of the old cows are tuberculous; of Leipzig, where twenty-eight per cent. prove affected; of Schwerin, where thirty-five per cent. are diseased; of Paris, London, and Edinburgh, where twenty-two per cent. prove consumptive.

With such data it is easy to follow each animal back to its herd and subject that to the tuberculin test. If we were to combine this restricting of slaughter to the inspected government abattoirs, with a careful record of the herds and their individual animals, it would prove easy and certain to discover every centre of disease and to speedily eradicate the contagium.

The desideratum in our present methods is a definite and effective system. Our tuberculosis commissions are in a sense free lances, with power to rove about the State and test a herd here and a herd there, as the urgency of the demand or their own judgment may dictate. And in the preliminary inquiry into the existence and relative prevalence of tuberculosis in different districts this has served a good purpose. But now that this purpose has been accomplished, this should give place to a system which will look toward something more definite in the way of the extinction of the disease. When a herd or district is purified of the infection, due precautions should be taken to prevent its reinfection, so that the same work will not be demanded again and again in the same district, and above all, that the purified herd shall not be exposed to diseased herds on all sides of it.

Let herds be excluded from cities and suburbs, or let the herds in such localities, as are the most dangerous to themselves and to humanity, be the first to be put under a rigid system for the suppression of the contagium. Next to this, the dairy counties, in which the bovine population is the densest, should be systematically attacked. When these shall have been purified, the herds of the State at large, where the danger of the concentration of infection is least, should be taken in hand. Every step, however, should be subordinated to the maintaining of the ground that has been already gained, and the advance of the work in such lines as will make it possible or easy to hold all newly acquired territory. The general plan must therefore yield in many cases, so as to clear up a whole district—the less densely peopled with cattle, as well as the more densely populated—so that the conquered territory shall be kept compact and easily defensible from first to last. The time for the sporadic dealing with individual herds, remote from each other, is past. The knowledge and the needs of to-day unite in demanding such an appropriation and such supervision as will secure a systematic and progressive advance over the whole State, and which will look toward the purifying of our herds in every locality.

A STUDY OF HYSTERIA AND HYPOCHONDRIASIS.[1]

By CHARLES E. LOCKWOOD, M.D.,

NEW YORK CITY.

ATTENDING PHYSICIAN DEPARTMENT FOR DISEASES OF THE NERVES, OUT-DOOR POOR, BELLEVUE HOSPITAL.

The period in which we live seems to be peculiarly fruitful in the production of malnutrition, degeneration, and diseases of the great nerve-centres, which has been variously ascribed to different factors. The fact that the census of 1890 showed that eighty-seven per cent. of the total population, over ten years of age, could read and write, would seem to be of interest in this connection; as one writer remarks, "it may be fearlessly asserted that in the history of the human race, no nation ever before possessed forty-one million instructed citizens." Then, in this age and in this country, the problems of human existence have been rapidly growing more vast and complicated, and the rapid succession of events, which are now daily reported to us from all quarters of the globe, together with the great strain on the higher cerebral centres incidental to the great struggle for wealth and existence, combined with the absence of proper periods of rest, and the lack of general systematic cultivation of out-door games and sports, and means of mental diversion, are hardly calculated to favor healthy cerebral nutrition.

It may also be reasonably asked whether the human brain is not passing through a period of great strain and readjustment to a new environment, and is suffering as a consequence until such time as advanced ideas shall indicate the proper methods of meeting the new conditions, and here it seems proper to call attention to the tendency to centralization, specialism, and the increased interest in athletics as a step in the right direction. However this may be, rich and poor seem to be equally affected, and in the field of my observation, the Out-door Department of Bellevue Hospital, New York, I have been surprised to observe the great prevalence of such conditions of the higher nerve-centres among the poorer laboring classes, embracing such occupations as are not usually thought to be attended with excessive mental strain, and on investigation one finds that they are all men and women of like passions with us, and that the unsettled intellectual convictions of the present century, ancestral tendencies, individual environment, all the various causes which tend to excite or depress the emotional nature, alcoholic excesses, absorption of nicotine and lead among workers in tobacco and lead, self-abuse, sexual excess, and syphilis, all play their *rôle* here, as well as elsewhere, in producing vital depression and favoring malnutrition and degeneration and abnormal mental states. In the study of the causes of hysteria and hypochondriasis we have to do with mental and physical factors, and largely with mental disturbance; it seems, therefore, fit to inquire carefully as to what favors healthy brain action and its opposite.

The human body may be compared to a kingdom inhabited by a large number of different denizens and visited by many intruders, who, having effected an entrance, gain control and work mischief. The thinking brain is the ruling monarch, and should be most

[1] Read before the Twelfth Annual Meeting of the New York State Medical Association, held in New York October 17, 1895.

carefully guarded and kept in the most perfectly healthy condition, and should reign supreme, choosing its code of principles and carrying them out inflexibly through its prime minister, the will. Anything which interferes with the healthy tone or working of the brain or its powerful agent, the will, affects the whole body unfavorably, and each reacts on the other, hence the maxim, "Mens sana in sano corpore." Now, what are some of the mental and physical conditions which are needed to secure healthy tone and action for the thinking portion of the human brain.

1. Hereditary transmission.

2. Proper mental and physical training, combined with a suitable environment, based on a careful study of the mental and physical conditions of the ancestry and the individual.

3. The correction of all physical defects calculated to interfere with the general nutrition. "If the brain is not well supplied with an abundance of nourishing and pure blood, its functions cannot be well performed.

4. The adoption of the most reasonable, convincing, and soul-satisfying theory of man's place in nature, his origin, mission, and destination.

5. The recognition of the animal propensities in the man, and the importance of their control by educated higher centres.

6. The adoption of a code of principles best adapted to promote the securing of the highest development, mental and physical.

7. The selection of some line of mental or physical work, based on a careful study of mental and physical peculiarities of the individual and ancestry, which shall give a definite and useful aim to life.

8. The keeping out of the mind all influences, ideas, and habits calculated to defeat the end in view, or cause mental or physical deterioration.

9. The keeping out of the mind all superstitious imaginations and unrealities which are calculated to weaken reason and self-control.

This is an age of materialism run riot. Every one seems to be looking for some cause which can be appreciated by the five senses, not laying enough emphasis upon the thoughts which are allowed to enter the human brain and which are just as powerful to produce disease as germs. We come into the world with powerful appetites and special centres for their functional exercise, and above them a higher centre, the seat of the reason and will, weak in many cases and not fit to rule, through inexperience, without the help of the most able and far sighted advisers—is it any wonder that with a certain hereditary predisposition and environment the lower centres in many cases gain control while the higher centre sleeps, and mind and body are deteriorated by force of evil habit and malnutrition until there seems to be no hope of healthy mental action, and every variety of morbid thought and morbid impulse runs through the poor, weak, unresisting brain, until all mental control is lost and the poor sufferer is like a ship which has lost its rudder, at the mercy of the winds, storms, and waves of evil and unrestrained passions, appetites, and morbid thoughts and impulses.

10. The early training of the young in the habit of self-control, as here parents most frequently lay the foundation for future hysteria and hypochondriasis.

11. The careful avoidance of alcoholic excess, especially in hereditarily predisposed individuals, and drug habits.

12. The selection of proper forms of mental diversion and recreative physical exercise, and the cultivation of such social relations as will stimulate the higher faculties and emotions.

13. The forming of habits of self-reliance and individual thought and action, regardless of external influences, so as to increase the power of each individual factor.

14. Submission to destiny.

Having enumerated some of the conditions necessary to promote healthy brain action, without claiming to have exhausted the subject, let us look for a moment at some of the causes which are productive of unhealthy brain action, and again we must mention :

1. Hereditary transmission.

2. Improper mental and physical training, combined with unsuitable environment.

3. Physical defects, which interfere with general healthy nutrition.

4. The lack of adoption of definite principles, looking toward uniformity of thought and action and formation of fixed habits, which tend to the making of a well-balanced mind.

5. The constant indulgence of the animal appetites against the voice of conviction, involving the weakening of self-control.

6. The lack of occupation and motive in life, allowing of too much introspection.

7. The harboring of beliefs based on superstitions and imaginations, involving the stifling of reason.

8. The excessive use of alcoholic stimulants, opium, or tobacco.

9. The lack of proper mental diversion and physical exercise.

10. The effect of low states of health, due to some poison in the system, involving continuous watching for outbreaks, or of chronic diseases, especially of the sexual organs, so that the mind is almost constantly pervaded by the same train of thought.

11. Climatic changes, especially when sudden and of extensive range, involving a frequent readjustment of the system, with consequent vital depression.

12. The circulation in the blood of poisonous germs, metals, or toxic matters, the result of malassimilation or indigestion, as happens in malarial poisoning, syphilis, lead and mercurial poisoning, alcoholic excess, uræmia, or uric-acidæmia, rendering the circulating fluid unfit for healthy nutrition, and predisposing to degeneration.

13. The tendency of the thought and practice of the present age, among young men and women, seems to be antagonistic to the consummation of marriage and the assumption of the duties of motherhood and fatherhood. Young men, discouraged by the extravagant demands of the other sex and their longing for luxury, idleness, and excitement, are led to lead isolated lives, finding their social pleasures in various ways, which lead, in any case, to unsettled convictions, a lack of definite aim, selfishness and introspection, and many deserving young women are driven to seek employment in various occupations or lead lives devoid of the incentives which tend to the highest development of the female nature.

14. The influence of a degenerate literature and art inculcating the following of the lead of the emotions, and the consequent stimulation of the lower centres and lowering of the influence of reason and self-control.

To sum up, anything which favors healthy ratiocination and increases the habit of self-control, or favors the conservation of that mysterious something which we call vital force, together with favorable hereditary transmission, or the use of proper measures looking toward the correction of hereditary defects, or unhealthy conditions peculiar to the individual, these tend to favor healthy brain action, and the opposite conditions unhealthy brain action.

There are two affections to which humanity is liable —hysteria and hypochondriasis—which, in my opinion, are peculiarly the result, in great measure, of defective action of the higher centres, the reason and will, in their inhibitory action on the lower centres ; in other words, long weakening of reason and will and defective training of the higher centres, the seat of these faculties, is followed by undue and unrestrained action

of the lower centres, producing diseased conditions, mental and physical, and this result is naturally favored by any cause which interferes with healthy nutrition.

Hysteria is a yielding of the mind to any morbid impulse that enters it.

Hypochondriasis is a mind habit of dwelling on bodily functions until it becomes second nature, and the mind becomes in this way sensible to impressions which, in health, are unperceived, and are now misinterpreted; or, in other words, it is a morbid concentration of the mind on the various bodily organs, functions, and sensations, to which the subject attributes false pathological significance.

The causes of the two conditions are partly physical, but largely mental; any physical condition which interferes with healthy nutrition, such as indigestion, malassimilation, reflex irritation, the circulation of toxic matters in the blood, may be a potent initial factor, but the habit of mental non-resistance, self-concentration, the paralysis of will, and the neglect to use the reasoning faculties in the interpretation of symptoms presented, are largely responsible for the phenomena presented by these two affections. The class of persons most liable to these affections are those of neurotic ancestry, and possessing a neurotic or mercurial temperament, with strong imagination and emotions, easily elated or depressed, and rather moved by impulse than reason, deficient in self-control, and without definite aim in life and mental occupation.

Following Dr. G. L. Walton's classification in Wood's "Reference Handbook of the Medical Sciences," the symptoms may be briefly classified under Disturbances of Sensation, Disturbances of Motion, Circulatory, Secretory, and Excretory Disorders, and Disturbed Mental Conditions.

As illustrative of disturbances of sensation, I refer briefly to the following cases, which have come under my observation.

Mrs. R——, a widow, had a sensation as though all the blood in the body was flowing into a space about the size of the hand, on the right side, accompanied with pain, a sense of tightness, and suffocation. She was suffering from fatigue at the time I saw her, and had been told that one lung was diseased. She also had a sensation as though the house was moving. She was completely relieved by teaspoonful doses of elixir of valerianate of ammonia, given every hour or two during the entire night.

Mrs. H——, while taking lunch with some friends, had a sensation as though a corkscrew was being bored up through her brain, and was told by her friends that her face was turning purple. I was asked by her husband to see her, as he feared apoplexy. Under the elixir of valerianate of ammonia, in drachm doses, when needed to combat symptoms of nervousness, and a course of Fellow's hypophosphites, there were no further attacks.

Mr. S. S——, never ill, except having had the grippe two years ago, followed by neuralgia, which was cured by galvanism and tonic treatment. He complains of a peculiar sensation when he gets run down and tired, as of something rushing from below the right clavicle and spreading over him; can bring on these attacks by thinking of them.

The following case well illustrates disorders of motion and circulation. Dr. T——, aged forty-three, unmarried, practised self-abuse excessively when young, having gotten into the habit while climbing a tree. Six months ago, while studying assiduously, had nervous tremor or excitement, and discovered on left side of the face, over the malar bone, a decided flushing, extending to the median line in front, and the face was hot and red on that side; a hissing or buzzing was noticed in the ears, and subsultus tendinum in different parts of the body was discovered, legs jerked and hands jumped in bed, and there was sighing respiration.

As illustrating disorders of secretion and excretion, Mr. T. D——, aged thirty-one, in November, 1891, had slight attacks characterized by a feeling of apprehension and as though the heart was quivering from side to side, like jelly. After these attacks the stomach was distended with wind, and he passed about two quarts of straw-colored urine. In this case there was also a disturbed mental condition. In April, 1892, he complained that his brain felt like a ball surrounded by a rind, and the brain wanted to work, but the rind remained passive.

A diagnosis of hypochondriasis or hysteria should be made only after most careful examination and interrogation of the different organs of the body, as organic disease is often masked by these two affections. The following history of a case which came under my care will illustrate this point:

Mrs. M. W——, aged fifty-three, consulted me in 1894, complaining of intermittent action of the heart, burning sensation in the region of the left ovary, tender spot over the seventh cervical vertebra, which aches and burns when she is tired, and great exhaustion after exertion, with mental depression and crying spells. She had undergone considerable treatment, for two years, at the hands of different physicians, with indifferent results. A careful examination of the urine showed a slight trace of albumin (specific gravity, 1.024), and mucous and hyaline casts, one with a renal epithelial cell attached. Treatment was conducted on the lines of a diet to restrict the intaking of nitrogenous matters, elimination and dilution of the urine, keeping the skin and bowels open to promote the elimination of waste and relieve the kidneys, but two months after I first saw her nausea and vomiting set in; with symptoms of uræmic poisoning, and in spite of careful treatment the patient died.

As regards the prognosis of these cases, all depends, it seems to me, as to whether we can so change the mental condition as to reinstate reason and self-control and divert the mind from self and introspection, to outside subjects and objects, and this can only be accomplished by supreme confidence of the patient in the correct interpretation of his condition and the methods employed, and unwavering perseverance until the mind regains a healthy equilibrium.

The pathology of these cases is obscure, but probably consists in a disturbance of the balance of nutrition, either through mental influence or otherwise.

Treatment.—Treatment may be considered under the heads preventive and curative. Prevention of the conditions under consideration may not always be possible owing to inherited predisposition, individual environment, and physical states; but in the line of preventive or modifying measures we may mention the cultivation of reason and self-control, the maintenance of healthy nutrition, the adoption of definite principles of living, based on the ambition to reach the highest mental and physical development, and the giving to life a definite aim and purpose by pursuing some line of work beneficent to others and self, the avoidance of all unnatural methods of stimulation of the animal appetites, a careful study of the individual and his ancestry, and so ordering his life as not to bring excessive strain on the great nerve-centres, but by careful cultivation of the higher centres to bring about that mental equilibrium characteristic of a well-balanced mind, in which the emotions are held in check by reason and will. A doctor must be, in the interests of health, a moralist, a close student of human nature and life in general, and not a mere giver of drugs.

In the way of curative treatment it must first be well established that there is no underlying organic disease, and all physical disorders, such as are due to functional derangement of different organs or the circulation of toxic matters in the blood, must be attended to, together with proper directions as to diet, mental diversion, physical exercise, and the cultivation of cheerful social surroundings, which, having been accomplished,

the mental condition most urgently claims our attention, and here the words of M. Paul Bourget, in his masterly address before the French Academy, on June 13, 1895, seem most pertinent. In speaking of the life of his eminent predecessor, M. Du Camp, he points to his youth as a time of emotional and intellectual confusion and revolt, when he wrote what he called "sad books," and he goes on to say, "To me the most singular and least agreeable fact is that I have suffered horribly from this condition of mind. Indeed, when I turn back to judge myself impartially, I perceive that I found my equilibrium only when near my fortieth year. Vague aspirations, hours of gloominess without a cause, motions without object, all these bordered close on hypochondria, and if any one should show me to-day that I have been somewhat insane, I should be neither indignant nor astonished." M. Bourget then says, "You recognize the very definition of that which was long called 'the disease of the century.' Call it by whatever name you please, it is an incapacity for accepting life, and the advice given by the English essayist 'that man's great work is to carve for himself in the hard marble of life the white statue of serenity.'"

Finally, M. Bourget sums up as follows: "Having commenced by considering life like a true child of the century, as a matter of emotions to be hated when it was not conformed to our desires, he arrived at a recognition of the fact that the whole worth in this life is in work, in submission to destiny, in the accomplishment of a beneficent task;" and here, it seems to me, we find the prevention and the remedy for all hypochondriacal states—the occupation of the mind by employment useful to others and ourselves, and serene submission to destiny. Such a plan will, I believe, bring about a larger percentage of good results, in the way of prevention and cure, than Christian science, treatment by suggestion, faith cure, etc., without the damaging effects produced in the minds of subjects by those unscientific theories.

As regards drug medication, it is a good rule not to use them unless the indications are very well marked, as they serve more or less to fix the patient's attention on self. The drugs useful in these conditions and accompanying functional derangements of different organs, which, when they include those of digestion and circulation, interfere seriously with the general nutrition, may be classed under the heads of sedatives, antispasmodics, excito-motors, anti-ferments, artificial digesters, and tonics. The sedative that I have found most generally useful is a combination of bromide of ammonium and tincture of cannabis indica in the proportion of fifteen grains of bromide ammonium and ten minims of tincture of cannabis indica to one teaspoonful of mucilage of acacia, flavored with essence of peppermint; this being given in teaspoonful doses every four hours for ten days. In cases where it seems advisable to administer the sedative in pill form, I have used a tablet made by the Fraser Manufacturing Company, which contains two and a half grains each of bromide of soda, bromide of potash, and bromide of ammonium, with five drops each of tincture of hyoscyamus and tincture of cannabis indica, giving one tablet three or four times a day. The elixir of the valerianate of ammonia, containing about one to two grains of the salt to the teaspoonful, has given me much satisfaction as an anti spasmodic. As an excito-motor in cases of sluggish action of the nerve-centres, attended with symptoms of slow digestion and general atony, I have found strychnia, in doses of one-fortieth to one-tenth of a grain, most efficient. As an anti-ferment in cases of nervous dyspepsia, so called, subgallate of bismuth, in doses of five to ten grains after meals, has given me most excellent results. The artificial digesters which I have found most helpful, have been preparations representing the different digestive ferments and an extract of malt rich in diastase. In the line of tonics I may mention sirup of hypophosphites, with small cases of strychnia, combinations of strychnine, quinine, pyrophosphate of iron, and dilute phosphoric acid, as in the Hammond mixture in use at the Outdoor Department, Bellevue Hospital, and another of the tincture of the citrio-chloride of iron, quinine, strychnine, and arsenite of soda, the formula of which is as follows:

R. Tr. ferri citro-chlor.	ʒ j.
Quiniæ sulphat.	gr. lxiv.
Strychnine	gr. ss.
Sodii arsenite	gr. 1½.
Alcohol	ʒ ij.
Elix. aurant., N. F.	ʒ viij.

Sig.: One teaspoonful after meals.

Pure cod-liver oil.

As to exercise in these cases, I have found walking in the open air the most useful form when taken in moderation, short of fatigue. Exercise on the bicycle may be of service if carried on with great care, but in many cases the nerve-strain incidental to this form of exercise has seemed to be great and attended with unpleasant after-effects. Frequent change of air and scene, and mental diversion, so as to fill the mind with new ideas, is most helpful.

In giving directions as to diet, our aim should be to secure the taking of as much digestible and nourishing food as possible, and aid its digestion and assimilation by such artificial digesters as are at our command; to avoid taking food when fatigued, and take the heartiest meal in the middle of the day.

In the line of hydropathic treatment the nutrition of the central nervous system may be improved by the proper use of the hot and cold douche.

34 West Thirty-eighth Street.

Failure of the Andrew Clarke Memorial Fund.—Through some bungling on the part of the managers it seems that the attempt to raise a fund for a memorial to the late Sir Andrew Clarke has failed. The responses, in answer to requests for money, did not come as was expected. The reason was that the managers of the fund did not choose the right kind of thing to put the money into. They attempted to organize a new ward or pavilion in the hospital as a memorial. Now, however beneficent an isolation ward may be, and however strongly it may appeal to the well-attuned instincts of the philanthropist, a ward for contagious diseases is not a thing that arouses enthusiasm. One cannot really think of a quarantine pavilion as being a great and inspiring memorial to the life and character of a brilliant and useful man. Furthermore, the sentiment among physicians is not one of extravagant fondness for more hospitals. The charities of this kind have been much abused, and the medical profession has suffered thereby. On the whole, we are not surprised that the Sir Andrew Clarke memorial has been a temporary failure. We hope that those interested in the project, however, will start again, and pick out a better object for their labors, and we are sure they will succeed. After all, a statue or a bust, which stands forever in some public place, and which calls the attention of the public, as well as the profession, to the fact that this man lived a great life, is the form of memorial that cannot be much improved upon, when the sum of money to be raised is rather limited.

The Prize of the French Institute, amounting to 12,000 francs, has been bestowed upon Professor Raoult, of Grenoble, for his researches in chemistry. The award this year was made by a committee of the Academy of Sciences.

Teetotalism in the Indian Army.—Out of seventy thousand English soldiers in India, twenty-four thousand are reported to have joined the Army Temperance Association, and profess to be total abstainers.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 23, 1895.

COMPULSORY VACCINATION.

THE verdict for damages recently given in Brooklyn against a medical officer of the Health Department of that city, for the compulsory vaccination of a protesting citizen, carries with it a wide-spread significance as bearing upon the surrender of the personal rights of a citizen to the greater interests of the community at large. In the particular instance in question, it is alleged that the vaccinator used force in compelling the submission of the plaintiff, who at the time was confined to bed by illness. It was also claimed that the sick man stated he had a tumor of the brain, and that he feared the vaccination might injure him. Notwithstanding all this, the vaccination was done, the victim swearing that when the dreadful incision was made in his arm "the blood spurted out" and he "nearly bled to death."

This is certainly a pretty bad case for an ordinary jury, whose intelligence was capable of such credulity as to impossible surgical accidents. Not only was a general verdict rendered in favor of the plaintiff, with money damages fixed at $1,500, but the jury added a supplement, to the effect that the defendant was guilty of assault and battery. As a result of all this, other similar suits against the health authorities in Brooklyn are threatened.

The vaccinator very prudently, and we believe truthfully, denies the use of violence even in language, and avers that he simply reasoned with the man, and then insisted on vaccinating him. No tumor of the brain was manifest, nor were there evidences of anything else within the skull case. The fact that the inspector vaccinated the unwilling victim at all, was, under the circumstances, considered by the jury as a criminal invasion of individual liberty, and an utter disregard of personal privileges.

It is very unfortunate that the oft-asked question concerning the personal rights of individuals as bearing on the regulations of health departments, should be so pointedly and directedly answered as in the present instance. Under a claim of legal damages it establishes a precedent which may tend in many ways to hamper the action of health boards, not only in their efforts to prevent the spread of disease on the one hand, but to arrest its progress on the other. This is to be regretted, more particularly as there is no statutory law providing for compulsory vaccination. Nor can the latter be urged without endangering the sacred rights of personal liberty.

There is, however, a very effectual offset to the aforesaid conditions in the extraordinary powers, advisory and administrative, that are given to departments of health. This is as it should be in view of the great interests at stake. The community at large looks to the health boards for the guarding of its health and life, and there is a tacit understanding that said boards shall be thoroughly defended and protected in the performance of these legitimate duties. Hence not infrequently even personal liberty must be sacrificed to public safety. Although this may not be done directly, the ultimate result is the same in curtailing or temporarily abolishing the privileges of an otherwise morally free agent.

If an individual refuses to be vaccinated, he can be confined in quarantine until it is demonstrated that he can go about with perfect safety to others. The same principle applies to quarantine on shipboard. In both instances no direct bodily harm is done the individual, but the community nevertheless is effectively guarded against contagion. The health authorities do not actually compel the scholar to be vaccinated, but they consistently and wisely prevent attendance at school until such means of protection are taken. While, however, the law gives ample scope for the exercise of due power and discretion on the part of a board as a body corporate, it does not appear that such a function can be delegated to any of its agents. The assumption by a single representative of such authority in a given case, in which also a reasonable protest is made, and especially when a given community is not in extreme peril, was the mistake made under the present circumstances. A great deal of trouble would have been saved if the case had been simply reported to the board and the entire responsibility of enforcing the letter and spirit of the law had been shifted accordingly. The time has gone by for any more arguments in proof of the utility and efficacy of vaccination, but it would seem that more experience is yet needed to teach us the best means of enforcing a provision which every right-minded citizen considers a very necessary one. The charge that the victim was injured by the operation is, of course, too absurd for sober consideration.

Whatever regret may be expressed at the outcome of the unfortunate verdict, there can be no doubt that the inspector acted in perfect good faith, and with a proper motive to do his best under what he supposed were surmountable difficulties, and it is no more than just that the Health Department of Brooklyn should stand by him in his trouble.

Medical Degrees in Russia.—New regulations are about to be made in Russia in relation to the degree in medicine. Doctors of medicine will in the future be regarded as belonging purely to the scientific grades of professional calling. The degree can only be taken after medical men have held the diploma to practise for three years. Within the five years following the examination the candidate must write a thesis on some professional subject, and if he fails to do this he must pass another examination. The new regulations are destined to make the acquisition of a degree harder than before, and tend toward encouraging specialism, which is carried on to a very great extent in Russia.

THE "REFORM" AS APPLIED TO THE NEW YORK MATERNITY HOSPITAL.

Our former editorials in relation to the so-called "reform" of the medical boards connected with the hospitals under the care of the Commissioners of Public Charities have not dealt in a specific manner with the injustice of the act from a specific stand-point. Since we do not propose that the profession shall lose sight of the issue at stake, nor, as too often happens, to allow the apparent victors to exult too freely over the apparent vanquished, we would refer to the honored and honorable record of the Maternity Hospital under the removed Board as glaring evidence of the injustice of the "deal," and of the self-seeking aim of the promoters of the "deal."

For the past ten to twelve years the Maternity Hospital has easily been the peer of any similar institution in the world. It taught the profession how to eradicate sepsis from the lying-in room; it inculcated the fact, by precept and practice, that death from puerperal septicæmia meant fault in technique; it proved the feasibility of saving the fœtus without imperilling the life of the woman through resort to major operation, instead of doing embryotomy; it was instrumental in dealing a death-blow to careless and to dirty obstetrics; its visiting and its consulting staff, irrespective of comfort, health, or money, responded night and day to the call of the pauper—at night crossing the river in a row-boat, deferred neither by ice nor fog; its roster carried the names of men recognized by the world as experts; up to January, 1895, its record was 1,601 consecutive deliveries without a death from sepsis; it had ever been kept free from political influence as regards appointments—when lo! at the instigation and dictation of a small number of professional men the Commissioners, without hearing the other side, acting as blind tools insensible to justice, remove this Board without trial, without cause! A new Board is substituted. Whatever the future promise of this Board—doubtless brilliant, for the budding ability is obvious—the dower of obstetric renown, or even experience, is not yet theirs!

The removed Board, we are informed, have no grievance as far as loss of official position is concerned, but naturally enough think it a poor reward for duty well done and unselfishly done, particularly since, if the instigators of this deal needed professors they were there in full maturity and therefore superior to the embryo.

Acts such as this tend to make pessimists of medical men—for the blow came from within the house, the fable of the cuckoo being again exemplified!

WILL THERE BE A CONGRESS IN MOSCOW NEXT YEAR?

The cable brings word that cholera still prevails to an alarming extent in many parts of Russia, as extensively, indeed, as it did during the heats of midsummer. During the two weeks ending October 26th, there were 1,490 cases of cholera, with 616 deaths, in the province of Volhynia, and 38 cases, with 12 deaths, in the province of Kieff. There have been persistent rumors of cholera in St. Petersburg, but they are as persistently denied by the authorities, so it is an even chance that there is no cholera there. The fact of the continued prevalence of the disease in Russia for several years past, and of the probability that it will still be there next summer, renders the holding of the proposed International Congress in Moscow during the coming August somewhat doubtful. It is true that it is some time from now to August, and also that it is a long distance from Kieff to Moscow, so that the presence of cholera in Kieff and the adjoining province now may seem to have a remote bearing upon the question of a meeting in Moscow in August. Nevertheless, if we are to credit the published reports, there has been more or less cholera in Moscow each summer during the past three years—much more than there was in Rome and its neighborhood when the assembling of the Congress in that city was postponed from October to April. We hope there will be no postponement from that cause, for, not to speak of the disappointment of many who are already beginning to plan for a visit to the ancient capital of the Tsars, it would be humiliating for an assemblage of physicians to run away a second time from a preventable disease.

But there is another event, the forerunning shadow of which seems to be deepening over Europe, which would more certainly postpone the Congress than would the most wide-spread epidemic. If the seemingly inevitable partition of Turkey should lead to a European war, as is possible, if not probable, there would be no chance for a peaceful assemblage of doctors in any of the large countries of Europe. For, even if the place of meeting could be changed to Madrid or some Swiss city, the difficulties of travel on the Continent would be too great to make the attempt to hold a Congress at all practicable.

However, war and disease do not always come when they are most expected, and we trust that the Congress will be held at the appointed time in the appointed city; and if it is, the readers of the Medical Record will, as usual, have the earliest, most complete, and best reports of the proceedings.

THE COMMISSIONER OF LUNACY AS AN EXPERT.

Attention has been called more than once to the reprehensible conduct of the medical member of the State Commission in going upon the witness-stand for pay. That he has no right to do so in this State cannot be disputed, for his testimony in court, when it is given by him as an "expert," may send the prisoner to a lunatic asylum or a prison. As the doctor and his associates are bound by law to recommend the discharge of improper subjects from the former, it can be seen how dangerous must be his position if he has given testimony in a particular case. If he has held on the witness-stand that a certain criminal is sane and the jury disagree with him, so that the prisoner is committed to Matteawan or elsewhere, the position of medical commissioner must be anything but pleasant, if he is consistent in his opinion, or possessed with an especially nice sense of honor. The law which gives the three members of the commission unbridled liberty

to make their own regulations and exercise a species of petty tyranny, if not something worse, in the way of exaction regarding dismissals and appointments of physicians, does not curtail their power in any way to do what they choose, so there is no existing law to prevent them accepting retainers. To those who are familiar with the Field and other cases, the necessity for some restriction must be apparent, and the section which legalizes their actions should be amended at Albany during the coming winter.

News of the Week.

Hospital Reformer to the Colleges.—I was a commissioner and ye took me in.

Better than Cannon-balls.—Some years ago Dr. Sahli, of Berne, advised the use of a cannon-ball, weighing about five pounds, for constipation. This cannon-ball was not to be taken internally, but rolled for some ten minutes every morning over the abdomen. Dr. Douglas Graham says, in the *Boston Medical and Surgical Journal*, that a much more effectual mechanical means, for the relief of constipation, is for the patients to percuss and pound their abdomens for a few minutes, morning and evening, with the inner border of their fists. It is well, he says, to do this in the direction of the ascending transverse and descending colon. Along with the percussion, friction and deep kneading may also be of use, but these are less effectual and more tiresome.

The Bulletin of the American Publishers' Association has come to us. It is a monthly publication, issued in the interests of medical publishers and advertisers.

The Texas Sanitarian has changed its name to *The Texas Medical News*.

Dentistry in Nebraska.—Nebraska has a new law regulating the practice of dentistry. It requires the registration of dentists, and their examination, unless they are graduates from a reputable dental college.

Tragedies of the Medical Profession.—The wife and daughter of a Vienna physician committed suicide, and a few days later the doctor shot himself. A French doctor, who had once held a good position, and who received the much-coveted ribbon of the Legion of Honor for his devoted service during a cholera epidemic, and his wife, recently committed suicide to save themselves from starvation.

Medical Portraits.—The *Journal of the American Medical Association* is energetically urging that the members of the Association send in their photographs. It thinks that in later years, when the post-historic Fiji Islander wanders over the ruins of the cities by the lakes and seas, he will find great pleasure and comfort in looking over the portraits of the medical men of bygone years. The American Medical Association numbers several thousand members, and our descendants will have to have abundant leisure if they expect to study appreciatively the faces of the deceased doctors of the nineteenth century. We suggest that it might be better for the *Journal* to collect only portraits of men who have arrived at a certain age limit, or who have reached some definite distinction. These are times when a man is very inconspicuous indeed if he does not get his picture printed, in the public press or the medical press, several times during his professional career. The swan is supposed to sing before he dies, but the doctor gets his photograph reproduced.

Dr. J. W. Carhart has written a novel, which is called "Norma Trist," a story of inversion of the sexes, based upon the Alice Mitchell episode.

Anarcotine.—This substance is one of the alkaloids of opium, and possesses no narcotic properties. Dr. William Roberts calls attention to it, and says that it ranks next in value, as an antiperiodic, to quinine. A dose ranges from 1 to 3 grains.

Took the Wrong Drug.—A death occurred recently in New Haven, Conn., caused by the carelessness of a drug clerk. The facts in the case were, according to the *Yale Medical Journal*, that the man asked for what was essentially a harmless medicine, of which he took, as he thought, a proper dose, and death resulted. The *Journal* very naturally suggests it is high time that legislative action be taken in regard to this matter, not only for the security of the physician who prescribes, but for the safety of the public.

A Thanksgiving Mistake. — An eighteen-year-old boy, living in Lilly, Pa., was shot, in mistake for a turkey, in the woods near his home. His friends waited fifty hours for him to die, and then sent for Dr. T. L. Armitage, who describes (*Medical Standard*) how he dressed the wound and cured the boy. We trust that the patient will yet get square with the turkey.

Legacy to a Surgeon.—It is stated that Sir Henry Thompson has received a legacy of $500,000 from a grateful patient. The heirs are contesting the will.

Queer Experiences by Doctors.—A doctor of Brenham, Tex., was recently horsewhipped by a young lady because he was so unpleasant.—A doctor living in Amsterdam, Mo., has been threatened with tar and feathers if he doesn't leave the town. This just at the beginning of the cold season.—Two doctors of Paris, Tex., had a fight, characterized by the local press as "bitter." One used a knife; but the other a fence rail. To the latter we should say, "*Ne sutor ultra crepidam.*"—A doctor in Petrona, Ind., was shot by one of his patients, because he, the doctor, would—or would not—(the account is vague) give the patient a hypodermic injection. The gun is sometimes mightier than the hypodermic.—The South African press advertises that there is a good opening for "a sober, steady, and handsome bachelor doctor" in one of the Transvaal towns. Send photo. This news is likely to cause a flutter among the younger members of the Academy of Medicine.

Iowa State Association of Railway Surgeons.—The annual meeting of the Iowa State Association of Railway Surgeons was convened at Des Moines, October 10th. A report on accidents to railway employees showed one employee killed for every six hundred and eight employed, and one injured for every seventy-nine. The election of officers resulted as follows: *President*, C. W. Coyt, of Missouri Valley; *Vice-President*, B. H.

Criley, of Dallas Center; *Secretary*, A. A. Deering, of Boone; *Treasurer*, D. S. Fairchild, of Clinton; *Judicial Committee*, J. M. Warren, of Sioux City; C. H. Philpott, of Ottumwa; V. B. Knott, of Sioux City.—*Medical Standard.*

The Late Dr. Edward R. Palmer.— A meeting in memory of the late Dr. Edward R. Palmer was held by the Louisville Surgical Society on October 26th. Letters of sympathy and regret were read, and eloquent tributes to the deceased were paid by Drs. Joseph M. Mathews, L. S. McMurtry, and T. L. McDermott.

Utah State Medical Society. — The first annual meeting of the Utah State Medical Society convened at Salt Lake, on October 3d, with about fifty members of the profession present. A number of interesting papers were presented. Several new members were admitted. The following resolution was adopted :

Resolved, That it be the sense of this Society that every member of it interest himself personally in securing the election of men for the next legislature who favor the maintenance of a high standard of medical excellence in the State of Utah, and that he continue to use his influence.

The election of officers resulted in the selection of : *President*, Walter R. Pike, of Provo ; *First Vice-President*, G. W. Perkins, of Ogden ; *Second Vice-President*, J. S. Richards, of Salt Lake ; *Treasurer*, C. M. Wilson, of Park City ; *Secretary*, J. N. Harrison, of Salt Lake ; *Board of Censors*, Drs. Bower, Gregor, Ewing, Beatty, and Jones. Salt Lake was chosen as the next place of meeting.—*Medical Standard.*

The Character of Dr. William MacLure.—There has never been portrayed in fiction a more beautiful character than Dr. William MacLure, the hero of some of the "Bonnie Brier Bush" stories by Ian Maclaren, or in real life Rev. John Watson. At a recent dinner given by the Liverpool Medical Institute, the novelist was asked to make a speech, and he paid a tribute to the medical profession which we hope and believe is deserved. We publish it because it should be read—as should the story of Dr. MacLure. "One is to answer a question that has been often and fairly asked—was there ever any doctor so self-forgetful and so utterly Christian as William MacLure ! To which I am proud to reply—on my conscience, not one man but many in Scotland and in the south country—I will dare to prophecy also across the sea. It has been one man's good fortune to know four country doctors, not one of whom was without his faults—Weelum was not perfect —but who each one might have sat for my hero. Three are now resting from their labors, and the fourth, if he ever should see these lines, would never have identified himself. Then I desire to thank my readers, and chiefly the medical profession, for the reception given to the doctor of Drumtochty. For many years I have desired to pay some tribute to a class whose service to the community is known to every country man, but after the tale had gone forth my heart failed. For it might have been despised for the little grace of letters in the style, and because of the outward roughness of the man. But neither his biographer nor his circumstances have been able to obscure MacLure, who has himself won all honest hearts and received afresh the recognition of his more distinguished brethren. From all parts of the English-speaking world letters have come in commendation of William MacLure, and many were from doctors who have received new courage. It is surely more honor than a new writer could ever have deserved, to receive the approbation of a profession whose charity puts us all to shame."

Medical Reform in Germany.—In future the State diploma, which alone confers the right to practise medicine and surgery, will not be granted to students until they have fulfilled ten half-year periods of study, instead of nine as at present. The degree of doctor in medicine will only be bestowed upon candidates who have successfully surmounted the State examination ; and after passing that test it will be necessary to attend the practice of a large hospital during twelve months.

A Medical Tariff.—The German Government has issued a regulation fixing the amount of fees for medical men. A practitioner in that happy land can claim 20 marks for an ordinary visit, and if it be necessary for him to make a profound investigation into the state of any organ he may increase his demand to 22 or 23 marks. In the event of a prolonged visit his time is valued at 3 marks for every half-hour commenced. Night visits may be charged for at double, or even triple, the foregoing rates : and a visit of urgency costs twice as much as an ordinary visit.

An Austrian Innovation.—A medical woman has been appointed house physician to a Vienna hospital—Officierstöchter Institute. This innovation has made much talk in Vienna medical circles.

Overdose of Medical Charities.—Dublin, too, has an overdose of medical charities. In a population of 356,240 there are 27 dispensaries which treat annually 100,216 persons, and 24 hospitals which treat 36,412. There are also 4,674 women annually who receive free attendance during confinement.

New York and the Mortality from Phthisis.—The State of New York has the largest absolute mortality from consumption, viz. : 14,894 deaths in the year 1890. Boston has the largest relative death-rate from this disease, viz. : 164.88 per 1,000 deaths. Out of the total 102,199 deaths from phthisis in the whole country, New York has about one-seventh. This is due chiefly to the denser population.

Clinical Department.

A CASE SHOWING THE ANTIDOTAL EFFECT OF ALCOHOL IN CARBOLIC-ACID POISONING.

By DONALD B. FRASER, M.B., M.R.C.S. Eng.,

STRATFORD, ONTARIO.

On May 4, 1893, about 1.30 P.M., Mrs. X——, while dining, quarrelled with her husband, rushed upstairs, and swallowed an ounce of liquid carbolic acid with suicidal intent. Mr. X—— followed his wife in less than fifteen minutes, to find her lying on the floor in a deep sleep, from which he could not rouse her. He noticed an empty bottle on the bureau, labelled carbolic acid, and felt its odor through the room.

Medical aid was immediately summoned, when two physicians promptly responded, made a hurried examination of the condition and surroundings of the patient, who was in a profound stupor, with pupils contracted to pin-points, injected atropine to antagonize the poison supposed to have been taken, and then used the stomach-pump.

Arriving on the scene half an hour later, I made a hasty investigation of the circumstances of the case, recognizing the characteristic odor of carbolic acid in the breath and evacuations from the stomach, and directed attention to the quiet, normal breathing.

After a brief consultation, although there was no staining or other evidence of the corrosive action of carbolic acid on the lips, tongue, or about the mouth, throat, etc., we diagnosed carbolic-acid poisoning, and decided to use the stomach-pump until the disappearance of the carbolic-acid odor in the water evacuated after washing the stomach. This odor was easily perceived three hours after the accident by a physician who then called, but it disappeared in the course of the next hour.

The physical condition of the patient four hours after swallowing the poison was as follows: The pulse was strong, regular, and not much accelerated; respirations undisturbed; temperature slightly under 98° F.; arms and legs occasionally jerking; and no sensations were elicited on pricking ends of fingers or toes.

Demulcents—such as olive-oil, glycerine, etc.—and lime-water and sulphuric acid were also administered with the stomach-pump about this time, and an effort was made to waken the patient with the faradic current, but without result. Mrs. X—— was now allowed to remain undisturbed until 9.30 P.M., when an attempt to restore her to consciousness succeeded. On first awakening she was dazed, rambled, and was unable to realize her position for a few minutes, but soon rallied and answered questions readily. When asked what she had used, without hesitation she replied carbolic acid in whiskey; and that she experienced but little pain or burning sensation, and declared she slept soundly, having pleasant dreams.

Vomiting soon set in, and continued almost without interruption twenty-four hours, when it suddenly ceased; and, with the exception of slight nausea and depression of spirits for a few days, she suffered little or no more inconvenience, and made a rapid and satisfactory convalescence, enjoying robust health ever since.

Mrs. X—— gave the following explanation for mixing the carbolic acid in whiskey. It appears she had previously seen a young woman take it in water, when the victim was severely burned about the mouth, throat, etc., and suffered excruciating pain. This incident dissuaded Mrs. X—— from taking a similar dose.

From subsequent events, however, Mrs. X—— appears to have had a fascination for carbolic acid as a poison, for she first mixed it in beer and cautiously drank a small quantity, when she suffered but little pain or burning sensation. Next she took it in whiskey, when she felt less pain or burning, and determined to try the last combination if she ever took poison.

The slight corrosive action and freedom from pain experienced on the present occasion proved the value of her experiments, and suggests a new and efficient plan of treatment in carbolic-acid poisoning. A mixture of equal parts of carbolic acid and alcohol may be poured over the back of the hand, leaving scarcely a trace of corrosive action if promptly washed off with alcohol. The white stain caused by the liquid carbolic acid can be removed by the immediate and continued application of alcohol. In the case of a young man who came to my office suffering from intense itching caused by a spider bite I applied liquid carbolic acid, which stained the skin white. This application was left on the affected part until it caused severe pain, when it was thoroughly removed with alcohol, followed by the application of a pad of absorbent cotton saturated with alcohol.

By this means the stain was removed and pain relieved until heat was felt in the pad, when both stain and pain reappeared. The heated pad was now discarded and replaced by one of a similar kind freshly prepared, when stain and pain vanished a second time, to return with heat in the pad. This phenomenon continued as long as heat developed in the pad, and ceased when it was no longer evolved. The only result of this treatment, besides relieving the itching, was an intense redness of the skin over the affected area, which disappeared in a few days, attended by desquamation of the cuticle.

This case also affords a striking illustration of the resemblance in the symptoms produced to carbolic-acid and opium poisoning. The diagnostic feature in the present case was the quiet and regular breathing.

Alcohol, apart from its power as an antidote, is required as a stimulant in the majority of cases of carbolic-acid poisoning, to combat the intense depression usually experienced; and it would therefore appear as if alcohol were a true antidote in carbolic-acid poisoning.

A CASE OF GUNSHOT WOUND OF THE ABDOMEN FOLLOWED BY PURULENT PERITONITIS, OPERATION, AND RECOVERY.

By JOHN RUHRÄH, M.D.,

RESIDENT PHYSICIAN, BALTIMORE CITY HOSPITAL.

C. S——, white, male, aged thirteen, family history negative. Previous history good. Brought into the City Hospital June 3, 1895, suffering from a gunshot wound of the abdomen.

The wound was inflicted accidentally, with a twenty-two calibre revolver, held only a few inches away from the abdomen.

The ball entered about the middle of a line drawn from the umbilicus to the anterior superior spinous process of the ilium. When seen by the visiting surgeon, Dr. John W. Chambers, it was seventeen hours after the reception of the injury. The abdomen was distended and tympanitic, very tender. Boy was suffering considerable pain and was very restless. He was placed on the operating-table immediately, and under chloroform anæsthesia and the usual aseptic precautions, the abdomen was opened. An incision six inches long was made in the median line and the viscera exposed. There was evidence of an inflammation of considerable intensity. The visceral layer of the peritoneum was reddened, and covered in many places with flaky lymph. In the cavity of the abdomen there was about five hundred cubic centimetres of thin reddish pus. The cæcum was perforated in two places by the bullet, and the intestinal contents had escaped from the gut. There was a gangrenous patch three

centimetres long by one and a half broad, evidently caused by the bullet. The bullet-wounds were closed with the Lembert suture, the gangrenous patch turned in, and the edges of the gut stitched together. The cavity of the abdomen was well irrigated with hot, normal salt solution. The bullet was not found. The bullet-wound was enlarged, and a gauze drain inserted. The surgical incision was closed with silkworm-gut sutures.

Patient rallied from the anæsthetic very nicely, and sustained but little shock from the operation. Nothing was given the patient the day of the operation except cracked ice. There was considerable nausea after the patient rallied, and when teaspoonful doses of iced milk and lime-water were given they were rejected.

The nausea continued on the following day, and the stomach rejected all food. Sulphate of magnesia, two drachms, with ac. sulphuric. dil., five drops, was given every hour. After the administration of this the vomiting ceased, and there was no return of the nausea or vomiting. This medication was continued during the day and an enema given in the evening, but the patient had no stool.

The following day the same doses were continued and another enema given, and there was a free passage from the bowels.

June 8th.—Dressings were removed and the drain partially withdrawn. There had not been very much discharge, though there was sufficient to stain the dressings.

June 10th.—Wound was redressed ; drainage entirely removed.

June 11th.—Retention of urine ; catheterized. From this date until the 19th he was catheterized three times a day.

June 13th.—Stitches removed.

June 19th.—Tenderness about the rectum ; some swelling and redness. This increased until on June 26th, when an abscess had formed. This was opened, and about two hundred c.c. of pus evacuated. This came from high up in the pelvic cavity. Patient experienced great relief and was able to pass his urine voluntarily. Abscess cavity packed with iodoform gauze. This healed rapidly, and patient made a rapid recovery.

November 5th.—Patient was seen yesterday. Perfectly healthy ; suffers no inconvenience.

A PECULIAR CASE OF TRISMUS.

By R. C. MATHENY, M.D.,

SPRINGFIELD, ILL.

Mrs. R——, aged thirty, the mother of four children, has for a number of years suffered from recurring attacks of intense headache. The attacks were of varying duration and severity, lasting from twelve to forty-eight hours, seldom accompanied by nausea. On August 13, 1895, she suffered an unusually severe attack, during the course of which she noticed that her jaws had become locked and she was unable to open them ; neither could they be forcibly separated. This condition lasted for seven weeks, the jaws remaining absolutely closed, and all nourishment was taken through the interstices between the teeth. This condition occurred during pregnancy, and continued until October 1, 1895, when she was delivered of a female child. The mother fell asleep shortly after the delivery, and when after a few hours she awoke, to her surprise the jaws readily opened. At first there was some stiffness of the muscles, but the condition gradually disappeared, and she has been entirely free from the lock-jaw ever since.

Dr. Duclaux, it is said, will be appointed to the head of the Pasteur Institute, in place of the late Dr. Pasteur.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PUBLIC HEALTH.

Stated Meeting, November 8, 1895.

Henry D. Chapin, M.D., Chairman.

The Relation of Bovine to Human Tuberculosis.—Several authors read papers on subdivisions of this subject.

Tuberculosis as Viewed by a Veterinarian.—Professor H. D. Gill, of the New York College of Veterinary Surgeons, read an introductory paper bearing this title. The danger of meat conveying disease had been recognized since Moses forbade the use of certain meats. But it was only of recent years that the subject had become of special interest to the public and veterinarians. Several causes had contributed to this, chiefly the discovery of the tubercle bacillus by Koch. The extent of the live-stock industry in the United States caused the subject to be of special interest here.

Veterinarians had discovered that herds of cattle chosen with the greatest care, and considered from appearances to be in absolutely perfect health, were in many instances riddled with tuberculosis. On taking the milk and flesh of these animals to the laboratory he found disease germs ready for transmission to man. Tuberculosis in man and cattle was caused by the same germ. In New York City there were over five thousand deaths annually from this disease in man. Some herds of cattle in the vicinity of this city showed tuberculosis in as high a percentage as sixty or even seventy per hundred. In many instances the diseased animal was to all outward appearances in perfect health. The disease could be transmitted from animal to animal, from animal to man, man to animal, or from without. The infection could come through the respiration, through the food, through objects licked by the animal. The infectious agent, when derived from without, had come from the discharges from the nose, mouth, bowels, milk, rarely from the uterus or vagina. The milk, especially, was liable to transmit tuberculosis when the udder was diseased, or possibly when it came from an animal with generalized tuberculosis, the udder being free. Of infected cattle, probably one-half had been infected by inhaling bacilli in the air, and a large proportion from taking bacilli in the food. Very rarely calves from the cows with advanced tuberculosis were born with the disease. Dr. Gill thought there was more danger of transmission from man to animals than from animals to man. The only safeguard for New York was to get milk from herds which had been tested. While recognizing that the tubercle bacillus was the chief agent, it should not be forgotten that a favorable soil added greatly to the risks. By inbreeding animals not predisposed to tuberculosis and already healthy, we might hope to get a stock capable of combating this dread disease.

The Work of Foreign Veterinarians in Tuberculosis.—Prof. Leonard Pearson, of the University of Pennsylvania, read a paper on this subject. Tuberculosis had been a live topic many years in Europe. Most European countries had a more or less perfect system of meat inspection which was carried out in great centres of population, and usually insured the consumer against harmful flesh. The method in Germany consisted in erecting municipal abattoirs, in which all slaughtering must be done and the flesh examined. The question of what must be done with the tuberculous carcass had excited much discussion.

The author gave the following summary, based on resolutions passed by representative bodies, or the views of distinguished veterinarians, in Europe. The system of compulsory meat inspection should be general. The flesh of tuberculous animals should be sub-

jected to special regulation. A part of this flesh must be destroyed, but some of it may safely be used for food. The milk from cows with tuberculous udders is extremely dangerous. Milk from tuberculous cows with healthy udders may be dangerous, and is always suspicious. Tuberculin is a reliable diagnostic agent. There need be no fear that tuberculin, properly used, will cause generalization of pre-existing disease. All herds should be tested with tuberculin, and tuberculous and healthy animals separated. Since tuberculosis is of importance in relation to public health as well as in relation to the live-stock industry, it is of interest to everyone that the disease should be restricted as far as possible. Hence, when it becomes necessary to condemn tuberculous animals and carcasses, the public should share the loss with the owner.

The Control of Tuberculosis in Massachusetts.—Professor F. H. Osgood, of Harvard University, read on this subject. In 1892 tuberculosis was first put on the list of contagious diseases in cattle in Massachusetts, and affected animals were ordered killed and their carcasses disposed of otherwise than in food, but no compensation should be received by the owner. At that time they relied simply upon physical examination. The first year there was not much opposition, but after the inspection service had been improved, and the wording changed from "cities and towns may appoint" to the words "shall appoint," opposition increased. The duties of these inspectors were: 1. To examine every herd in their respective districts by physical examination. They should make such examinations as often as the Board of Cattle Commissioners should direct. During the year 1893 two inspections were ordered. As a result, a large number of emaciated, tuberculous animals, detected by physical examination, were destroyed. The law also provided for the inspection of carcasses at the time of slaughter by these local inspectors, and those found tuberculous were to be disposed of by burial or rendering. At the expiration of the year they met with considerable opposition from farmers and butchers, who went to the legislature in 1894 and made a demand for compensation. The legislature then allowed one-half value. The commission's power was enlarged, permitting them to make such regulations as they deemed advisable for the eradication of tuberculosis from the herds. It also became their duty to at once provide some measures for the prevention of importation of tuberculous animals. For these animals they applied the tuberculin test, and although some mistakes were made, that year 18,692 cattle were excluded from the State. While some mistakes did occur, yet only one quarter of one per cent. of tests proved erroneous, the test being verified in every instance by post-mortem. Since that time, and under the new law which went into operation last June, they had tested in the neighborhood of six thousand animals, and the percentage of errors had been only one-tenth of one per cent. If the lesions were not found sufficiently developed to be evident to the eye of the owner, the case was put down as an error. The local inspectors quarantined animals suspected to have tuberculosis, and since June the percentage of these proven to have tuberculosis was fifty-two. The commission, during the last year, had only been able to advise systematic examination of all herds. The law had been changed, providing full compensation, and after that many owners of herds asked to have examination made. The average price paid for condemned animals under full compensation had been $37 as against $21 under half compensation. Now, too, they were allowed to use tuberculin as a test, which he said had been shown not to be deleterious. During the past twelve months the cattle commission had tested 24,000 cattle, and of this number 3,450 had been destroyed as tuberculous. In several large herds as high as ninety-five per cent. had been found diseased. One noted dairy, with 70 cattle, which had been regarded by him as healthy from physical examination, showed under tuberculin 30 tuberculous cows. There had been no cases since destroying these and disinfecting the premises with steam, bichloride solution, and whitewash. New cases were not likely to arise unless from introduction of infected cattle into the herd. New arrivals should always be examined before admitted. A number of drugs had been sent them for cure of tuberculosis, but as far as tested they had proven useless.

The Best Methods for the Eradication of Tuberculosis.—Professor James Law, of Cornell University, read on this subject (see p. 730).

The Transmission of Tubercle Bacilli and Tubercular Products in Milk.—Professor Harold C. Ernst, of Harvard Medical School, read on this subject. He divided it into two parts: 1. The possibility of the occurrence of the infectious element in milk from cows with tuberculous disease in the udder. 2. The more difficult question, whether this infectious element was ever present in milk from cows with no appreciable lesion of the udder.

Regarding the first question, the most recent work with which he was familiar was contained in the Report of the Royal Commission upon Tuberculosis, published this week. The gist of the report was that the commission had found tubercle bacilli in milk from cows whose udder was diseased, but not in the milk of cows whose udder was free from tuberculous disease. This latter part of the report did not coincide with Dr. Ernst's work, for while the tubercle bacilli found by him in the milk of cows with tuberculosis, but with a healthy udder, were few, yet careful search, with use of many cover-glasses and going over a large field, had revealed some. By feeding pigs with milk from cows with tuberculosis, but without apparent lesion of the udder, about one-third developed tuberculosis, but with other animals there was less success. So that, as a result of his own work, it would seem that milk from tuberculous cows with no apparent lesion of the udder, was possessed of the infectious element of tuberculosis in not a very small proportion of the cases, and he thought a positive result of this nature was worth more than a long series of negative results.

But the first point having been settled, the next one of interest to us as physicians was, how much this infectious element in milk threatened the human being. As bearing on this question, Dr. Ernst quoted several letters received by him in response to interrogatories sent out five years ago, and while the evidence was not absolutely positive, yet in a number of instances it was highly probable that tuberculosis had been contracted from taking milk from the tuberculous mother or animal. Dr. Ernst said that all milk from tuberculous cows, whether with or without disease of the udder, should be condemned for food.

Dr. George B. Fowler said it was extremely difficult for boards of health to execute laws in the line of their duty when they had not with them the sympathy of the public and the board of appropriation; but with the weight of authority of to-night in their favor, they felt that it would be possible to go ahead boldly against the use of food containing the infection of tuberculosis.

Dr. William H. Thomson said that he had been taught early to look upon tuberculosis as an hereditary disease. One of the greatest advances was made when it was shown to be infectious. For some time he had accepted the general view, that the infection usually took place through dried sputum, etc., floating in the air and being inhaled. More recently experiments had been made in the London hospitals for consumption, going to prove that the dust taken from consumptive wards was very slightly infectious to animals, and he felt convinced that food containing tubercle bacilli and becoming lodged in the fauces and pharynx was the chief source of infection. The tonsils and

mucous membrane of the fauces were often sore or abraded, food became lodged there, and fatty foods especially were difficult of removal. Lesions in the intestinal tract were also a source of infection. Dr. Thomson said one practical lesson was to keep the mouth clean and disinfected. Asking pardon for a personal allusion, he said that formerly he had been subject to sore throat, but during the past four years he had not had an attack, and he attributed it to washing the mouth after every meal with a mixture of eucalyptus, benzoic acid, and peppermint water.

Dr. Joseph D. Bryant hoped that through the Board of Health, so ably represented by Dr. Fowler, the consumers of milk in New York would soon have the positive assurance that their milk came from cows which were free from tuberculosis. He thought this could be accomplished without any great difficulty, provided the Board of Health applied the screws in such a way as to touch the pockets of those who wished to sell milk in this city.

SECTION ON GENERAL SURGERY.

Stated Meeting, November 11, 1895.

B. Farquhar Curtis, M.D., Chairman.

Aluminium Corset.—Dr. A. M. Phelps showed an aluminium corset, and also a Hessing corset for use in cases of crooked spine, especially lateral curvature without disease of the vertebræ. The Hessing corset was much used in Germany, was made of steel bands riveted together and covered by cloth, and differed entirely from putting on a brace and turning up a screw in order to keep the patient in corrected position. It was fairly light, and useful in mild cases in women. There were two or three varieties of it. Plaster-of-Paris was rather thick, heavy, and hardly porous enough, yet it was the best jacket we had for Pott's disease of the spine, and it was also serviceable in lateral curvature; but in the latter class of cases aluminium was, so far as he had tested it, freer from objections than the others, but it was somewhat expensive, costing fifty dollars or more. A plaster corset was first made, the patient being suspended; this was filled with plaster, and over the latter the aluminium corset was hammered into shape. It had numerous perforations smaller than a dime.

Answering Dr. Gallant, he said that if the patient changed much in shape and size, it would be necessary to make a new corset. The weight of the instrument, aluminium, was about two pounds.

Epithelioma of the Roof of the Mouth.—Dr. C. N. Dowd presented a man, near fifty years of age, on whom he had operated, removing the teeth, alveolar processes, and considerable of the roof of the mouth on the upper right jaw for extensive epithelioma of these parts. The operation was performed fifteen months ago, and the patient had since been in excellent health. The operation left a slight perforation into the nostril, which the patient stuffed with cotton. It caused no annoyance.

Cure of Flat-foot.—Dr. Royal Whitman presented a young man on whom, a number of months before, he had done forcible osteotomy on the right foot for a marked degree of flat-foot. The left foot showed the same deformity, less marked and uncorrected. In this instance, and in others when necessary, he performed tenotomy on the tendo-Achilles, in addition to forcing the foot into position. Plaster-of-Paris bandage was put on for a while, and the patient was still wearing what was called the Whitman splint, consisting of a broad piece of metal fitting the sole and sides of the corrected foot, worn in the shoe. Patients submitting to this treatment and carrying out instructions subsequently, attained a physiological cure of their flat or weak foot, and could be assured that there would be no return of it. Four weeks was frequently long enough in the hospital, and even during most of this time they could walk about. This patient now stood about sixteen hours a day at his work, without pain.

Dr. Willy Meyer thought surgeons had usually done cutting operations in hospitals for flat-foot because other treatment required too long a time. If by the method mentioned by Dr. Whitman the patient could go out in six weeks, the method would become a practical one in general hospitals.

Dr. A. M. Phelps said that spasm of the muscles prevented many of his patients from returning to work so soon—within a month.

Dr. Whitman said he would not advise heavy lifting so soon, but it was better for the patient to walk about, since it tended to keep the foot in correct position.

Casper's Ureter-cystoscope.—Dr. Willy Meyer showed this instrument, and mentioned two cases in which he had, with its aid, successfully catheterized the ureters, one patient being a man, the other a woman. The instrument differed from Nitzer's cystoscope, being more especially adapted to illuminating the site of the urethral orifices and introduction into them of a small catheter connected with the instrument, and directed at an angle of forty-five degrees, corresponding to that of entrance of the ureters into the bladder walls. Nitzer had accused Casper of copying his instrument, but Casper claimed originality, and Dr. Meyer thought he certainly deserved credit for presenting a very ingenious and practical instrument to the profession. By its aid Casper had succeeded in catheterizing the ureter thirty times, in twenty-two patients, with only one failure. Dr. Meyer had used it in three cases, catheterizing the ureters six times in all. To catheterize the other ureter in the male it was necessary to withdraw and reintroduce the ureter-cystoscope, in the female it was not. In the female he would prefer Kelly's method of urethral work, for his instruments, though more numerous, could be boiled, while the ureter-cystoscope could not be disinfected in this manner.

Dr. Frederic E. Sondern said that six cubic centimetres of urine was sufficient for analysis if one used economy, which was necessary in connection with catheterization of the ureters. The ordinary urinometer, or any modification of it, could not be employed for taking the specific gravity of this small amount, but for this purpose he used Westphal's specific-gravity balance. The whole amount was then put into a tube and a centrifugal apparatus was employed to precipitate sediment for examination for tubercle bacilli, etc. The urine was then filtered through filter-paper, and about five cubic centimetres remained. The reaction was taken. One cubic centimetre was sufficient to determine the percentage of urea, 1 for sugar, 1 for albumin, the remaining 2 for chlorides or other chemical tests.

Dr. Bangs and Dr. F. Tilden Brown thought it likely the mouth of the ureter could be found more easily with the ureter-cystoscope presented by Dr. Meyer than with others which they had tried.

Disadvantages of Non-absorbable Sutures in Hernia Operations.—Dr. W. B. Coley reported a number of cases of abscess, sinus, and recurrence of hernia after "radical" operations in which non-absorbable sutures had been used, the cases having been operated upon by various surgeons, and subsequently appearing at the Hospital for the Ruptured and Crippled. Four cases had been reported by him on a former occasion. To this number he added thirteen others.

In the first case silk had been used; sinus remained; sutures came out at different times; relapse after four months. Case 2: Silkworm gut; sinuses followed; two months in healing; several sutures came out; relapse in a few months. Case 3: Modified Macewen operation; silver-wire suture; patient in hospital several weeks; two months afterward sinus; relapse a few

months later. Case 4: Operation in April, 1888; under treatment for sinus until October, 1888; hernia a few months later. Case 5: Double hernia; operations at separate periods; silk; recurrence on both sides. Case 6: Buried silk; sinus followed; four sutures extruded; sinus scraped out; two more sutures were removed; second operation for recurrence, silkworm gut being used; same year a second relapse occurred. The other seven cases were more or less similar, sinuses following non-absorbable suture; recurrence of hernia.

Dr. Coley said his personal experience with non-absorbable suture in hernia was limited to three cases, silk being used; one case refused to heal until the sutures were cast off, and relapse occurred after three months. The second patient was well three years after the operation.

Out of two hundred and fifty cases of hernia operations, in which he had used tendon suture, there had not been trouble with the suture in a single instance.

Non-absorbable suture acting as a foreign body, must be held responsible for the bad result in the other cases. The suppuration and weakening of the walls caused relapse, and in Dr. Coley's opinion non absorbable suture material should be entirely abandoned, unless for special conditions.

The Chairman, Dr. Curtis, thought Dr. Coley may have exaggerated the disadvantages of non-absorbable suture, for surgeons who performed a good many operations for hernia seldom saw the suture suppurate its way out. Dr. Coley was unusually well situated to see many of these cases, as far as they occurred in the hands of various surgeons, yet it would be observed that he had really seen comparatively few.

Dr. Crary had seen no trouble arise from cases in which silver wire had been used.

Dr. Cole thought a strong point in Dr. Coley's paper was the fact that, in a few cases in which he had used non-absorbable suture material suppuration had occurred, while in two hundred and fifty cases in which absorbable suture was used, no trouble had arisen. Dr. Cole said they had given up non-absorbable suture in tenotomy, because of its acting as a foreign body and causing trouble, even when primary union had been obtained.

Dr. Dowd remarked that, theoretically, non-absorbable suture ought to be all right, but we were dealing with a practical question. In practice there was a good percentage of cases in which trouble did arise. Therefore he thought we should use absorbable suture.

Dr. Coley referred again to some of the cases reported in his paper, to show that it was not a question alone of primary union, for even when this had been obtained the non-absorbable suture had at times caused trouble subsequently as a foreign body, working its way out and establishing a sinus, thus weakening the walls and leading to secondary hernia.

Medical Fees in Russia.—The Russian Government is nothing if it is not parental. How wisely the "Czar of all the Russias" looks after his "children" has been aptly illustrated by his government taking in hand the question of medical fees. Medical men in Russia have now to charge according to a fixed scale, of which the following are the chief details. The towns are divided into three classes: those having more than fifty thousand inhabitants, those having between that number and five thousand, and those having fewer than five thousand. Patients are also divided into three classes, the first including capitalists, landowners, manufacturers, bankers, merchants, and superior government officials, the third the rest of the population. The fees for the first class have been fixed at five roubles; for the second, three roubles; and for the third, thirty kopecks.—*The Sanitarian.*

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 5, 1895.

Edward D. Fisher, M.D., President.

Traumatic Neurasthenia.—Dr. C. E. Nammack presented a policeman who, on October 12, 1892, had attempted to stop three runaway horses attached to a steam fire-engine in the Centennial Parade. He was successful in this, but although not physically injured he received a profound psychical shock. One week later it became necessary for him to seek medical advice for the relief of pains in his chest. On the advice of Dr. C. L. Dana, he went abroad, and remained there from June, 1894, to October, 1895. He had been perfectly well up to the time of this accident, and his family and personal history were excellent. He remained on police duty for some time, but found himself unable to attend to his work, even though his promotion to the rank of roundsman had rendered this less monotonous than formerly. The first symptoms noticed were diminished power of persistent application and nervous irritability. Mental exaltation then became marked, and insomnia became most distressing. Hyperæsthesia and paræsthesia were not noticed. The principal subjective symptoms were pain over the heart and dyspnœa on exertion, profuse sweating, and insomnia. Examination recently showed the pain and temperature senses normal, tactile sensibility impaired, and hyperæsthesia wanting. Both visual fields showed the shifting type of contraction. Color perception was fairly good. There was no motor weakness of the eyes, and no abnormal pupillary reaction. Smell and taste were not affected; station and gait were good; there was some tremor of the hand. The knee-jerks were slightly exaggerated. The heart action was weak and greatly accelerated by walking; there was no enlargement of the heart or valvular disease. Slight irritation of the skin led to persistent redness. His weight had fallen from two hundred and twenty to one hundred and seventy-five pounds. Micturition was not vigorously performed. The urine was normal. The sexual desire was weak, although the power was good. The diagnosis in this case, the speaker said, lay between traumatic neurasthenia, traumatic hysteria, and simulation. The last was excluded by the absence of motive, of striking symptoms, and of efforts to exaggerate slight symptoms. Hysteria was excluded by the absence of anæsthesia, contractures, spasms, etc., and of paroxysmal phenomena. The patient had had the benefit of skilful treatment, and improvement had been slow but steady. Apparently hydrotherapy had benefited the patient the most. The case was interesting as being free from the usual complications arising from prospective lawsuits.

Dr. C. L. Dana said that when he saw this case he made the diagnosis of traumatic neurasthenia. The case was an interesting and typical one, and was chiefly of importance on account of the absence of the complications referred to.

Dr. Nammack, in closing, said that formerly considerable stress had been laid upon the condition of the visual fields as a differential point between traumatic neurasthenia and hysteria, but that now this had been pretty much abandoned.

A Case for Diagnosis.—Dr. Pearce Bailey presented a man, sixty years of age, a carpenter by occupation. There was no hereditary taint except that the father had had tic convulsif. The patient had been healthy up to forty years of age, at which time the symptoms referable to the nervous system first appeared. The first symptoms followed a severe shock from falling into water, and were, slight headache, dizziness, impairment of memory, and nausea. Twelve years ago his left leg became numb and paralyzed, and this lasted for two weeks, when it temporarily disappeared. Six years ago the right leg became similarly affected, and now one leg was as bad as the other. Two years ago

his hands became so uncertain in their movements that he could no longer use his hammer. At this time he noticed that when he accidentally struck his fingers with the hammer it did not cause him pain. He was also obliged to use a cane when walking. At the present time there is no active pain, no trophic disturbance, and no bladder or rectal affection. There is slight roughening of the first sound of the heart. The left palpebral fissure appears to be smaller than the right, and there is slight inequality of the pupils. There is no paralysis of the ocular muscles; the optic disks are rather pale. The disorders of motion consist in a spastic and ataxic gait. The Romberg symptom is well marked. Fibrillary twitchings are not observed except when the arms are held out from the body for some time. The only sensory symptom of note is an almost absolute insensibility to pain all over the body. The temperature sense is retained.

The speaker said that he had been unable to classify this case.

Dr. B. Sachs said he saw no reason why this case should not be considered one of combined sclerosis. The ataxia of both upper and lower extremities, the increase of the deep reflexes, and the marked sensory disturbances all pointed in that direction.

Dr. M. Allen Starr said he also thought it was probably a case of combined sclerosis, both posterior and lateral columns being affected. It was not usual to have a loss of the pain sense in such cases, but he thought instances of this kind had been reported.

The President said that in the absence of the pain sense all over the body, including the head, would remove the case from the ordinary class of combined sclerosis.

Dr. Joseph Collins said that while he believed the case was one of combined sclerosis yet it was quite possible that the entire symptom complex in this case was dependent upon a functional condition. It must at least be conceded that the universal analgesia in this case was functional, as no possible anatomical lesion can be postulated to explain it.

Dr. Frederick Peterson said that it seemed to him that all the symptoms were those of a typical case of combined sclerosis and ataxic paraplegia. General analgesia was, of course, extraordinary, and could not be explained by combined sclerosis, but must be accounted for in some other way.

Dr. Sachs said that admitting that the general analgesia was not common in combined sclerosis, still there might be functional symptoms superimposed on an organic condition. The walk, the increased reflexes, and the moderate amount of ataxia all seemed to point inevitably to a combined sclerosis.

Dr. Dana said there could hardly be any doubt that the general analgesia was a functional condition. No such analgesia could be produced by any known organic lesion. It seemed to him to be a hysterical condition superimposed upon the sclerosis.

The President said that the loss of the pain sense could be explained on its functional character. The ataxia in the hand seemed to be not the ordinary ataxia, but that form seen frequently in hysteria. He had for a long time observed a case of hysterical paraplegia, in which there had been a beautiful ataxia very similar to that shown in the case before the Society.

Dr. Bailey expressed the opinion that in a purely functional case there would be some affection of the sense of touch as well. The left palpebral fissure was certainly smaller than the right, and the left pupil was also considerably smaller than its fellow; hence, there was evidently some organic lesion higher up than an ordinary cord lesion. He had never seen a functional sensory involvement of just that character.

Lumbar Puncture of the Subarachnoid Space.—Dr. George W. Jacoby read a paper with this title. He said that his experience with this comparatively new method dated back only six months, but it had comprised 35 cases, with as many as six punctures in one case. Among the cases treated were 17 of tubercular meningitis, 1 of purulent meningitis, 1 of abscess, and 3 of acute mania. The operation was done between the third and fourth lumbar vertebræ, in the interlaminar space, using preferably the needles measuring 8 ctm. in length and 1 mm. in diameter, with rather broad bases, so as to dispense with the syringe, which is chiefly used as a handle. The depth of the puncture and the amount of force to be used were matters of experience. If the anatomical relations were first carefully studied upon the cadaver, there was no more danger from lumbar puncture than from opening a deep-lying abdominal abscess. In a case of cerebrospinal meningitis treated by Von Ziemssen, the removal of sixty or seventy cubic centimetres at various intervals gave relief from headache for several days after the puncture. In the experience of the reader of the paper, beyond the relief of headache in cases of brain tumor, no change had been noticed to follow the puncture, except in cases of meningitis. In these general improvement was noted. That the brain pressure was actually reduced could be shown in infants before the closure of the fontanelles. In cases of brain tumor immediately following the operation, the headache became almost unbearable for about fifteen minutes; then it gradually subsided, and there was a comparative freedom from pain for several days. He had also noticed an increase in the pulse-rate after puncture, lasting twenty-four hours. In one case, a child, six years of age, suffering from headache, unable to stand or walk, and having bilateral choked disk, there was marked relief after removal of the fluid. It did not follow, of course, that there was any relation of cause and effect between the puncture and the improvement. In another case, one of meningitis, occurring in a child, four years of age, who was in a semi-comatose condition at the time of the puncture, 60 c.c. of fluid were withdrawn. The next day the temperature was almost down to the normal, and the child completely recovered in a week. It is probable that this was not a true case of meningitis. Practically he had seen little or no benefit from this treatment in cases of tubercular meningitis. In these cases death was due to toxins rather than to brain pressure; hence there was an excellent reason for the removal of the fluid. Reports of cured cases of tubercular meningitis had always been doubted, but one well-observed case was known to have recovered. It had been asserted that inasmuch as ordinarily only twenty cubic centimetres were removed, it was probable that only the spinal fluid was removed, and that the communication between the spinal sac and the brain was obstructed. Puncture in cases of hydrocephalus, and the effect on the fontanelle, show that the fluid can be made to pass from the spinal sac into the brain. The reader of the paper then detailed experiments that he had made upon a rabbit, using considerable pressure and a colored fluid. They showed that the communication between the spinal and subarachnoid cavity was not as free as we had been led to assume. Further experimentation, however, served to confirm what had already been known anatomically and clinically—that a free communication existed. From this consideration it was evident that we were warranted in utilizing lumbar puncture.

The value of the lumbar puncture as a diagnostic aid could not be denied. Attention must be paid to the pressure on the fluid, the presence and amount of albumin and sugar, and the presence or absence of blood or pus, and of micro-organisms, such as bacilli. Normally the fluid comes out drop by drop, but if it is under much pressure it may gush out. The scientific gravity is not of much value, and cannot ordinarily be determined on account of the small quantity of fluid removed. The presence or absence of albumin and sugar is likely in the future to furnish important cor-

roborative information. In brain tumors and brain abscess the albumin is only slightly increased. In the differential diagnosis between meningitis and brain tumor the presence of more than one per mille of albumin in the fluid would be additional testimony in favor of an inflammatory condition. It should be remembered that after repeated punctures the amount of albumin increases very considerably. Examination for pus, blood, and micro-organisms is more important. It is hardly to be expected that tubercle bacilli would be found in the cerebro-spinal fluid, for in sero-fibrinous exudation of pleurisy it was well known that tubercle bacilli were not found. However, in the majority of lumbar punctures in cases of tubercular meningitis, tubercle bacilli have been found in the cerebro-spinal fluid. The fluid should be allowed to stand for twelve hours, and then the coagulum teased out, dried, and prepared for examination in the usual way. As a rule there are but few bacilli present. As the clinical diagnosis is difficult except in well-developed cases, it is highly important to have in this examination of the cerebro-spinal fluid an additional aid to the diagnosis. In tubercular meningitis the fluid is clear and contains tubercle bacilli; in purulent meningitis the fluid is creamy, and contains streptococci or other micro-organisms; in brain abscess the fluid is clear and contains no micro-organisms.

Blood found in the cerebro-spinal fluid, and not due to the accidental puncture of a meningeal vessel, may be found in spinal, meningeal, and in inter-ventricular hemorrhage. The diagnosis of secondary ventricular hemorrhage has been exceedingly unsatisfactory. Blood has been found in the spinal sac in cases of ventricular hemorrhage. We are not justified in all cases in diagnosticating this condition from the presence of a small quantity of blood in the cerebro-spinal fluid, as such contamination is often produced by the puncture. Again, in subdural hemorrhage the passage of blood from the cerebral to the spinal membranes might take place. Two of the author's cases emphasized the importance of lumbar puncture when there was hemorrhage into the spinal canal. The removal of the blood in these cases reduced the local pressure, and so at least placed the patient in a condition more favorable to recovery. In any spinal injury, whatever its nature, lumbar puncture must increase the patient's chances of recovery. In three cases of acute mania lumbar puncture has been done. The fluid was found to be sterile.

In conclusion, the speaker said that by means of lumbar puncture cerebro-spinal fluid might be easily removed from the subarachnoid space, spinal cord, and cavities of the brain. It is only of direct therapeutic value as a palliative in reducing excessive pressure. It is very important in the diagnosis of various inflammatory affections of the different membranes, and in the recognition of hemorrhage into the ventricles, as into the spinal canal.

Dr. W. M Leszynsky asked if it were necessary to use the syringe.

Dr. C. L. Dana said that the Society should express its gratitude to the author for calling attention to this subject, which had been rather neglected in this country. He had himself tried lumbar puncture on a number of cases of alcoholic meningitis, or so-called cerebral œdema, but with a purely negative result. He had also found that in this class of cases lumbar puncture was not very easily carried out on account of the restlessness of the patient, and the tendency to large deposits of adipose tissue in such subjects. The operation was also quite painful. He had seen the fluid gush out in a steady stream in some cases.

Dr. Starr asked if there were any difficulty in stopping the flow of fluid. In operations on the spinal cord he had encountered great difficulty in closing the wound and stopping the flow of cerebro-spinal fluid. In two recent operative cases the flow had obstinately continued, and had been associated with an exceedingly severe headache. In both of these cases the gush of fluid had been very considerable.

The President said that he had not always observed such a great quantity of intra-spinal fluid as had been alluded to by the last speaker. As he recalled autopsies on cases of ventricular hemorrhage it did not seem to him that blood in the spinal canal had been very commonly found.

Dr. Leszynsky said that since a paper had been read before the American Neurological Society about one year ago, very little had been said in this country regarding the dangers of this method, and he would like to ask the reader of the paper for information on this point.

Dr. Jacoby, in closing the discussion, said that the syringe should not be used at all except in those cases in which a very small quantity of fluid was to be withdrawn for purely diagnostic purposes. If the needle were simply introduced, and the fluid allowed to drop away, the pressure in the spinal canal would not be dangerously reduced. The operation is exceedingly simple, but it is not so in the adults. In the latter he preferred to operate under an anæsthetic. Children should be held on the lap with the back arched so as to facilitate the introduction of the needle. A little iodoform collodion over the puncture was all that was necessary to stop the flow of cerebro-spinal fluid. There were no dangers connected with the operation except such incidental ones as breaking of the needle against the vertebræ. If an anæsthetic were not used in an adult, and the patient suddenly straightened out, the needle would snap off.

Deformities of the Hard Palate in Degenerates, with Exhibition of Casts.—Dr. Frederick Peterson offered a paper on this subject. (Only a portion of it was read.) He said that his observations in this direction extended over a period of eleven years, and comprised examinations on upward of one thousand persons, one hundred criminals, six hundred idiots, and five hundred neuropaths of other kinds. On account of the frequent mention of the Gothic palate he had adopted an architectural nomenclature in the following classification which he offered:

Pathological Palates.—(*a*) palate with Gothic arch; (*b*) palate with horseshoe arch; (*c*) the dome-shaped palate; (*d*) the flat-roofed palate; (*e*) the hip-roofed palate; (*f*) the asymmetrical palate; and (*g*) the torus palatinus. In illustration of these varieties of abnormal palate, seventeen casts of the hard palate were then presented, mostly selected from among the four hundred and fifty idiots on Randall's Island. The seven varieties are to be looked upon merely as types. Each type presents variations and combinations with other forms. Among the flat-roofed palates would be included all such as are nearly horizontal in outline, as well as those with inclined roof sides but flattened tables. In the hip-roofed palate there is a marked pitch of the palate roof in front and behind. It is usual to find asymmetry of the face and skull in cases with an asymmetrical palate. The torus palatinus (Latin, *torus*, swelling) was first mentioned by Chassaignac as medio-palatine exostosis. It is a projecting ridge of swelling along the palatine suture, sometimes in its whole length. It is always congenital, and varies considerably in both shape and size. But two or three cleft palates were found among the many idiots examined, and as a number of such palates had been found in subjects who were far from being degenerates it was not thought proper to include the cleft palate among the well marked stigmata of degeneration.

The Committee on the Terminology of the Nerve Cell reported as follows: The term *neuron*, applied by Waldeyer in 1891 to the nerve-cell, with all its ramifications and processes, has been adopted by current writers on neurology, and by such eminent neuro-anatomists as Cajal, Van Gehuchten, Lonhossek, Edinger,

Dejerine, and others, therefore we advise that it continue to be used and understood in Waldeyer's sense, as indicating the nerve-unit. Assuming for the purposes of terminology that this cell-unit be divided into (*a*) cell-body; (*b*) protoplasmic processes, including all processes except (*c*); and (*c*) axis-cylinder process with collaterals and end brushes. The term *neuron* includes *a*, *b*, and *c*.

As a matter of convenience to the members of the Society, and as a justification, if any were needed, of the utility of the committee's work, the following list of synonyms and proposed substitutes for the word *neuron* is given:

To indicate the *cell-unit* or *neuron*:

Neuro-dendron, proposed by Kölliker.
Neura, proposed by Rauber.
Neurocyte, proposed by P. A. Fish.
Neure, proposed by Frank Baker.
The *cell*, the *neuron*, and the *dendrons*, proposed by Schaeffer.

The axis-cylinder process has received the following names:

Neuron, proposed by Schaeffer.
Neuraxon, proposed by Kölliker.
Neurit, proposed by Rauber.
Neurite, proposed by Fish.

The other (protoplasmic, etc.) processes have received the names:

Dendrons, or dendrites, proposed by Schaeffer.
Dendrites, proposed by His and Fish.
Cellulipetal processes, proposed by Cajal and Van Gehuchten.

The committee would recommend that the term axis-cylinder process be still used in its long-accepted sense, to indicate part *c* of the neuron. Without making the recommendation it expresses the opinion that some word like neurite will probably come into use as a synonym for this axis-cylinder process. The committee also recommend that the old term, "protoplasmic processes," continue to have its ordinary and legitimate use, but express the view that the word dendrite will be a useful synonym.

The committee beg to express obligations to Dr. Frank Baker, of Washington; to Professor Burt G. Wilder, and to Dr. Pierre A. Fish, of Utica. Signed: Drs. Charles L. Dana, Edward D. Fisher, William H. Thomson, B. Sachs, Joseph Collins, and J. Arthur Booth.

The Samuel D. Gross Prize.—The second quinquennial prize of one thousand dollars, under the will of the late Samuel D. Gross, M.D., will be awarded January 1, 1900. The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens. It is expressly stipulated that the successful competitor, who receives the prize, shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut St., Philadelphia, before January 1, 1900. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

Progress of Medical Science.

A Simple Expedient for the Treatment of Nocturnal Enuresis.—Dr. Stumpf has given an account of a simple and apparently rational expedient which he has successfully adopted in the treatment of nocturnal enuresis, especially in older children. He was led to try it on the basis of the fact that the passage of even a few drops of urine through the sphincter vesicæ excites the action of the detrusor to such an extent that the call to urinate becomes almost imperative. It is well known how difficult it is to restrain the act of urination after even a small amount of urine has passed the sphincter vesicæ and entered the urethra. His theory is that during sleep the sphincter of the bladder is apt to become relaxed, so that as the child lies horizontally in bed, a little urine passes the sphincter and enters the deep urethra. The irritation of this urine causes at once strong reflex action of the detrusor, and the bladder is at once emptied in a full, strong stream. It is a well-known fact that in nocturnal enuresis in children the urine does not leak away gradually, but the bladder is emptied at once, a point which is in support of this theory. In order to prevent the passage of the urine into the urethra when the sphincter becomes relaxed during sleep, a simple expedient is adopted, namely, the elevation of the pelvis, so that an accumulation of urine of ordinary amount in the bladder will gravitate back and distend the fundus, and not press against and tend to pass the sphincter. The elevation is secured by allowing the child only a single, small, flat pillow under the head, and placing one or two ordinary pillows under the thighs so that they lie at an angle of 130° to 150° with the horizontal spine. This simple expedient was entirely successful in curing two inveterate cases, one of a boy, aged nine, and one of a girl, aged fifteen. It was then tried in twelve cases and was uniformly successful. It was usually necessary to continue the treatment for three weeks, after which time the children were able to return to their former sleeping position without relapsing. The writer has found it unnecessary to have recourse to the time-honored measures of limiting the amount of liquids, frequent waking up during the night, etc. The chief difficulty about the treatment is to see that the children maintain the position throughout the night. Small children particularly are apt to wiggle and toss about and have to be watched, put back in position, etc. The method is therefore especially adapted to older children, in whom the position can be more easily maintained. This method is certainly so simple and apparently so reasonable as to merit extended trial, especially as the time-honored methods of treating this pernicious habit are in so many cases unsuccessful. It will be rather interesting if the elevation of the pelvis, which Trendelenburg introduced into abdominal surgery, and which has so extended and facilitated work in that field, should also prove of service in preventing children from wetting the bed.—*The Boston Medical and Surgical Journal.*

The Treatment of Acute Rheumatic Endocarditis.—In the *Liverpool Medico-Chirurgical Journal*, July, 1895, Dr. Richard Caton gives the results of a definite inquiry pursued for thirteen years concerning acute rheumatic endocarditis and its treatment. Upward of three hundred cases of acute and subacute rheumatism came under close observation in the hospital ward, a certain proportion, perhaps one in three or four, developing cardiac difficulty. The usual history is that the patient leaves the hospital cured of rheumatism, but with a maimed heart that causes much suffering and shortens life. The great questions are: How can endocarditis be prevented during acute rheumatism? And what treatment during its incipient stage, when it

occurs, best favors recovery? To answer these, the recorded experience of Europe and America was carefully consulted. The opinion of modern writers proved highly conflicting, Niemeyer and Osler holding all measures preventative or curative as practically useless; while Sibson and others pointed out the value of absolute and protracted rest, both as prophylactic and as an aid in the cure of incipient endocarditis.

Treating the rheumatic trouble by salicylates and doing practically nothing for the heart inflammation gave such poor results that in 1885 a definite plan of treatment was adopted in all cases, with a view of preventing endocarditis if possible, and mitigating its severity when present. As the outcome of the new measures, twenty-nine out of thirty-nine cases left the hospital well and with normal heart-sounds. Ten were less fortunate and were discharged with a bruit present. These results are so good that Dr. Caton fears his readers may fail to accept it altogether, thinking that perhaps mistake or error has crept in somehow. Yet such is not the case, to the best of his knowledge and belief. The method in brief is this: Prolonged, absolute rest in bed, the body clothed in flannel garments only, a milk diet, gentle cholagogues, salicylates in such measures as the disease seems to demand, and small blisters followed by poultices in any joint where pain fails to yield. When an abnormal heart-sound is heard, even simple "woolliness" of sound, or what the French call *assourdissement*, ten grains of potassium or sodium iodide are given three times a day in addition to the salicylates, and a blister about the size of a florin is placed over the apex of the heart. As soon as the irritation of this blister is subsiding, a second is applied close to it, then a third, and so on, the patient being kept perfectly quiet and strictly forbidden all exertion and exposure. The blisters occasion little or no discomfort. The heart is examined daily. In a week or ten days there is a gradual subsidence of the murmur: day by day it is less distinct and then is entirely absent. Sometimes several weeks will elapse before this desirable change is established. Prolonged rest is an important factor in bringing it about. The thirty-nine cases thus treated were, on the average, forty-one days in the hospital, and confined to bed thirty-five or thirty-six days.

How does the blister act? Not, surely, on the old-fashioned theory of so called counter-irritation. Organs situated some distance beneath a small blister can be affected solely through the nervous system, and acted upon through reflex centres. If a cutaneous nerve is stimulated, nerve-cells in the spinal and sympathetic centres are influenced and the impression is reflected to the visceral branches. It may be said that this is a mere theory. But it is a theory which explains many things. It explains the fact that a slight chilling of the skin of the thorax may cause pneumonia and bronchitis; that a splash of cold water will excite respiration in the infant, or set agoing the action of the heart during a faint. The nervous system consists of a series of segments arranged in a line, corresponding to the various somites of the body. Each nerve-segment governs, to some extent, the nutrition of its own somite, alike as regards epi-, meso-, and hypo-blastic structures. In a previous paper, read before the Physiological Society at Oxford, the author thinks he proved his theory by demonstrating the fact that stimulation of the surface skin alters the diameter of the arterioles in the lung, and causes variation in the electrical conditions of the thoracic and abdominal organs, as manifested by the galvanometer. Stimulation of the skin of the abdomen by heat, by chemical irritation, by faradism, or by mechanical irritation, produces instantly a variation in the electrical potential. The subject, occupying many months of hard work in the laboratory, is too extensive to be made clear in the space of a few lines. Turning to more familiar evidence, few persons will deny the soothing effect of a poultice in bronchitis, nor can any one explain it satisfactorily in any other manner than the one just stated. Inflammation is impaired vitality. This impaired or perverted vitality exists in the tissues of the heart when rheumatic endocarditis is set up. A temporary stimulus is applied by reflex means to the trophic nerves of the heart, helping nature to overcome the defective action. That is the theory on which this treatment by blistering is based. The assisted natural powers succeed, where, if unstimulated, they would fail.

Senile Epilepsy and Griesinger's Symptom of Basilar Thrombosis.—In the *Zeitschrift f. klinische Med.*, Bd. 28, Dr. Naunyn reports some interesting cases of senile epilepsy. Epileptic attacks are especially com- [illegible] addicted to the tobacco habit. To them tobacco is not a relaxation after a day's work, but a nerve stimulant which enables them to accomplish tasks which would otherwise be difficult of accomplishment. Not infrequently, too, when the mouth becomes parched as the result of continuous smoking, recourse is had to alcohol in some form or another to give a further fillip while enabling him to tolerate still another cigar or two. Under these circumstances tobacco acts as a cerebral irritant, and interferes with the vaso-motor centres of the brain to such an extent that the vessels are unable to adjust themselves forthwith to the condition required for healthy and untroubled sleep. Every smoker is familiar with the fact that a change of tobacco or an unusually strong cigar is apt to keep one awake at night, and this tendency is accentuated when smoking is an aid to work and not a mere pastime. The same remark applies to alcohol when it is used as a stimulant. The real cause is often overlooked, and drugs are employed where a change of habit ought to be insisted upon. Attention to the ordinary rules of "tobacco hygiene" would save many from this distressing condition of chronic insomnia. Smoking early in the day should be discountenanced, and it is equally undesirable within an hour or so of retiring to rest. The best remedy for the tobacco habit, short of total abstention, is to take a short walk in the open air after the [illegible] artery obstruction. Naunyn thinks the spontaneous attacks in his three patients were due to cerebral anæmia, occurring from the deficient supply of blood to the brain that is caused by arterial sclerosis and weak heart-action. Senile epilepsy, he believes, as a rule, due to cerebral circulatory disturbances that have their origin in disease of the heart or blood-vessels. Such cases do not improve under bromides. Small doses of digitalis are to be preferred.

Appendicitis and Rheumatism.—In *The Lancet*, August 24, 1895, Dr. G. A. Sutherland advances a theory which, if true, may perhaps prove that the constitutional treatment of appendicitis is as important as local and surgical measures. The vermiform appendix is rich in lymphoid or adenoid tissue, which suggests the possibility of its being the centre for the production of leucocytes or lymphocytes. Elsewhere in the alimentary canal the importance of adenoid tissue is fully recognized, and the action of the lymphocytes produced there has been fully explained. According to Berry's researches, the function of the appendix is, (1) leucocyte producing, and (2) secretory. Leucocytes he considers useful in the destruction of micro-organisms and the absorption of proteids. Such protective power would be of great service, for processes of decomposition going on unchecked in the cæcal region would probably result in symptoms of auto-intoxication that would be extremely common. Usually regarded (appendicitis) as a purely local condition, due to such local causes as catarrh, concretion, cystic dilatation, etc., the author thinks it also quite possible that the vermiform appendix may be acted upon by poison circulating in the blood and thus become acutely or chronically inflamed. Rheumatism may be such a poison. The term "abdominal tonsil" has been ap-

plied to the appendix; and there are in reality many points of resemblance, both anatomical and pathological, between the tonsils and the vermiform appendix. If the former constitute the "first line of defence for the alimentary canal," the latter may be regarded as the second line of defence. Rheumatism afflicts adenoid tissue elsewhere. Why not here? While purely local or mechanical causes of appendicitis do exist, there may be others. And, in certain cases, the pathology may be this: The presence of a constitutional poison producing inflammation of the lymphoid tissue in the appendix, depriving it of its normal protective functions, and thus inducing a condition that permits the entrance of micro-organisms and a resulting septic peritonitis or appendicitis.

Neuro-dendron, proposed by Kölliker.
Neura, proposed by Rauber.
Neurocyte, proposed by P. A. Fish.
Neure, proposed by Frank Baker.
The *cell*, the *neuron*, and the *dendrons*, proposed by Schaeffer.

The axis-cylinder process has received the following names:

Neuron, proposed by Schaeffer.
Neuraxon, proposed by Kölliker.
Neurit, proposed by Rauber.
Neurite, proposed by Fish.

The other (protoplasmic, etc.) processes have received the names:

Dendrons, or dendrites, proposed by Schaeffer.
Dendrites, proposed by His and Fish.
Cellulipetal processes, proposed by Cajal and Van Gehuchten.

The committee would recommend that the term axis-cylinder process be still used in its long-accepted sense, to indicate part *c* of the neuron. Without making the recommendation it expresses the opinion that some word like neurite will probably come into use as a synonym for this axis-cylinder process. The committee also recommend that the old term, "protoplasmic processes," continue to have its ordinary and legitimate use, but express the view that the word dendrite will be a useful synonym.

Post-diphtheritic Cardiac Paralysis.—Dr. Veronese says that no case has yet appeared in literature where death occurred entirely without warning, some suspicious symptoms having always been present for twenty-four hours at least. It attacks boys more frequent than girls, and is most common between the ages of six and fourteen. Children under six are almost never attacked, probably because in severe cases they usually succumb early in the disease; but adults are not altogether exempt. It varies in different epidemics, but occurs also among sporadic cases. Puny children, especially the tubercular and nervous, are more apt to be affected than the strong, yet in all cases it is preceded by severe general or local symptoms. The latent stage, that is, the period between recovery from the local process and the appearance of cardiac symptoms, lasts usually from two to eight days, but may cover from four to six weeks, although in the latter case the cardiac paralysis is the termination of a severe general post-diphtheritic paralysis. The reason that the cardiac appears so much earlier than other forms of paralysis is due to the fact that, owing to the delicate mechanism of the heart, a tiny lesion, by affecting important nerve-centres, may produce most serious results on an organism already weakened or degenerated by the diphthiretic process. In the so-called latent period a series of suggestive symptoms will not escape close observation, of which the most important are great prostration, apathy, somnolence by day, sleeplessness and restlessness at night, increasing dilatation of the heart with corresponding changes in the sounds, alterations in the character and rhythm of the pulse, increased frequency of respiration and signs of pulmonary œdema, nausea, more or less constant pain in the epigastrium and increasing albuminuria. Fever is never present, at least as a result of the cardiac affection. An attack of syncope announces that the disease has reached its height, but the first one is rarely fatal. In cases which recover after two or three anxious days, the symptoms of stasis due to cardiac weakness begin to pass off, œdema rarely lasting more than two weeks; but convalescence is very slow, requiring from two weeks to six or more months. Permanent lesions, apart from a mild grade of hypertrophy, do not seem to follow post-diphtheritic paralysis. The prognosis is very doubtful, though not always fatal; the milder the symptoms and the slower their development the better the outlook. The anatomical lesion may be a parenchymatous degeneration of the heart with interstitial changes, fatty degeneration of the myocardium, parenchymatous and interstitial degeneration of the vagi and the nerves and ganglia of the heart, or degeneration of the sympathetic, especially the ganglion and plexus cœliacus. It is probable that death is due less to degeneration of the heart than of its nerves and ganglia, and reflexly to degeneration of the sympathetic, especially the cœliac plexus.—*The Boston Medical and Surgical Journal.*

Recent Advances in Cerebral Surgery.—According to Professor von Bergmann, in cases of tumor of the brain surgery has of late done very little beyond facilitating a correct diagnosis, and rendering operative interference less dangerous. In Jacksonian epilepsy surgical treatment is usually followed by relapse, and can effect a certain cure only in those cases in which the convulsions are due to the compression of a circumscribed cortical motor centre by a tumor, as for instance, a cyst of traumatic origin. On the other hand, very decided progress has been made in the operative treatment of different forms of intra-cranial suppuration of otitic origin, such as cerebral abscess, epidural suppuration, ineffective thrombosis of the lateral sinus, and leptomeningitis. The most dangerous forms of chronic aural suppuration, which is usually excited by a collection of cholesteatoma in the interior of the ear, are indicated by intercurrent acute and subacute attacks, with fetid discharge, and by the presence of polypoid granulations on the tympanic cavity and the auditory meatus. The extension of the inflammation through the thin and carious tegmen tympani sets up pachymeningitis, which in its turn gives rise to an extra-dural or epitympanic abscess, or to an intra-dural cerebral abscess. The cerebral abscess, when small and in an early stage of development, is situated at the surface of the brain, but as it enlarges it sinks into the substance of the affected lobe. As the diagnosis between a superficial and epitympanic abscess on the one hand, and a cerebral abscess on the other, is attended with much difficulty, von Bergmann holds that it is necessary in performing an operation to expose to view both the extra-dural abscess and the part of the temporal lobe most likely to be involved in the extension of suppurative process. An operation is described by which the upper and anterior surfaces of the petrosal bone are exposed through a quadrangular opening made in the squamous portion of the temporal bone, just above the line of the zygoma, and between a line in front drawn directly upward to the sagittal suture from the tragus and a parallel line behind carried upward from the posterior border of the mastoid process. By this wound the mastoid antrum and cells may be opened if necessary, and the sigmoid fossa be reached. In conclusion Bergmann alludes to the successful results of the surgical treatment of infective thrombosis of the lateral sinus. Exposure and incision of the sinus, with ligature of the internal jugular vein, proved successful in 6 out of 13 cases treated by Jansen, of Berlin. These cases, added to those of Macewen and other surgeons, show that the operative treatment resulted in recovery in 27 out of 45 patients. Thrombosis of the lateral sinus, it is pointed out, is often associated with extra-

dural abscess on the roof of the tympanic cavity, and in most cases of cerebellar abscess forms a communication between this collection of pus and the suppuration in the middle ear. In exposing the outer surface of the mastoid process and the bone lying behind this, search should be made for the mastoid emissary vein. Not only is the orifice a good guide to the sinus, but in addition the state of the vessel may help the diagnosis. If it contains pus, suppuration in and about the lateral sinus is indicated ; if it be blocked by a thrombus, this will be a sure sign of thrombosis extending to the cavernous sinus.—*Centralblatt für Chirurgie.*

Extract of Supra-renal Gland.—The attention paid to tissue extracts lends some interest to the recent physiological researches of Dr. D. Gourfein made a series of experiments in the therapeutic laboratory of Professor Provost. The experiments were made upon frogs, guinea-pigs, rabbits and cats. The investigators showed that one could extract from the supra-renal capsule a toxic substance which is soluble in alcohol and is not destroyed by heat. This substance injected under the skin of animals produces a constant series of symptoms. In mammals it consists in a progressive weakness and dyspnœa, which continues until death. If respiration is kept up artificially, death ensues from paralysis of the heart. Animals that can vomit do so rapidly after the injection. The sensorium is not affected. The principal action of this substance is exercised upon the central nervous system. The special point of interest in connection with the investigations of Dr. Gourfein is the determination of the fact that the supra-renal capsule possesses a powerful poison which acts upon the nervous system, rather than upon any of the glandular or muscular tissues. In this connection we may refer to the results of the studies made in the same direction by Dr. Oliver and Professor Shäfer, of London. They found that the supra-renal capsules were glands, which, like the thyroid, were strictly secreting organs. The material which they secrete was an active principle, which increases the tone of all muscular tissue, and especially produces this effect upon the heart and arteries. On the other hand, they found that the removal of the capsule produces extreme weakness of the heart and muscular system generally, and a great loss of tone in the vascular system—a similar condition to that found in Addison's disease. Their experiments have been confirmed by Szymonowicz and Cybulsky. Their results, however, seem to be almost identically opposite to those obtained by the experimenter above referred to. Dr. Gourfein, however, used a substance obtained by a special process from the gland, and it is possible that the method he employed had something to do with the difference in the results secured.

A Case of Recovery after Trephining in Tuberculous Meningitis.—Dr. James Kerr, of Bradford, England, reports in *The Lancet* the history of a tuberculous meningitis, occurring in a boy of ten. The disease having progressed to the stage of coma in the course of the third week he was trephined. An opening was made one inch and a quarter above, and the same distance behind, the left auditory meatus ; a half-inch button was removed, and the dura-mater opened. Very little fluid was removed. The patient made a recovery.

Tobacco Insomnia.—Among the distressing ailments to which the brain-worker is exposed one from which no small proportion of them suffer is the inability to sleep. This is particularly frequent among those who are called upon to burn the midnight oil, to use the consecrated phrase. These sufferers complain that they feel most lively just when the time has come to retire to rest, and that a long period of restlessness precedes a troubled slumber from which the slightest noise awakens them, that is to say, not only may tobacco temporarily prevent sleep, but, short of that, it renders it less deep, and consequently less refreshing. The result of an inadequate amount of refreshing sleep is to render them irritable and heavy during the day, and the feeling of lassitude and incapacity for intellectual work is especially pronounced during the forenoon. But too frequently the complaisant practitioner counsels recourse to this or that narcotic or hypnotic, with the immediate result in a certain proportion of cases of the formation of a habit which not infrequently culminates in physical and mental wreck. A grave responsibility attaches to those who lightly seek to relieve a symptom, which is really a warning, by recourse to a dangerous palliative. The inability to sleep is often merely the outcome of an unnatural mode of life, and if this be corrected the disability disappears of itself. Men who work late are commonly addicted to the tobacco habit. To them tobacco is not a relaxation after a day's work, but a nerve stimulant which enables them to accomplish tasks which would otherwise be difficult of accomplishment. Not infrequently, too, when the mouth becomes parched as the result of continuous smoking, recourse is had to alcohol in some form or another to give a further fillip while enabling him to tolerate still another cigar or two. Under these circumstances tobacco acts as a cerebral irritant, and interferes with the vaso-motor centres of the brain to such an extent that the vessels are unable to adjust themselves forthwith to the condition required for healthy and untroubled sleep. Every smoker is familiar with the fact that a change of tobacco or an unusually strong cigar is apt to keep one awake at night, and this tendency is accentuated when smoking is an aid to work and not a mere pastime. The same remark applies to alcohol when it is used as a stimulant. The real cause is often overlooked, and drugs are employed where a change of habit ought to be insisted upon. Attention to the ordinary rules of "tobacco hygiene" would save many from this distressing condition of chronic insomnia. Smoking early in the day should be discountenanced, and it is equally undesirable within an hour or so of retiring to rest. The best remedy for the tobacco habit, short of total abstention, is to take a short walk in the open air after the last pipe. Under no circumstances should drugs be recommended for this form of nocturnal restlessness.—*Medical Press.*

Cure of Uterine Disease by Vibrations.—Dr. Bourcart would revolutionize uterine therapeutics by extending Brandt and Kelgren's principle of using manual vibrations to insure absorption of inflammatory exudations (*The British Medical Journal*). In the case of the uterus instruments are required. Liedbeck has already invented a good apparatus for producing vibrations by electric means. In the case of the uterus the vibrations must be rapid, very regular, and penetrating. The vibrations can be perfectly transmitted through the abdominal walls. Bourcart, acting on the knowledge of these facts, has contrived a portable dynamo, to which he fits on a vibrator, which he places with his right hand against the parietes. The uterus is pushed toward the parietes by the left forefinger passed into the vagina. In the same way the Fallopian tubes and ovaries may be pressed in the direction of the vibrator. Bourcart declares that subinvolution is particularly benefited by the vibration treatment. In metrorrhagia from fibroids it is equally useful; the tumor may even diminish in size under a course of this treatment. He treats endometritis by vibrations transmitted by means of a specially constructed stem, but he admits that further study of this new variety of uterine therapeutics is required.

Mixed Infection in Phthisis.—At the close of a paper on this subject Elsner draws the following conclusions (*The Boston Medical and Surgical Journal*): 1. Tubercle bacilli can, without the presence of added bacterial infection, cause changes in the lung, giving rise to symptoms of acute pneumonia in chronic or

latent phthisis, which cannot be differentiated without bacteriological examination from non-tuberculous pneumonia. 2. Concurrent infection in tubercular phthisis modifies very materially the course of the disease, giving rise to many acute exacerbations and anatomical changes; hence the conclusion is justified that the clinical picture of the disease is, as a rule, complex. The double infection must be taken into account when indications for treatment are considered. 3. An acute croupous pneumonia can attack lung tissue, the seat of tuberculous infection, or run its course in any part of the healthy or diseased lung. As a rule, the tuberculosis, if latent, is lighted into activity. 4. Aspiration from cavities of streptococci or other bacteria may give rise to acute pneumonia, a streptococcus pneumonia. Early and profuse hæmoptysis is present in a majority of these cases. 5. Mixed infection in pulmonary tuberculosis is an important factor in lowering vitality and the resistance of the patient; all septic and pyæmic processes arising in the course of tuberculous disease may be traced to it. 6. The differential diagnosis of tubercular pneumonia is ofttimes made with great difficulty. In all cases bacteriological examination must be made repeatedly, and culture experiments add to the refinement of such diagnoses. Without repeated microscopic and bacteriological examinations it is impossible to determine the pathological significance of the innumerable exacerbations of pulmonary tuberculosis.

Spengler has endeavored, in fifty cases, by means of bacteriological examinations of the sputum and carefully conducted autopsies, both from the bacteriological and anatomical stand-point, as well as by a careful comparison of their clinical histories, to get some explanation of the different types in which phthisis manifests itself. As a result he arrives at the following conclusions: 1. In tubercular phthisis only a small percentage of the cases are uncomplicated cases of tuberculosis of the lungs. If fever is present in these pure cases, the extent of the mischief is much greater than the physical examination would lead one to suppose, and the prognosis is unfavorable. They become still more unfavorable in case a mixed infection is added. These cases are adapted to the tuberculin treatment. 2. Most cases of phthisis are complicated by a mixed infection with streptococci, and may be classified as active or passive, according as fever is present or not. The prognosis of the active form is good if it complicates a local tuberculosis, remains circumscribed, and receives prompt climatic treatment. Other bacteria, as well as the streptococcus, may complicate tuberculosis, such as Fränkel's diplococci, staphylococci, tetrageni, influenza and pseudo-influenza bacilli, and others. If secondary bacteria appear in a few colonies only in several sputum examinations, fever, if it be present, is not due to the mixed infection but to the tuberculosis, or to some focus of infection other than the lungs. If fever is absent and yet streptococci are found in considerable abundance, the sputum should be carefully washed in order to rid it of accidental impurities from the upper air-passages; and then, if they still persist, the presence of bronchiectasis or cavities may be inferred.

The therapeutic indications are self-evident. Early diagnosis is essential before secondary infection has occurred; and the treatment should be specific, that is, with tuberculin. Mixed infection can only be combated by pure air, either at sea, in the desert, or on the mountains.

After the secondary infection has been overcome, and tuberculosis alone remains, tuberculin is again indicated. Huguenin arrives at similar conclusions, and says that the prevalent idea that patients with fever are not fitted for high altitudes is radically wrong, as it is those cases with pus-infection in the lungs and secondary fever who are fitted for that, and only that.

Curative Treatment of Puerperal Infection.—Dr. Pinard states that the new therapeutics of puerperal infection comprise three methods of treatment well known: intra uterine intermittent irrigation, continued irrigation, and curettage. These methods have been employed separately or combined, according to the exigencies of the case. (*The Medical Press.*) Intermittent irrigation, first employed by Recolin and Levret, and recommended by Gensoul, Roche, and Lemuel Weiss, in 1858, has become current treatment, especially since Pasteur revealed the true nature of infection. For the purpose Professor Pinard uses the glass sound of Fariner, which is very easy to introduce, and when ordinary precautions are taken, cannot break. The antiseptic liquid he employs is a solution of biniodide of mercury (1–4,000) at 103° F. Being a partisan of low pressure, he places the reservoir containing the liquid for injection only ten inches above the level of the patient, as in this manner the liquid cannot penetrate into the veins, or the uterine sinuses. The amount injected generally exceeded three quarts, or until the liquid returned is quite clear. Continued intra-uterine injections is entirely of French origin, but to a German, Schücking, of Halle, is due the honor of being the first to apply it to obstetrics. Since 1885 Professor Pinard has employed it frequently in his service. The method of operating is about the same as in the first case, but the sound is made of metal, as the glass might break. The antiseptic liquids are: A solution of biniodide of mercury (1–4,000); a solution of phenic acid (1–100); a saturated solution of boric acid. Fifteen quarts of the first solution are injected, and followed by the second, and as soon as the temperature of the patient has come down to the normal it is replaced in its turn by the third. Objections have been made against this method, not only as regards the difficulty of adopting it in private practice, but also as regards the fact of leaving a sound *à demeure* for days and nights, which might produce an accident by the movements of the patient. M. Pinard considers that such a danger could only be feared where the instrument was not properly fixed to the patient. In any case he never witnessed the slightest accident in all the cases he had tried it. The operation of curettage followed by Pinard differs but slightly from that usually practised, with the exception of the absence of anæsthetics and the non-employment of the speculum. As to the former, M. Pinard considers it both needless and dangerous—needless because the pain produced by the operation is very slight, and dangerous because in post-partum curettage the hemorrhage is frequently abundant under anæsthetics. In concluding, Pinard said that it was admitted by all that no physiological phenomenon produces a rise in the temperature throughout the course of a normal confinement, and for this reason any increase should put the attendant on his guard against the invasion of septic matter. Consequently, in every lying-in woman who presented within the six days following the delivery, a rise in temperature, puerperal infection should be suspected and treated accordingly. A temperature of 101° F. in the axilla was a certain indication for intra-uterine injections. If after a second injection the temperature continued to rise, continued irrigation or curettage should be substituted. The latter operation should not in any case be done until three days have elapsed since the delivery.

Septic Surgery.—We have left unwashed those things which we ought to have washed, and we have handled those things which we ought not to have handled, and there is no health in us.

Opium Eaters. in India, average from four to twelve grains of the drug per day.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WOMEN'S PETITION TO THE COLLEGE OF PHYSICIANS—DR. BUZZARD'S ADDRESS—CLINICAL SOCIETY—MEDICAL SOCIETIES OF LONDON—THE CASE OF DR. R. B. ANDERSON—DEATH OF INSPECTOR-GENERAL SIR WILLIAM MACKENZIE, K.C.B., ETC.—HOSPITAL SUNDAY FUND—DR. BARRY, THE FEMALE ARMY SURGEON—ANTI-TOBACCONISTS ON HEALTH.

LONDON, November 1, 1895.

THE women have made an assault on the Royal College of Physicians, the oldest of our corporations, and came within view of victory. The form of attack adopted was a petition from the staff of the School of Medicine for Women to recognize the institution and admit its students to examination. The petition was also signed by the staff of the Royal Free Hospital, at which these students receive their clinical instruction. Further, a great array of influential names was appended. Before the meeting to consider it, a counter-statement was got up by some of the fellows and signed by some most influential opponents. This is rather piquant considering the secrecy in which the ancient college has usually tried to shroud its proceedings. There was a serious discussion on the subject, but several of the speakers addressed themselves to the question whether medicine was a suitable calling for woman, rather than that before the meeting, which was, whether the college should follow the example of several other bodies and open its doors to both sexes. The former question will settle itself, for there are now some two hundred female physicians among us, and if the calling should prove unsuitable or in opposition to public opinion, another generation will determine. As to the second question, fears were expressed that if admitted to the licentiateship, these "new women" would aspire to membership, then to the sacred order of fellowship, and perhaps ultimately grasp—*horribile dictu*—the presidency itself.

The college, as the oldest body, may fairly hesitate to follow the lead of some of the more advanced corporations. It has interests and traditions to consider and respect, and there are internal changes which are far more urgent to enable it to retain its position. Some eighteen years ago the question was discussed, but the changes since then have altered the circumstances. There is now no difficulty in the way of women obtaining registerable diplomas, and admission to one more would do nothing to determine their right to study medicine. The men may therefore, without any injustice, retain to themselves some of their institutions. The vote has been a surprise to both sides. One hundred and nine fellows took part in it, and of these fifty voted in favor of the admission of the other sex and fifty-nine against; a majority of only nine for the *status quo* is a surprising event, and the women regard it as a great victory. On a former occasion the votes were, I think, fifty to thirty-six, so, it looks as if the trend of opinion was in favor of the women.

Next week the question will come before the annual meeting of the College of Surgeons, and we shall see whether the members will attend in sufficient force to represent fairly the opinion of the working practitioners, who are threatened with the competition of women, for it is to be remembered the late meeting consisted only of consultants. At the coming one of the sister college those in general practice have the suffrage.

Dr. Buzzard delivered his address to the Clinical Society this day week. He glanced at the great change that has taken place since the establishment of the Society twenty-eight years ago, when the first president's address did not hint at the investigation of diseases with a view to their prevention as appropriate work for such a society, but was occupied chiefly with the administration of remedies. The change brought about may be said to be largely due to the researches of Pasteur and the patient work of Lister. As an application of the scientific method the president naturally mentioned what has been done in myxœdema, for the work has been largely identified with the Society. Other examples named were the great number of cases of paralysis and convulsive diseases now known to depend on syphilis, and the recognition of the influence of alcohol in causing a form of progressive paralysis. In reference to micro-organisms he remarked that in diseases of the nervous system the infective origin of hydrophobia, tetanus, leprosy, and diphtheritic paralysis admitted no reasonable doubt, and he suggested as a field of inquiry the possible dependence of some chronic nervous diseases upon infection. Infantile paralysis, from the occurrence of epidemics, he had little doubt, was infective, and perhaps the form of progressive muscular atrophy, in which the lesion occupied the same anatomical position, might have a similar origin. Insular cerebro-spinal sclerosis probably was another example, as to chorea and some forms of epilepsy the suggestion was only a conjecture at present, but one worthy of investigation. The supposed heredity of Friedreich's ataxy and other family diseases might be open to the doubts some express respecting tuberculosis and cancer. The subject must be considered from its clinical, bacteriological, and chemical aspects, and no society was better qualified to pursue the investigation.

After the address there was a paper on a rare form of contagious impetigo, and one detailing three successful cases of pleural effusion treated by early excision. The latter gave rise to some discussion as to whether paracentesis would not have been sufficient. Mr. Parker gave the history of a case of excision of the patella for primary sarcoma, recorded in the "Transactions" (vol. xx.). The girl, aged eighteen, continued well for three years, when recurrence took place. Another operation was done, and three years more of freedom obtained. Then new growth in the lymphatic glands deep in the pelvis occurred, and an attempt to remove them was only partially successful, and death from exhaustion followed in a few weeks.

At the Medical Society, on Monday last, the battle of buttons and bobbins in intestinal operations was waged with some energy. One speaker objected to all "artificial contrivances," a rather large objection for a surgeon. Another repeated the stale joke that we all had Murphy's buttons in our mouths, and should soon have them in our intestines. Another remarked that the results in the cases brought forward were no better than those obtained by the older method in much graver conditions, such as gangrenous gut in hernia. Another deprecated the importance attached to rapidity in operating.

The case of Dr. R. B. Anderson has gone through another step, though I am afraid not one in advance. He endeavored to get the High Court to pronounce that its former decision was void, or at least voidable, on the ground that Lord Esher was interested in the decision on account of an action which was then pending against him, and which would be influenced by the judgment in his case. The contention was repudiated by all the judges of the court as nonsense, and Lord Esher suffered himself to speak in terms I hardly care to characterize as coming from the bench. He might at least have refrained from insulting remarks if he had not the sense of judicial impartiality sufficiently strong to impose silence on him in such a case. It only remains for Dr. Anderson to take his case to the House of Lords, and I trust the Civil Rights Committee will be supplied with funds, for which they have appealed to the public, to enable them to see him through.

It is with great regret I have to report the death of

Sir William Mackenzie, K.C.B., C.S.I., M.D. He died on Tuesday, last "full of days" and full of honor. He was eighty-four years of age and served his country well. His Indian career extended, I believe, over forty years, and of course he had long since retired. His rank was Inspector-General. I had the honor and pleasure of his friendship, and regarded him as one of the ornaments of his profession. In every society in which he moved he was the type of a perfect gentleman. *Si sic omnes.* Such men are indeed "the salt of the earth."

The Hospital Sunday Fund has this year gone up by some £15,000. It was feared at first that the average might not be reached as some of the collections were known to have fallen off. But *The Hospital* got up a special appeal which has produced the noble sum of £18,000. This quite eclipses *The Lancet*, which has done so much for the fund all along, but I am glad to see that no jealousy of such an unexpected success has been produced. In fact *The Lancet* has some very generous words of congratulation for its smaller contemporary, which though not exactly a medical journal, being devoted to the interests of hospitals and charities, and the special organ of nurses, is read by a good many doctors. The editor of *The Hospital* is Mr. Burdett, the originator of the Nurses' Pension Fund. He is also one of the secretaries of the Stock Exchange, and no doubt his city influence has been exercised to help. I hope now the administrators of the Sunday Fund, which has leaped up to £60,000 from about £42,000, will do justice by putting aside the ignoble jealousy of specialties which has so marred their valuable work.

Some amusing correspondence has lately appeared respecting the career of Dr. James Barry, who served as an army surgeon from 1813 or 1815 to 1859, then retired on half-pay, and died in 1865, when it was found at the autopsy that the army surgeon, who had attained the rank of Inspector-General, was really a woman!

There have been other impersonators of sex, *e.g.*, Chevalier d'Eon, but few, if any, can have gone through all that Dr. Barry must have endured. "A Modern Sphinx" is the title of a novel by Lieutenant-Colonel Rogers, whose hero, Dr. Fitzjames, is drawn from the life of Dr. Barry. This novel was reproduced under the title of "Madeline's Mystery," and contains many anecdotes said to be true. I think both volumes are out of print.

The Anti-tobacco Society thinks that smoking in the streets should be put down by proceeding against the offenders under the health acts for creating a nuisance. Surely these amiable people might take up some nuisance more obviously injurious to the public health.

ONE CAUSE OF ATROPHY OF THE UTERUS.

To the Editor of the Medical Record.

Sir: In your issue for November 2, 1895, p. 640, Dr. Hilbert B. Tingley narrates a case of atrophy of the uterus in a woman, twenty-two years of age, following the birth of her second child, and asks the question, "What was the cause of the atrophy?"

The report states that owing to a uterine hemorrhage on August 26th (fourteen days after labor), she was thoroughly curetted under anæsthesia on September 2d, "and a large handful of fragments of placenta, etc.," was removed. The most reasonable inference as to the cause of the atrophy is the curettage that had been resorted to. This probably was followed by complete obliteration of the uterine cavity, with subsequent atrophy of the organ. An exactly similar case has been reported by H. Fritsch, in the *Centralblatt für Gynäkologie*, 1894, No. 52. A young woman, twenty-five years of age, was delivered of her first child on January 21, 1892. The puerperium was free from fever, but there was a continuous discharge of blood. A consultant advised a curettage, which was carried out under anæsthesia by the attending physician on February 24, 1892. The husband stated that he saw the doctor remove "a large piece of flesh," which was quite hard. The uterus was packed with gauze, then hemorrhage ceased, and the patient made a good recovery. But since then she had not menstruated and had remained sterile. She was perfectly healthy, had no symptoms save the amenorrhœa and sterility. On examination the vaginal portion of the cervix was found entirely gone, there being only a small opening in the vaginal vault. It was impossible to pass the finest sound through this into the uterus, which on bimanual examination was found to be very much atrophied. Fritsch made an attempt to bore an opening into the uterus, but failed. These cases are instructive, and must serve as a warning that during the period of post-puerperal fatty degeneration of the uterine tissues a vigorous curettage may be followed by very serious consequences.

Hiram N. Vineberg, M.D.

127 East Sixty-first Street. November 4, 1895.

"BACTERIOLOGICAL DIAGNOSIS."

To the Editor of the Medical Record.

Sir: In July, 1894, I had occasion to complain to the Health Department that cultures were being taken by their inspectors from typical cases of diphtheria where no useful end could be gained by so doing. I complained of the danger to a very weak and nervous child of having a strange doctor insert the swab and make the necessary examination to secure reliable cultures.

In doubtful cases it was suggested by me that the attending physician would, for his own protection, send in the culture-tube; to make a cultivation from a typical case was only finding work for inspectors, and exposing cases to a serious and unnecessary risk.

Dr. Edson immediately replied: "The matter will be thoroughly investigated at once. I consider the point made by you an excellent one." I believe some time since there was a motion adopted by the Board of Health that employees were not to interfere with private cases unless for unavoidable reasons, which would be in the same lines as my suggestion.

I had occasion to report two cases of diphtheria, November 5th, and was excessively annoyed to find cultures had been taken from the two patients on November 7th. Both were typical cases that there could be no shadow of doubt regarding diagnosis.

Imagine my amazement at receiving a report, "Laboratory No. 7,705," saying "the case did not admit of an exact bacteriological diagnosis as the inoculation was made at so late a period of the disease." The case was about forty-eight hours old, and the pharynx is now (three days after taking culture) covered with exudate. The other report, "Laboratory No. 7,729," said: "Bacilli present, slightly resembling diphtheria bacilli, not sufficiently characteristic for positive identification; a prompt confirmatory culture is requested." This could not be furnished as the infant died from exhaustion before receipt of request. This case was not twenty-four hours old when culture was taken. Both cases were very severe in local and constitutional symptoms, and typical cases of diphtheria.

The question occurring to me, and which must suggest itself to all general practitioners is this: If we cannot get a correct and definite report in a typical case, how can we rely on the report in a doubtful case? I have frequently had reports on cultures from the Health Department Laboratory where the clinical symptoms did not bear out the bacteriological report; but this is the first time it has been clearly demon-

A CONTRIBUTION TO THE STUDY OF THE NATURE, CAUSE, AND TREATMENT OF SUSPENDED ANIMATION IN THE NEW-BORN.[1]

By J. DOUGAL BISSELL, M.D.,

ATTENDING GYNECOLOGIST TO DEMILT DISPENSARY; ATTENDING PHYSICIAN TO NORTHWESTERN DISPENSARY.

The age of empirical medicine has passed, and we live to-day in an era which demands experimentation as the foundation of all theories and doctrines. "The truly scientific investigator is an analyst and purist who seeks to establish the values of single in place of combined forces." He searches for the hidden laws of nature where alone he believes truth to dwell, and accepts only that which is demonstrable. History tells of but few men living before the sixteenth century who sought to unravel the complex problems of disease through the study of the laws governing the body in health.[2] It was not until 1543 that Vesalius[3] published his experiments, which demonstrated the effect produced upon the heart when the lungs of animals were inflated by air. In 1664 Robert Hook[4] introduced artificial respiration, the principle of which has ever since been the recognized means of reviving life where suspended animation exists. But to Marshall Hall we are indebted for having made the first great advance in the study of the nature and cause of asphyxia, one of the forms of suspended animation, and for having established a procedure for inducing artificial respiration superior to any previously suggested.[5] While his researches greatly advanced our knowledge upon the subject, yet we are also indebted to many other observers, and to some even before his time, for valuable suggestions regarding resuscitation. In 1824 Dewees described a plan of extreme value, which, unfortunately, has not received until of late much consideration. He advised "placing the child's mouth downward, and holding the body and hips higher than the head . . . renew the inflation alternately." He further stated that "owing to the tenacity of the fluid within the windpipe we cannot at first force air into the lungs, but by a little perseverance we overcome the obstacle, and the mucus becomes so thinned as to flow readily from the mouth and at once relieve the child. This operation should never be neglected, nor should it soon be given up, especially if we can excite a few pulsations of the heart, or in the cord.[6]

In 1883 Professor Simpson, of Edinburgh, in discussing a paper on "Resuscitation of the New-born Infant," remarked that his practice was to "first hold the infant up by the heels, to allow any fluid to run out of the air-passages, and then perform artificial respiration by Schultze's method. The danger of blowing air into the lungs was that the lungs might be injured by the forcible distention.[7] During the past year Prochownick also advocated suspension by the feet with the same object as did Dewees and Simpson.[8]

While it is a common practice among many accoucheurs of the present day who recognize the value of gravity in assisting in the removal of mucus from the air-passages, to invert the child for a few minutes previous to putting into execution one or more of the generally accepted methods of resuscitation, yet no observer, to my knowledge, has advocated the persistence of this procedure without the aid of any other method, and with the principal object in view of encouraging circulation and thereby inducing respiration.

Among recent observations upon the subject of asphyxia neonatorum, those made by Dr. Alexander Morrison are perhaps of the most interest and importance. In an article published February 24, 1894,[1] he describes this condition as being a disease of the circulatory and not of the respiratory system. The conclusion I arrived at from the study of the cases herein cited is practically the same, though reached by an entirely different line of reasoning, and entirely independent of any knowledge of his work. His views upon the important relation which the ductus arteriosus bears to cyanosis, and thus to asphyxia neonatorum suggested to me, however, the additional value of suspension as respecting its influence through the ductus arteriosus upon the change in the direction of the circulation lungward.

The value of inversion, *per se*, as a direct means of resuscitation, was first advanced by Nélaton. Dr. Chisolm states, in speaking of the way in which resuscitation is accomplished by suspension under these circumstances, that "it is a mooted point whether resuscitation is brought about by an additional supply of blood to the anæmic brain alone, or by the emptying of the blood from the great reservoir, the liver, through the vena cava, into the cavities of the heart, stimulating them into renewed activity. Most likely both of these influences work."[2]

The application of inversion to conditions of suspended animation in the new-born is the outcome of my experience with it in chloroform narcosis, and in Case I. of the following series:

Case I.—On September 1, 1893, I was hastily summoned to a child I had delivered the previous day at the New York Asylum for Lying-in Women. Living in the institution at the time, my response was immediate. On arrival I found the child presented every appearance of death, being cold, blue, limp, and breathless. While questioning the nurses concerning the circumstances under which the child was found, I noticed a shallow gasp, followed by the dropping of the chin, so characteristic of approaching death. Finding that there still remained a spark of life, I ordered a vessel of hot water to be brought, hoping to revive the infant by immersing it. While the nurse was preparing the water, a new thought occurred to me. The similarity between the condition presented in the child and that of chloroform narcosis when cyanosis occurs, suggested the idea of treating the condition as due to a similar cause. Having on several occasions successfully treated chloroform-poisoning by Nélaton's method, *i.e.*, suspension by the feet, I at once resorted to this procedure. Great was my delight when, after the lapse of a few minutes, breathing, though feeble, was resumed with some regularity, and the appearance of the child became more lifelike. On placing the infant in a horizontal position, respiration again ceased, with the accompanying cyanosis, complete muscular relaxation, slow and feeble pulse. Again suspending it, I was rewarded at the end of about two minutes with the same satisfactory result. During the cyanotic state the pulse was 45 to the minute and very feeble. Almost immediately after the first deep inspiration it increased to 150 per minute. Concluding from these observations that suspension by the feet would give the best chances of recovery, I determined to keep the child in this position and await the result. During the first ten minutes breathing and heart action were quite regular, and the general appearance comparatively good, though complete muscular relaxation continued. Suddenly respiration again became labored and heart-action slow and feeble as before. For one minute and a half there was no effort at breathing, then a feeble gasp or two, followed by regular breathing and increased heart-action. This seizure was not nearly as

bad as those which occurred when the child was in the horizontal posture. I therefore felt greatly encouraged as to the ultimate result, and persisted in the inverted position. Voluntary movements of the head and arms were not observed until more than twenty minutes had elapsed. During the first two hours collapse occurred four times, lasting in each instance from one and one-half to two minutes. These seizures were, however, not so severe as the first, and their intervals became successively greater. At the end of this time one of the attending physicians, Dr. Tull, for whom I had sent, arrived. The condition of the infant then was incomparably better than when first discovered, yet so grave as to cause the doctor to express little hope of restoration. Finding now that the horizontal position still occasioned depression when resumed, I arranged with pillows an inclined plane, upon which the child was placed and kept with its head down for four hours. It steadily continued to improve, and the seizures became less frequent and less severe. Six hours after efforts at resuscitation were begun, the horizontal position was resumed, without apparently any deleterious effects. Nourishment was then administered every few hours, and from that time on recovery was uneventful. At the end of two weeks it left the hospital in good health.

I am unable to say what occasioned this asphyxiated condition. The child had been noticed half an hour before calmly sleeping. It is possible that it vomited and strangled, but there were found no evidences of such about its crib or clothing. The exact length of time the child was cyanotic is uncertain, as it was found in that condition ; at least three minutes elapsed from the time it was discovered to the time I first inverted it.

To resume : There was found cyanosis, feeble respiration, slow and weak heart-action, want of volition. Suspension by the feet for two hours, succeeded by an inclined position, with head down for four hours, resulting ultimately in the restoration of the normal functioning of the heart and lungs, and natural appearance and powers of the infant. Prolonged suspension with head down showed no bad after-effects. During each cyanotic seizure while respiration was suspended (from one to two and a half minutes) the pulse-rate remained at 45 per minute, but on the first deep inspirations it invariably increased to 150 per minute.

My thoughts were directed by this success to the study of the probable advantages such a procedure would possess in cases of suspended animation in the new-born ; but it was not until November 20, 1893, that an opportunity was presented to put the idea into practice.

Case II.—On the above date I attended, at the New York Asylum for Lying-in Women, now known as the Old Marion Street Maternity Hospital, a primipara, aged twenty-nine, nine months gravida. She was a large, strong, and well-proportioned German woman ; presented no history of special interest during her pregnancy, excepting that there was present in her urine a small amount of albumin. Presentation of child, vertex ; position, L. O. A. Up to about twenty minutes before delivery the fœtal heart was regular and strong—140 beats to the minute. Labor progressed normally until within a few minutes before I delivered, when there suddenly occurred a profuse discharge of blood. The uterus had spontaneously and almost completely emptied itself of the amniotic fluid half an hour after the second stage began, and one hour before delivery, so that the discharge was almost entirely pure blood. I then examined for fœtal heart-sounds, but was unable to find them. Low forceps were immediately applied and child extracted. The condition of the child was that of apparent death, the form of asphyxia neonatorum spoken of in text-books as anæmic. It was pale to a marked degree, with general and complete muscular relaxation. No appreciable pulsation could be discovered in the cord, or over heart, and no respiratory action. With the assistance of a nurse the child was held up by the feet between the mother's limbs, while a warm receiving blanket was thrown around it and the umbilical cord. I then placed my mouth to the child's mouth, and, pressing upon the throat to prevent the air from entering the stomach, blew the mucus out of the pharynx through the nose. I might here incidentally state that I now consider the step unnecessary, and by no means devoid of danger ; and, as will be seen, was not resorted to in any of the succeeding cases.

About three minutes after birth a feeble gasp was made, following which a considerable quantity of bloody mucus flowed from the nose. The mouth and throat were then mopped out with a piece of cotton on a stick. Finding that the almost imperceptible pulsation in the cord did not improve at the end of the fourth minute, I tied and severed. The flow of blood from the untied or placental end was very slight. The child, covered well with a warm blanket, was taken in the inverted position near a lighted gas stove, and the position persisted in (two hours and twenty minutes) until recovery. Two minutes after the first gasp, or five minutes after delivery, another faint effort to breathe was noticed. These gasps continued about one every two minutes during the first half hour, and in the succeeding half hour improved to one every ninety seconds, and one every seventy seconds. After the first hour the gasps were a little deeper and for fifteen minutes occurred one every sixty seconds, improving during the next thirty minutes to one in every forty seconds, then in the remaining thirty-five minutes one in every twenty seconds, which ended the two hours and twenty minutes of suspension, when breathing became suddenly regular. Heart-action was not sufficiently strong to be counted until after the first gasp had been taken ; then it was noticed to be about forty to the minute, and remained so, with slight variation occurring immediately after gasps, until regular breathing was established, when it increased to 85 per minute. At the end of the first hour the conjunctivæ and skin were as dry as parchment and as lifeless as if death had occurred. There was absolutely no reflex action until just before respiration assumed regularity. At that time slight muscular volition was also noticeable, and in an effort to cough there was expelled a considerable quantity of bloody mucus. This mucus evidently came from the trachea, where it was lodged either by the efforts on the part of the child to breathe in utero, or my attempt at clearing the air-passage by the mouth-to-mouth method. The position of inversion, that is, the head down, with legs and arms up, which was maintained from the beginning to the end, was the only procedure adopted after freeing the mouth and nose of mucus. The child was of course very feeble for a time after resuscitation, but soon rallied, thrived, and left the hospital on the twenty-first day perfectly well. It was seen eight months after, enjoying excellent health.

The points of especial interest in the above case are : The extreme anæmic condition of infant ; the gradual but steady improvement in respiration ; the dryness of the skin and conjunctiva during the first hour—becoming less and less as respiration and circulation improved ; the length of time reflex action was absent ; the completeness with which the air-passages were freed from mucus ; the length of time elapsed before regular breathing was established.

Case III.—Labor began at 3 A.M., November 22, 1893 ; second stage, 10 A.M. Membranes ruptured spontaneously at 10.15 A.M. Presentation, vertex ; position, R. O. P. The mother, a multipara, aged twenty-nine, was strong and healthy. During second stage she suffered severely, head of fœtus making very slow progress. At 1.45 P.M. fœtal heart was strong and regular, 140 per minute. At 2.15 I discovered that the heart-sounds were very feeble, and determined to deliver immediately.

The operation was uncomplicated and took but a few minutes. The instruments inflicted no appreciable injury to the child. Considerable hemorrhage, though not of an alarming nature, immediately followed its birth. Its condition, however, was that of complete exhaustion, muscular relaxation and want of reflex action; pulsation in cord about forty to the minute; distinct though very feeble. The infant, weighing 9 pounds, was well developed, but pale, though not so anæmic as the previous case reported. It was immediately suspended by the feet and covered with a warm receiving-blanket. The mouth and throat were then mopped out with a piece of dry cotton on a match-stick.

Four minutes after birth the cord was ligated and severed. The first gasp was made about three minutes after delivery, and was followed immediately by a flow of bloody mucus from the nose and mouth. Shallow inspiration was continued at the rate of one every eighty seconds, for fifteen minutes, at the end of which time five or six short breaths were taken in rapid succession. These were followed by an interval of two minutes without an effort to breathe. Inspirations were then resumed, somewhat more full, and continued one every sixty seconds for fifteen minutes, again terminating in a succession of rapid respiratory acts. Another interval of two minutes then elapsed when breathing was resumed at the rate of one every forty seconds, and continued so for twenty minutes, terminating as before in a rapid succession of respirations, followed again by another interval of two minutes. Breathing was then resumed at one every thirty seconds, becoming, with heart-action, stronger and better, and at the end of one hour and twenty minutes from the time suspension was begun both lungs and heart functioned normally. During the first half-hour heart-action grew stronger, but did not increase beyond 45 to the minute, excepting during the several successive and rapid respirations, when it was always accelerated, but at no time reached as much as 60 per minute until regular breathing was established, when it became normal, or 130 per minute.

Nothing eventful occurred in connection with the case during the following thirteen days while the child remained in the hospital. It left in perfect health. What occasioned, in this case, interference in fœtal circulation, I am not positive. There was a discharge of blood before delivery and immediately after birth, but no more than is often seen in uneventful labors. The cord was of usual length and position; the placenta had upon its uterine surface a blood-clot, but not of sufficient size to indicate an extensive separation of that organ from the uterus. The peculiar feature of this case was the succession of rapid breaths occurring every fifteen or twenty minutes, being invariably followed by an interval of two minutes before breathing was resumed.

Case IV.—Primipara, aged twenty, entered hospital May 14, 1894, 8 A.M., in labor. She had had several labor-pains before admission. Examination showed vertex presentation; L. O. A. position. Cervix tense and not sufficiently dilated to allow the passage of the forefinger. She complained a little of backache, but had only one labor-pain during the remainder of the day. At 5 P.M. the cervix was softer and more patulous; the vagina well lubricated with mucus. At 6 P.M., finding that the head was descending, but that there was no protrusion of the bag, I passed my finger up through the cervix and discovered that the amniotic sac was intimately attached to the lower segment of the womb. These adhesions I immediately broke up as high as I could reach. In about half an hour the bag was found descending and distending the cervix. At 10 P.M. labor-pains began again. At 10 A.M. the next morning (May 15th) pains became so severe that morphine, grain ¼ hypodermatically, was administered. At 11 A.M. bag of waters was ruptured artificially, and at 11.58 A.M. child was born. Fœtal heart-sounds remained throughout labor about 132, full and strong. Greatly to my surprise the child's condition at birth was that of extreme cyanosis, with complete muscular relaxation. It was immediately suspended by feet, covered with a warm receiving-blanket, and mouth and throat mopped out. Pulsation in the umbilical cord, at birth, was 125 to the minute, quite regular and strong. At the end of four and a half minutes, although the child had made no effort at respiration, I tied and severed cord, thinking that in so doing the infant, being thrown upon its own resources for oxygen, would soon breathe. It was not until two and a half minntes after severing cord, however, that any effort at respiration was noticeable. This feeble effort was succeeded by an interval of three minutes, during which time mucus flowed from the mouth and nose. Then a deeper inspiration was made, followed by an interval of two minutes, terminating in a succession of respirations. But it was not until sixteen minutes after delivery that respiration became regular and muscular volition was established. A considerable quantity of mucus, slightly tinged with blood, was then expelled from the throat. Pulsation before ligation of cord was 125 to the minute. Immediately after ligation it fell to 60 per minute, and remained so until respiration became regular, when it rose again to 125 per minute.

To resume: There was a marked degree of cyanosis at time of birth. Though no effort to respire had been made for several minutes after birth, the appearance of the child steadily improved under the influence of the inverted position. The first inspiration was made about four minutes after the mouth and throat were mopped out and two and a half after the cord was tied and cut. The heart-action fell immediately upon ligating the cord from 125 per minute, full and strong, to 60 per minute, and did not assume its normal functioning until regular respiration was established. No blood was allowed to escape when the umbilical cord was severed.

I have attended three other cyanotic or apoplectic cases since this one; but as none were extreme nor presented any features of peculiar interest, I will not impose upon the reader a further account than to say that they were all resuscitated from within six to nine minutes by the same procedure as that employed with those cases whose histories have been given in detail.

The following procedure I now invariably adopt where suspended animation exists:

As soon as delivery is completed the child is held up by the feet. Any mucus that may be in the mouth or throat, obstructing the free entrance of air, is wiped out with a cotton swab. A warm receiving-blanket is immediately wrapped around the child, and also about the umbilical cord, if it remain unsevered for any length of time. In placing the covering about the babe it is best to bring the arms up alongside of the body, so that there will be no hindrance to the act of respiration when it is begun. The child is then removed, still in the inverted position, near to a warm stove or radiator, that it may not suffer from the loss of heat, and is kept suspended until resuscitation has taken place. If improvement is satisfactory, however, the child may soon be placed in an inclined position in the lap of the nurse. If we have to deal with the apoplectic form it is well to allow the umbilical circulation to continue for several minutes after birth; the engorged vessels are thereby relieved without the loss of blood, as occurs when leakage is allowed from the severed cord. Should efforts at respiration not be made during the first two or three minutes, it is best to ligate and sever cord, and thus throw the child upon its own resources. With the anæmic variety I think it is best to tie and sever the cord immediately after birth so as not to allow an increased loss of blood.

Of all methods adopted to insure artificial respiration that of alternately flexing and extending the body upon itself is perhaps the most highly valued and universally used. There are many varieties of this method,

but in principle they are all essentially the same. On flexing the body the thoracic cavity is compressed, causing expiration. On extending the body the thoracic cavity is expanded, causing inspiration. The best plans of procedure are probably those advocated by Schröder, Schultze, Sylvester, and Dew. Schultze's method is perhaps the most powerful and successful of the above named, and for these reasons we will consider it as the type of this class.

In order to handle the infant, according to the prescribed plan, it should be naked. In this condition it is thrown up over the shoulder and down between the legs with considerable violence. This rough handling of the uncovered child must necessarily expose it to a loss of heat, exhaustion, and physical injury.

In the newly born asphyxiated the congestion in venous organs, such as the liver, has been shown by autopsies to be very great. Schultze claims, as one of the advantages of his method, that the manipulation induces the emptying of the right heart, and in that way relieves this internal congestion. He seems to lose sight of the fact, however, that the position which the child is made to assume in inducing expiration forces the blood suddenly from a considerable area into the engorged organs themselves, and that such manipulation may therefore play no small part in the rupture of vessels already distended to their utmost capacity. In this connection I might state that both Korber and Koffer have each reported a case of rupture of the liver with fatal termination as the result of Schultze's method.[1]

If violence or sudden force is used in any of the methods which alternately flex and extend the child, the same danger is, of course, incurred, and when benefit is derived from them I believe it to be due partly to the pressure on the liver, encouraging thereby the emptying of that organ into the heart. The difficulty is to regulate or determine the amount of force to be used under these conditions.

Schultze advises that "where spontaneous effort at respiration is made the method is to be desisted from in order that the spontaneous respiratory process may not be interfered with by the artificial."[2] It is impossible always to tell when spontaneous respiratory efforts are being made, because, while the operator is throwing the child up and down, it is part of the time completely out of the line of vision, and the first efforts at respiration are too shallow and too feeble to be heard. The possibility of inflicting injury also offers a serious objection. Schultze himself reports a case which suddenly died soon after resuscitation, the autopsy revealing a fractured clavicle, the broken bone having perforated the pleura and lung.[3]

Inflation of the lungs stands, perhaps, next in importance. It may be accomplished by the mouth-to-mouth method, or through tubes passed into the trachea. Budin says that while the throat is freed by the mouth-to-mouth method, the mucus being blown through the anterior nares, yet it does not insure the entrance of air into the lungs, because of the flaccidity of the air-passages, and that even if such is accomplished, viscid matter may be driven before and obstruct a certain number of bronchi.[4]

Mundé states that "post-mortem examination of the lungs of children that have died after efforts had been made to resuscitate them, showed, frequently, points of ecchymosis, which was evidence that too much force is often used in such cases."[5] He also remarks, in speaking of cases where the Marshall-Hall and Sylvester methods were used without success, that the mouth-to-mouth method was resorted to, and, "by this means some were resuscitated, but too frequently the air instead of entering the lungs simply went into the stomach."[1]

Before meeting with the above, in the study of the literature of the subject, I delivered a syphilitic fœtus which had been dead *in utero* several days. I tried to inflate the lungs by blowing through its mouth, but found that instead of filling the chest I distended the abdomen. The air-passage is almost as flaccid in the "still-born" child as in the dead-born; therefore such a procedure is always accompanied by a grave risk. This mishap might to some extent be averted by pressing upon the throat so as to close the œsophagus, which, however, must also hinder somewhat the passage of air into the lungs.

There have been many instruments devised for inflating the lungs, but the ordinary gum-elastic catheter is perhaps most frequently used. In adopting instrumental insufflation we are always liable to use too much force; but aside from this danger, the necessary skill and practice which it requires constitute a considerable objection, for, as Budin says, "Any instrumental insufflation is often very difficult; it is a true catheterization."[2] He might have added that an inexpert operator is just as apt to pass the instrument into the œsophagus as the trachea.

Several successful cases have been reported, treated by the faradic current.[3] In order to make the diaphragm act by this means, the current must be applied so as to stimulate the phrenic nerve. Dr. Polk has well observed that stimulating the diaphragm to act by the electric current was one of the most uncertain things in medicine.[4]

Mundé thinks that one is apt to do too much with the faradic current; to make it too strong or to repeat it too frequently, thus producing convulsive contraction of the diaphragm, which interferes quite as much with the resuscitation of the child as if nothing had been done.[5]

But aside from these objections, were the method even more certain, we could not on all occasions avail ourselves of it, because batteries are not always to be had when wanted.

Hypodermatic injections of brandy or whiskey have also proven efficacious in some cases. But it is not always possible to gauge the amount necessary. Dr. Rodenstein reports a case where, after a faithful trial of both Sylvester's method and the catheter without success, brandy was injected and restoration soon followed. "He acknowledged a fault, however, in that he overdid the matter, over-stimulating the child, and it died within twenty-four hours of convulsions."[6]

Hot and cold water plunges alternately, spanking, etc., are means adopted to induce respiration by reflex action. Where the cases are not extreme they hasten restoration, but in exhausted cases the accompanying shock from such procedures only increase, I believe, the exhaustion, and subject the infants to greater danger. With regard to artificial respiration in general, I believe it to be of value when it is performed without the accompanying shock and injury which may be occasioned by some of the recognized methods. I think that the artificial expansion and contraction of the lungs induces a blood flow to and from these organs which must in turn affect beneficially the entire circulation and necessarily the nerve centres governing respiration.

The value of inversion as an agent in restoring life in the still-born but yet viable child will be more fully appreciated by bearing in mind the following important points in the fœtal circulation.

Nearly the whole of the maternal or placental blood,

[6] Ibid., October, 1881, p. 888.

on its passage to the fœtal heart, traverses the liver,[1] where, during this stage of life, a quarter or more of the entire volume of the system is to be found.[2] In this organ, the liver, we therefore have a great reservoir for the storing of nutrient blood, which, to the infant who has not yet breathed, is practically its only source of oxygen.

In the fœtus and the still-born child the blood "passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities."[3] The pulmonary arteries transmit only sufficient blood to nourish the lung tissue, while the ductus arteriosus conveys the blood of the right ventricle into the general circulation.

Suspended animation in the new-born may be due, first, to impairment of the umbilical circulation occasioned by pressure upon the cord, or entanglement of the cord upon itself or around the child; second, to the loss of blood resulting from placenta prævia, or partial or complete separation of placenta before birth of child; third, to shock following injuries received during labor, from instrumental interference, or traction on body in breech presentation.[4]

These may be classified under the two recognized forms, viz., apoplectic or cyanotic, and anæmic or syncopal. In the apoplectic form, which is occasioned by a direct interference with the umbilical circulation, there exists not only superficial venous congestion, but also general stagnation in the circulatory system, and diminished supply of maternal or placental blood.

In the anæmic form, when due alone to the loss of blood, there exists a depletion of the circulatory system as well as a deficiency in maternal blood-supply. When due alone to shock from injury, the maternal blood-supply is also affected, it being lessened because of the enfeebled heart-action of the child.

In both forms we find the circulation to be of primary consideration, and it is to the improvement of this we must look for the awakening to activity of the nerve centres governing the respiratory organs.

According to the theory of Dr. Hall, respiration is established in suspended animation through a centric influence which he terms "ecstaltic;"[5] that is to say, in the apoplectic variety respiration is caused by the action upon the medulla of the excessive carbonic acid in the circulation. In the anæmic it is occasioned through "the impression produced upon the medulla by the loss of blood."[6]

[1] Gray: p. 841.
[2] Chapin: Keating's Encyclopedia of Diseases of Children, vol. iii., p. 403.
[3] Gray: p. 841.
[4] It may be incidentally noted that severe traction in breech cases often results in injury to the medulla, under which circumstances resuscitation is impossible, as death must instantaneously follow.
[5] Hall on Asphyxia Neonatorum: its Cause and Treatment, p. 11.
[6] Cazeaux: Midwifery, p. 506.

The physiological cause of the first, as well as the succeeding inspirations, *I believe to be due to the appreciation on the part of the medulla, through probably the sympathetic system of nerves, of the want of a proper proportion of oxygen in the system*, a similar cause to that which occasions the demand for food or drink when true hunger and thirst exists.

The respiratory centre remains inactive during fœtal life because the placental blood contains the required proportion of oxygen; but when from any sudden cause, natural or unnatural, this proportion is decidedly interfered with, the activity of the medulla will be aroused and respiration attempted.

During the act of labor the sinuses of the uterus diminish in size in direct proportion to the contraction of that organ, and the capacity for maternal blood must diminish likewise; through this physiological process nature shuts off from the child, about the time of birth, the accustomed supply of nutriment. If the body is born without delay after the head has passed the perineum, attempts at respiration will generally be made at, or soon after, expulsion; but if the head rests over the perineum, and the body in the genital canal, for any length of time, the child will almost invariably attempt to breathe, but without success, as the pressure upon the chest and abdomen is too great to allow their expansion.

If there exists an abnormal condition, such as the birth of cord before the head, entanglement of it around neck or body, or pressure upon it in breech presentation, the interference in blood-supply to child is more sudden and decided than from uterine contraction alone; hence the demand for oxygen becomes more urgent, resulting generally in active efforts being made by the fœtus to inspire before birth.

While the immediate change, after delivery, of placental breathing to that of lung breathing is not essential, as life can be maintained for several minutes on the reserved supply of oxygenated blood, the continuance of heart-action is essential, and may be considered as the test of the viability of the child.[1] It may be too feeble to be immediately recognized, but if the condition is that of suspended animation, and not death, nature will, I believe, invariably restore herself if aided by the child being placed in such a position as will enable her to work to the greatest advantage.

When the infant is very feeble the first inhalations are extremely shallow, and sometimes do not increase in depth, though the interval between each may lessen until an hour or more has passed. Each inhalation, however, increases the amount of oxygen in the system until the required proportion is reached to establish rhythmical functioning of the lungs.

When complete exhaustion or injury to the medulla occurs, heart-action must necessarily cease forever, and under these circumstances no method of resuscitation employed should be charged with failure.

The position of inversion effectually aids, by the action of gravity, the emptying of the contents of the liver into the heart, nourishing in turn that organ, and by the continued action of the same law the flow from the heart to the medulla is also materially assisted.

Therefore, as the course of the nutrient blood from the liver to the nerve centre of respiration is almost direct, and as the circulation is encouraged by the influence of gravity, a greater volume of this blood, consequently a greater quantity of oxygen, is supplied to the nerve-centre in a given length of time than would be if the body were kept in any other position.

In this connection I might state that Dr. Haultain, of Edinburgh, has reported [illegible] were heart-action continued under the assistance of artificial respiration for two hours and a quarter, spontaneous inspiration was never once attempted. The autopsy showed a basal intra-cranial [illegible] evidently injured the respiratory centre without affecting the circulation (Edinburgh Medical Journal, April, 1875, p. 941). Such observations exceptional.

Gravity also exerts an important influence upon the direction of the circulation lungwards, for it aids directly the emptying of the contents of the right ventricle into the pulmonary arteries, and by the increased blood-pressure in the aorta which it occasions, hinders the flow through the ductus arteriosus, and encourages thereby the pulmonary circulation.

Under the influence of this law the direction of the blood-current from the right ventricle is therefore changed, the general circulation encouraged and improved, and the vigor of the exhausted nerve-centres revived by an increased supply of oxygen to them.

Inversion is not associated with the slightest danger. Nature seems to favor the position in utero, and if the position is not maintained long, after regular circulation has been established, the danger of congestion of the brain is no greater than it was before birth. The head and neck are sufficiently extended under the influence of gravity to allow of the unobstructed ingress and egress of air, and the escape of mucus from the air-passages. The capacity of thoracic and abdominal cavities is in no way encroached upon, and by keeping the arms up against the chest, entire freedom of the respiratory muscles is insured.

The apoplectic form of suspended animation is restored more quickly than the anæmic, and the general appearance will be found to improve soon after inversion is begun. With the anæmic the death-like pallor and want of reflex action may continue even for hours, or almost up to the time regular respiration is established.

After the child has been severed from its mother, the continuance of the position may be maintained by an assistant or nurse, while the accoucheur's attention is directed to whatever else demands it. This procedure may be used in connection with some of the recognized methods, and will be found of great assistance to them all; but where it is desired to test its independent value, there should be none other used with it; for, where there is a combination of methods we cannot tell with certainty which is the efficacious one. When the infant has considerable vitality, almost any method, or combination of methods, may be serviceable in hastening restoration, but in cases where vitality is low, extreme manipulation, being exhausting, is detrimental.

So that as long as there is vitality in the child the value of inversion over other methods increases in proportion to the exhaustion.

The simplicity of this procedure will, I believe, be the greatest obstacle to its popular favor, for it seems that the natural impulse on seeing a still-born infant is to "work over it," to "spank life into it," and thereby often to spank life out of it

That no artificial means was adopted to stimulate respiration in the above-cited cases would seem to justify the conclusion that the recuperative power of nature is a more important and valuable factor in the restoration of the still born yet viable child than has been heretofore conceded; and should there be established from this beginning a means by which coming generations will be benefited, I would ask only for the credit of having directed the old maxim, *vis mediatrix naturæ*, into a new channel.

Miss Kate Marsden, who figured for a time as a friend of the Siberian lepers, and enjoyed the patronage of the English and Russian royal families, as well as the approval of many notable clergymen and philanthropists, has apparently ended her career. Certain charges were brought against her which a committee of investigation found to be sustained by the facts. The London *Times* published the committee's report, and was sued for libel by Miss Marsden. She has now, however, withdrawn the suit and so abandoned her struggle.

TWO CASES OF MORPHINE-POISONING TREATED PRINCIPALLY BY FORCED RESPIRATION.

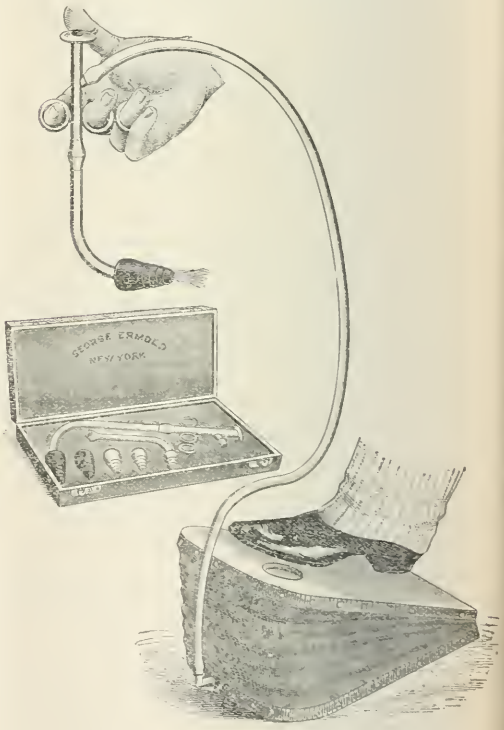
By JAMES D. VOORHEES, M.D.,

HOUSE PHYSICIAN, PRESBYTERIAN HOSPITAL, NEW YORK.

Cases of acute morphine-poisoning occurring in a city hospital are more of a rarity than one would imagine, but when they do come in, no matter how extreme the condition of the patient, they should all get well.

The drug kills by paralysis of the respiratory centre, so if the body is artificially supplied with air, and if it can be done completely in a well-regulated manner and long enough, so that all the poison has been gotten rid of by excretion, the organism ought to return to its normal condition. This artificial respiration cannot be kept up adequately and sufficiently by the Sylvester method, as we all know, but Dr. O'Dwyer, of this city, has contrived a modification of the method originated by Dr. Fell, of Buffalo, to do this. It is by means of a tube inserted into the larynx, the air being forced in by a bellows, thus avoiding tracheotomy.

The apparatus, then, consists of a foot-bellows, rubber tubing, and an intubation attachment. The last



consists of a metal tube (as in cut), curved at right angles, on the distal end of which is a grooved cone which fits the laryngeal socket. The cones are of different sizes. The proximal end has two openings, one receiving air from the bellows and the other closed by the thumb during forced respiration. The thumb is removed during expiration, or the collapse of the chest. The insertion is comparatively easy. A mouth gag is used, the tongue drawn out, the epiglottis held back by the first finger of the left hand, and the tube inserted in the median line by the right hand. When well in the larynx, on inspiration the chest rises fully and no air escapes except when the cone is too small, when a larger size can be put in. This is kept up regularly twelve

times a minute, and atomized water is forced into the tube occasionally to keep the passages moistened.

CASE I.—A German, thirty-seven years of age, a cook, had taken morphine irregularly, but had no habit. After a fracture of the leg he became despondent, and at 6 P.M., on July 23, 1895, took twelve grains of morphine in shellaced pills, ½ grain each. He was brought to the hospital at 9.30 P.M., comatose, cyanotic, pupils contracted, respirations feeble, and four a minute; pulse feeble, irregular, and 150 a minute. He was given strychnine sulphate, $\frac{1}{30}$ grain, and atropine sulphate, $\frac{1}{30}$ grain, hypodermatically immediately, and then his stomach was washed out. The Sylvester method was tried, as his color, breathing, and pulse became worse, but with no benefit. O'Dwyer's tube was then (10.30 P.M.) inserted and worked at twelve a minute. The patient's whole condition improved—pulse and color soon normal. The stomach-tube was again inserted *alongside* of the laryngeal tube, and the organ washed completely, and then four grains permanganate of potash left in.

At 10.45 P.M. atropine, grain $\frac{1}{100}$, was given. At 11.30 P.M. the patient could be aroused, but pulse was not good, and he was given coffee, eight ounces, by rectum, and strychnine, grain $\frac{1}{30}$, hypodermatically. At 12 M. patient became restless. The tube was removed and he was made to sit up. Notwithstanding efforts to keep him awake, he in about two minutes became cyanotic, and pulse rapid and feeble. The tube was replaced and condition became good immediately. At 1 A.M. potassium permanganate, grain ½, was given hypodermatically; no appreciable effect. At 2.30 A.M. tube was again removed, but cyanosis returned. It was put back again and kept in place till 5.45 A.M., when the patient became so restless that its removal was a necessity. Even after this, till 7 A.M., to keep him awake the slapping of a towel was required, for when left alone his respirations would go down to eight and ten a minute. At 6 A.M. atropine, grain $\frac{1}{100}$, was given. From 2 to 6 A.M. his temperature gradually arose from 101.6° to 105.8° F., when he was given a cold sponge, from which he got a drop to 102° F. At 7.45 A.M. he was sent to the ward. Temperature, 101.5° F.; pulse, 120; respiration, 16. Patient was able to sit up and speak, though hoarse, and complained of thirst. He was given whiskey every four hours and a croup kettle started.

Besides this laryngitis he developed a glossitis from the use of a tongue forceps. These complications kept his temperature up five days, when he was discharged cured. Tube remained in seven hours and fifteen minutes.

CASE II.—A German, aged fifty-six; a druggist. No previous morphine habit. Out of work and despondent, and on July 24, 1895, at 12 M. took thirty grains morphine in powder. He was found in Central Park about 4.30 P.M., and brought in by the ambulance, the Sylvester method being used on the way. On admission, at 5 P.M., pupils contracted; cyanosed; no effort at respiration; pulse fair. O'Dwyer's tube was immediately inserted and atropine, grain $\frac{1}{60}$, given hypodermatically. The tube did not fit well, and it was removed and a smaller cone inserted, but this worked worse and the former was replaced, and by pressure against the teeth did better. It was difficult to get the stomach-tube by the laryngeal tube, but after about an hour attempting it was successful, and the organ was thoroughly washed with water and tannic acid, and four grains of potassium permanganate left in.

At 10.30 P.M. the patient was fairly conscious and his throat full of secretions, so the tube was removed and he was made to sit up. Attempts to keep him awake and breathing, by the wet towel and electricity, were fruitless, and in two minutes pulse became bad and color cyanotic. Dr. O'Dwyer himself inserted the tube, and his condition became good immediately. At 11 P.M. he was given potassium permanganate, grain ½, hypodermatically.

July 25th, 2.05 A.M.—Patient became very restless and tube was removed. During this time, besides the initial dose of atropine, he received $\frac{1}{100}$ grain three times, and coffee and whiskey by rectum twice. Temperature rose to 103.5° F. Admitted to ward at 3 A.M., and kept awake with towel. At 10 A.M. temperature 104.5° F., face a little cyanotic, coughs, and is hoarse.

Complications: Glossitis, laryngitis, and bronchitis, which kept his temperature up for five days, and then discharged cured. Tube was in nine hours and five minutes.

Remarks.—1. The above cases are very bad ones, almost *in extremis* when first seen.

2. They show how ineffectual artificial respiration by the Sylvester method was; how atropine, stimulation, and potassium permanganate would have been without results. Of course each helped toward a safe termination, and perhaps the permanganate was not used in large enough doses and as frequently as required.

3. They show how easily the tube and bellows can be used and how quickly it acts, and that the stomach-tube can be used at the same time.

4. One interesting result is the high temperature. Is it due to the effects of the drugs, to its antidotes, to hyperoxidation, or to the beginning inflammations of the tongue, larynx, and bronchi? It seems most reasonable to suppose to the last.

5. This apparatus can be bought cheaply and should be in every hospital, for it can be used in other emergencies, as in apnœa due to ether or chloroform narcosis, and it has been used in this, the Presbyterian Hospital, in cases of apoplexy, tumors of the brain, and fractures of the skull where the respirations stop first. In two cases operations on the skull were performed while the tube was in the larynx.

6. So we see that in prolonging life, as well as in saving it, this intubation is of the highest value.

The above cases occurred at the Presbyterian Hospital during the service of Dr. Walter B. James, with whose kind permission I publish them.

WHAT CONSTITUTES THE WELL-QUALIFIED DOCTOR.[1]

By EDWIN STERNBERGER, M.D.,

SURGEON TO MOUNT SINAI HOSPITAL DISPENSARY, NEW YORK.

WITHOUT any introductory remarks whatever, in order to give you the gist of my paper at the outset, I will say that, in my judgment and in the opinion of others, the general practitioner and the specialist of to-day are not properly equipped, or perhaps I had better use the term schooled, or experienced, for the scientific work which they are called upon to do. Now, this statement may seem to you, on first thought, to be rather a broad one. But I feel sure that after you follow me carefully in what I am going to say you will, on further deliberation, concur with me in the above apparently bold assertion. You certainly will admit the following:

1. To be a thoroughly scientific and conscientious general practitioner, as the term implies, the doctor must be trained, or rather educated, in all the branches of medicine.

2. For the specialist to be absolutely thorough in his especial sphere or specialty, it is necessary that he be familiar with all other branches outside of his own.

Both of these statements require qualifying, otherwise you might think that I am entirely too radical in my views. Perhaps if all of us in the medical profession were more radical, *i.e.*, more thorough in our methods, far better results and more scientific work would obtain. Does it not appeal to you that in order for the general practitioner to render the very best possible treatment to his patient, or perhaps I had

[1] Read before the Metropolitan Medical Society of New York, October 22, 1895.

better say, to give an intelligent opinion to his patient, he must necessarily be versed in all the departments in medicine? Only by doing so does he perform his duties or obligations honestly and scientifically to his patient? It is not to be expected that the general practitioner should conduct the treatment of a special form of disease that requires the expert or specialist. But I do claim that it is his duty to learn what the nature of the disease is, in short, to make the scientific diagnosis. How often does it happen that the unfortunate patient is treated by the family doctor for a disease, the diagnosis of which is never made, simply because of the ignorance of the attending physician?

Ignorance in medicine as well as in law does not admit of an excuse. The patient certainly relies upon his medical attendant for receiving the proper treatment. He surely does so until he is convinced he is not getting the right treatment, or until a friend, or perchance a friendly physician, advises him to make a change by consulting Dr. ——, who is a specialist in the department to which his malady belongs. I am referring now to an ordinary case, one that a well-educated physician with proper experience would recognize and either treat properly or refer to the proper specialist. Such an instance as the above, I am sure, happens repeatedly—not only in the small town but in the large city as well.

You must not think, gentlemen, that I, for a moment, am finding fault with the physician who is attending an obscure case. Far from it. For in such a case the well-meaning, the honest, the conscientious physician will then seek further counsel by suggesting a consultation. By way of parenthesis I would say that it does happen, and not so very infrequently, that the experienced and well-educated physician, believing that he himself knows it all, takes it upon himself to conduct the whole case without consultation, even though the family persistently wishes it. Such action on the part of a physician is surely open to harsh criticism.

Let us consider, now, the importance, the great necessity for the general practitioner to be thoroughly, or at least partially, familiar with all the branches of medicine. Take any one of the specialties, gentlemen, the skin for example, and I am sure it will appeal to every one of you that a knowledge of this specialty is indispensable for the general doctor. It will stand him in good stead to be a moderately good dermatologist to prevent any unpleasantness which might arise through ignorance, even though his conscience doesn't tell him that he owes it to his patient to recognize a skin eruption.

I don't suppose for a moment that I am exaggerating when I say that many an eruptive fever case of a virulent character, under the care of a general practitioner of limited experience, progressing favorably or unfavorably, as the case happens to be, causes the physician or the family very little, if any, concern, notwithstanding the grave conditions prevailing. Again, see how exceedingly important it is for the general practitioner to make a correct diagnosis in small-pox or typhus. Suppose he isolates a case that he is positive of as being contagious. Just look at the discomfort, outside of the trouble and expense, it puts a family to. Now, I am not referring to a suspected or doubtful case. This method of conducting a case is perfectly in order when practised by the experienced doctor, who does it then solely as a precaution. I am referring to the doctor whose lack of proper experience does not justify his making a positive diagnosis. I cannot help believing that many of the cases of small-pox and typhus, especially the former, that we read and hear of, even those reported by the Board of Health, are not genuine cases. It takes a great deal of experience to be able to make the positive diagnosis of either one of these diseases. One must have seen verified cases before venturing a positive diagnosis.

Not long ago I had occasion to refer a suspicious case, which I thought might be small-pox, to one of our prominent dermatologists. After assuring me that it was not small-pox, he commented on this very subject, and virtually remarked exactly what I have just said.

How imperative it is for the general practitioner to know positively what he says when he informs his patient that he is suffering from syphilis. By erring in such an instance as this, from lack of proper education and experience, is certainly worthy of much censure.

Let us now turn to ophthalmology. To the improperly trained practitioner a case of virulent purulent conjunctivitis never suggests itself as one likely to be gonorrhœal in character. He perhaps has heard of such a condition. But to recognize it, or even have the disease occur to him, is altogether out of the question.

In just such an instance as the above, see how much depends on a correct early diagnosis and the proper treatment. The ignorance of the physician in such a case might cost the innocent patient one or both eyes.

In obstetrics it is of the greatest importance that the general practitioner should be thoroughly experienced; for in this branch of medicine, which is ordinarily conducted by the family doctor, where emergencies can arise at any moment, the physician must have at his finger's end the proper method to pursue at the critical time.

How many doctors are there who regularly attend cases of labor, in conjunction with their general practice, who have had the proper scientific training in midwifery? I venture to say it is the great exception for a general doctor to have had any experience or systematic schooling whatever as an accoucheur when he begins his private practice. I am sure none of you will take exception to this assertion, because you all know or have seen cases that have been mismanaged by the general physician, simply on account of deficient early training.

I know from my own experience, while an interne at the Sloane Maternity Hospital, that this specialty requires personal management and manipulation under careful supervision—not merely observation and book-reading—to properly fit one to conduct a labor case.

That the general practitioner should be conversant with the principles and practical part of surgery, particularly minor surgery, cannot be disputed by anybody. Yet how many of our general practitioners are at all able to conduct a minor surgical case according to true scientific principles? I venture to say mighty few; especially is this so of those who have been in practice for many years. You might say that the old practitioner has an excuse for not practising surgery (simple or minor) according to modern methods, because the present methods, particularly the aseptic and antiseptic ones, were unknown to him when student and interne. This I contend is no legitimate excuse. It certainly behooves a conscientious practitioner, just because modern methods have superseded old-time ones, to familiarize himself, not alone by reading but by actual experience, with a more recent technique. How many take the pains to do so? Surely very few. All of you present, I am sure, have seen, as I have, most wretched minor surgery practised by men who have tremendous reputations as conscientious and scientific practitioners. I am not in the least exaggerating, and I know you don't think that I am, by making these sweeping assertions. I could quote innumerable cases, but I am so positive that you all can recall cases, as I can, that I hardly think it necessary to take up your time by doing so. I hardly deem it necessary to take up any more of the specialties to show you the indication for the general practitioner being proficient in all departments. The mere fact that I have directed your attention into this channel of thought will be sufficient to cause convincing examples to suggest themselves in those specialties not dwelt upon.

Coming now to the different specialties, I will take, first, that of neurology, to illustrate the truth of my second statement, namely, "For the specialist to be absolutely thorough in his especial sphere or specialty"

it is necessary that he be familiar with all other branches outside of his own. All of us, even those who are not neurologists, know how important it is for the nerve specialist to be well acquainted with ophthalmology, particularly with ophthalmoscopy. The nerve specialist, again, must be familiar with dermatology, for we well know that there are many skin diseases depending directly on a derangement of the nervous system. If the neurologist has not had a good skin training, he might, while treating a nervous case with an eruption, have difficulty in determining whether the eruption is due to the disordered nervous condition or to some other cause unbeknown to him. With a proper dermatological experience the neurologist could seldom be placed in such a dilemma, and a differential diagnosis would be plain sailing for him. Furthermore, when you consider how frequently a cough is of a nervous or hysterical origin, how much more satisfaction would it be to the neurologist if he were familiar with laryngology, so that he might determine for himself that there was no throat lesion that could account for the cough. Again, before he can conclude that the cough is of nervous origin he must have excluded the lungs; hence you see the indication for the neurologist to be apt at making a physical examination of the chest.

When we consider the department of surgery no one can dispute the fact that for a surgeon, above all other specialists, to be thorough in his sphere, particularly as a diagnostician, he must be well qualified in all branches of medicine. It is apparent to every one of us, without citing examples, that the surgeon must be a good physical diagnostician. The ability to percuss and auscultate is, perhaps, as important a quality for the surgeon to possess as the general practitioner. That the general surgeon should be a gynecologist admits of only one argument.

In doing an exploratory laparotomy, for instance, it does not infrequently happen that the surgeon after entering the abdomen finds a condition of affairs that, strictly speaking, belongs to the domain of gynecology. How embarrassing it must be for the surgeon and how unfair to the unfortunate patient when a condition like this is met with and the operator is not competent to manage the case simply because it turns out to be purely gynecological. Such an instance as this, gentlemen, is by no means a fanciful one, for believe me when I tell you that I was an eye-witness to such a case.

Conversely, I can well state at this point, that for the gynecologist to do justice to his work and to save himself from embarrassment, he must have had a good surgical training. It often happens that the gynecologist in performing a laparotomy, even though he is quite sure of his diagnosis, has to deal not with a gynecological case but with a surgical one.

Thus you see, gentlemen, in the several specialties that I have referred to, the strong indication, the necessity, for the specialist to be well informed and experienced in other departments besides his own.

Possibly the instances I have brought up have not been very striking ones, but I feel sure they will serve my purpose in calling your attention to this exceedingly important question of a broader and more liberal education and training of the doctor.

I cannot close my paper without dwelling for a moment on the important subject of emergencies, the proper management of which all doctors, whether specialists or general practitioners, ought to be thoroughly familiar with. Every one of us who practises medicine should know, not from reading but by actual experience, how to administer an anæsthetic, and how to manage a possible emergency in connection with its administration. I contend that the position of anæsthetizer is, oftentimes, if not always, as important as that of the operator.

That all of us should know, instinctively, how to cope with hemorrhage cannot be emphasized too strongly. There are doctors, and many at that, who either become flustered or are wholly incompetent when confronted with a severe case of hemorrhage. In connection with hemorrhage I cannot let this opportunity pass by without referring to the extraordinary results from infusion when practised properly.

It is not my purpose here, gentlemen, to describe the methods and technique of infusion or how to control hemorrhage. I merely want to attract your attention to a subject that above all others requires careful consideration by the medical fraternity.

SARCOMA OF THE NASAL CAVITY; LIGATION OF BOTH EXTERNAL CAROTIDS; DECIDED BENEFICIAL EFFECT.

By M. D. LEDERMAN, M.D.,

LECTURER ON DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC; ATTENDING AURAL SURGEON, UNIVERSITY MEDICAL COLLEGE DISPENSARY; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL, ETC.

Malignant disease of the nasal passages is happily not a frequent manifestation. Unfortunately its origin is so insidious that when symptoms arise which demonstrate its existence the disease has already assumed a formidable aspect. As the prognosis in such cases is usually of a serious character, we can only hope to alleviate suffering by employing strenuous measures. No remedy is so prompt in its action, nor so justifiable in its application in suitable cases as surgical interference; and as the latter, though extrinsic in my case, has had so marked an effect upon the pathological process, I offer this curtailed contribution, trusting it may prove of some interest.

Observers have reported instances of adeno sarcoma, fibro-sarcoma, myxo sarcoma, spindle-celled sarcoma, round-celled sarcoma, osteo-sarcoma, and rarely melano-sarcoma, invading this region. The round-celled variety probably appears most frequently. Sarcoma in this vicinity, if not stimulated by medicinal or mechanical irritation, is inclined to run a slow course. It is more often met with before the age of forty years, in a number of recorded cases presenting itself before the age of puberty, and terminating fatally after an average duration of from three to four years. It is claimed that the small round-celled type is the most malignant, developing very rapidly and prone to reappear even after it has been seemingly eradicated. The malignant nature of the growth grows less as the proportion of normal tissue elements in the structure of the tumor increases. The osteo-sarcoma is another of this group which grows with astounding pace. In a patient suffering from the latter form of the disease, whom I had the opportunity of examining, the tumor, which originally started in the nasal chamber, had eroded through the basilar portion of the occipital bone, extending into the maxillary antrum; into the ethmoidal and sphenoidal cells; through the floor of the orbit, causing pronounced exophthalmos, necessitating enucleation of the eye; descending through the soft and hard palate, appearing in the mouth. Attempts at extirpation were made before it had reached such enormous proportions, but they failed to arrest its growth. When last seen the neoplasm occupied the entire right side of the face. Morphine in ten-grain doses was taken as the only relief.

Direct surgical treatment in cases of sarcoma of the nasal passages should be carried out early and thoroughly. At times, however, we meet with patients in whom this procedure is not feasible nor justifiable, owing to the extensive spread of the disease. Such was the state of affairs existing in the case which I herewith report. The question naturally arises, what means are to be employed in similar conditions?

Dr. Coley has had some promising results from injections of erysipelas and bacillus prodigiosus toxins. Protonuclein has been recommended as being of service in diseases of a malignant nature.

As far back as 1849, Van Buren[1] ligated the right common carotid artery in a patient afflicted with sarcoma of the nasal cavity, attempting to retard the progress of the growth in this manner. Though the patient succumbed eighty-two hours after the operation, the tumor had already appreciatively diminished. Dr. W. C. Jarvis[2] mentions a cure of a similar case by ligation of both common carotids and the subsequent exsection of a portion of the superior maxilla.

The history of my case is as follows: Charles B——, varnisher, twenty-six years of age, was referred to me in May, 1895, by Dr. A. Mayer, for a growth in the nose, which he thought was malignant. For over three years the young man had repeated attacks of nose-bleeding, lasting for several hours, which were difficult to arrest, and compelled him to stop work. As a child he remembered having an occasional hemorrhage from the nose, and also recalled having colored blotches over his body (very likely some variety of purpura). He felt quite weak after the prolonged epistaxis, and had to rest before he felt able to resume work. Frontal headaches were very severe for two years past, and were the principal cause of complaint. Obstructed nasal respiration on the right side became annoying. Anosmia gradually followed, but no ocular disturbances appeared. At that time he was examined by a surgeon, who evidently recognized the disease, as he suggested exsection of the superior maxilla, with the possible enucleation of the right eye. To this Mr. B—— objected, as the eye had not troubled him in the least, and he did not suppose his affliction to be so serious a matter. The patient's general appearance aroused suspicion. He was cachectic and emaciated. On inspecting the nose a large fleshy mass was observed presenting at the right vestibule, the anterior and lower portion of the growth being of a grayish color. It was impossible to see the attachment, as the tumor filled the entire cavity. On attempting to locate same by means of a probe a profuse bleeding resulted. Cocaine was applied to arrest the hemorrhage and at the same time to facilitate the examination. On posterior rhinoscopy the growth was found occupying the right and left choanæ, being attached to the pharyngeal vault and upper portion of pharynx, and to the pterygoid plates of sphenoid bone. It almost encroached upon both Eustachian orifices, the hearing being slightly affected. Owing to a deflected septum to the left, no view could be obtained through this side anteriorly. There was some space on the left, posteriorly, along the floor of the nose, through which the patient was able to breathe.

Fearing a prolonged bleeding the galvano-cautery was employed in removing a portion of the tissue from the right side. A tampon of punk (surgical sponge) checked the copious bleeding which followed. Microscopical examination showed the specimen to be a small, round-celled sarcoma, with very little intercellular structure. As the disease was so extensive, a bad prognosis was made. Suggested some possible benefit from the use of the erysipelas and bacillus prodigiosus toxins. The patient received the first injection of two minims into the anterior portion of the tumor on the morning of May 25, 1895. Dr. H. A. Cohrs, of Brooklyn, who lived near Mr. B——, was kind enough to note the effects of the toxins during the interim. He informed me that the patient developed chills after leaving my office, and that they continued until he saw the patient at 2 P.M. same day. Mr. B—— had vomited several times; complained of violent pains in the back and joints, and of severe headache. The face was considerably swollen, and the conjunctivæ much injected. Temperature (rectal), 104.8° F.; pulse, 120. At 5 P.M: The vomiting had ceased; pain was less; temperature, 103.6° F.; pulse, 115. At 8 P.M.: Pain in joints and back absent; conjunctivæ normal; headache milder; temperature, 102.8° F.; pulse, 110. At 11 P.M.: Temperature, 101.8° F.; pulse, 100; was very restless; morphia sulph. (gr. ¼) was given by mouth.

May 26, 1895, 11 A.M.—Temperature, normal: pulse, 88; felt very weak; was not able to come to the office.

May 28, 1895.—Mr. B—— came to see me. He felt much depressed; had no appetite, and stated that his throat was very sore. This was due to an herpetic eruption, situated on the uvula and hard palate. The mucous membrane was swollen and painful. A similar lesion existed at the corners of the mouth. Odontalgia was also troublesome. Infection was quite marked in this instance. As the temperature had remained normal another injection of one minim was given. At 7.30 that evening the temperature was 101° F.; pulse, 90, and intermittent. Similar symptoms reappeared, but in milder form.

As the reaction was severe it was thought best to have the patient under daily observation, so he was placed in the Polyclinic Hospital.

On June 3d, 1.30 P.M., gave an injection of one minim. At 4 30 P.M., temperature was 103° F.; chills and nausea became pronounced. Whiskey administered on account of depression; headache became agonizing. Sulfonal given to promote sleep. Temperature receded to 99° F. the following day, and Mr. B—— felt more comfortable.

June 4th, 1.30 P.M.—Same quantity as last was injected. Similar train of symptoms arose. Temperature, 101° F. Cephalalgia became unbearable, and hypodermics of Magendie's solution had to be repeated daily. Iodide of potassium in ascending doses gave no relief. Patient refused further injections of the "toxins," so a surgical measure was proposed. He willingly acquiesced to any procedure that would offer some amelioration, as the headache caused him great suffering.

Drs. Wyeth and Dawbarn examined Mr. B——, and came to the conclusion that the attachments of the sarcoma were too extensive to permit of direct surgical manipulation. Ligation of both external carotid arteries was suggested as being justifiable in this case. Dr. Dawbarn kindly performed the double ligation; eight days intervening between the operations. The veins of the neck were found greatly engorged. Our patient made a good recovery, and left the hospital at the end of the month. At the time of his departure the headache was much improved.

Being advised to go to the mountains, he spent the remainder of the summer among the Catskills. There he lived on fresh albuminous food. His appetite promptly returned after reaching the higher altitude. On his return, August 27, 1895, the parts were examined, and I was surprised to find so decided a diminution in the nasal portion of the growth. It was about one-third of its previous size, and its attachments to the middle turbinated body could now be readily seen. Breathing, in a modified degree, could be carried out through this side, but it was still considerably obstructed owing to the mass occupying the posterior nares, which, though somewhat reduced, yet occluded the greater part of the choanæ. The breathing was better on the left side. The tumor seemed less vascular and more fibroid in character. Probing did not cause any bleeding.

As the patient was much improved, further local operative treatment was postponed. My intention is to remove the pendulous nasal mass with the cold snare, avoiding the possible stimulation of the disease, which might arise if the galvano-cautery wire was employed. Furthermore, direct treatment can now be attempted without starting what might previously have been a serious hemorrhage. As the collateral circulation increases, this danger is naturally augmented.

Mr. B——, in the meantime is taking an alterative tonic, and living on a nourishing diet. He is again able to continue at his work, having gained twenty pounds in weight.

New York, November 30, 1895.

THE ARMY RATION.

THE recent experiments of the United States Government to test the value of a concentrated army ration have quite naturally proved a failure. They were instituted by the Secretary of War with a view of reducing the bulk and weight of food without impairing its nutritive functions. This appeared to be necessitated by the fact that the American army is more in need of possible improvements in this line, in view of the heavy, tedious and long transportation of supplies across the plains and through districts that are incapable of affording the proper amount and quality of food in times of emergencies. The German army, for example, when moving in small bodies, always purchases supplies on the march as wanted. The same is true of the French, Russian, Austrian, and other European armies, but at the same time the soldiers usually have in their knapsacks what is called an "emergency" ration, generally sausage or preserved meat of some kind. The soldiers of the Japanese army in the late war with China carried an emergency ration of rice in a little tin case strapped to the top of their knapsacks.

The reports made by the different military departments to whom the questions were referred are interesting as bearing upon the value of food products generally, and on the physiological questions involved in the digestive and nutritive processes more particularly. Theoretically speaking it would appear that the problem had been solved regarding the amount of food necessary to sustain life and the varieties of sustenance that gave in minimum compass the greatest amount of nourishment.

All the observers agree, however, that the old-fashioned ration of bacon and hard-tack in suitable bulk is the most practical that has ever been suggested. The quantity of food necessary to keep a soldier in good condition is fixed at twenty-two ounces. The latter amount is increased for obvious reasons to twenty-six ounces.

When the theories were put to a practical test the result was as might have been anticipated. Various concentrated food tablets were employed in Colorado, but more than half the men who were victims to the experiment became candidates for hospital treatment. The following extract from the report speaks very significantly on some very essential and striking facts:

"A company of the Seventh Infantry, at Fort Logan, near Denver, was detailed and furnished with condensed rations, consisting of coffee, soup, bread, and bacon. The coffee and soup were in small tablets, which, when placed in boiling water, were ready for consumption in two minutes. The bread was in small flat cakes, the weight and hardness of a brick, but when moistened swelled out like a sponge. The bacon was compressed and needed only to be warmed in a frying-pan. The soldiers started out with ten days' rations, but the campaign was brought to an abrupt end after four days of fifteen-mile marches. The food not only did not satisfy the hunger or give strength, but seemed to irritate the stomach. After the first meal two of the enlisted men had to be placed under the surgeon's care. At the end of the second day thirty of the seventy men in the company were ill, and on the fourth day the whole command went into camp, and couriers were sent to town for hard-tack and ordinary coffee and bacon. Some of the soldiers were seriously ill with a stomach complaint, and were confined to the hospital for several days."

All this goes to show that not only very much is to be learned regarding laboratory feeding, but that we are also far from the proper appreciation of nature's complex requirements in food taking. Thus far the human laboratory, with its multiple, interdependent, and complementary methods, has a monopoly of its own in fixing the proper standards for digestion, assimilation, and subsequent growth. There is a natural law pervading the whole that must not be violated by too radical attempts at modification or improvement. The stomach pouch is constructed with a certain capacity for food which cannot be gainsaid by any chemical formula which mere human ingenuity may create or theoretical reasoning devise. Each of the varied and subtle processes of digestion must necessarily adapt themselves to the construction and functions of an organ that has a purely vital as well as a merely chemical duty to perform. The stomach must earn its living in its own way, as by such purely physiological effort in bringing each and all of its mechanical, vital, and chemical functions into play, it can best maintain its health, activity, and usefulness. No prepared or concentrated food can relieve it of any or all of its activities in that gradual conversion of a legitimate quantity and quality of food that constitutes a natural and perfect digestion. In such an aspect a moderately full stomach is something more than a feeling. Its work must be distributive rather than restrictive. It must be healthfully distended with food bulky enough to occupy spare places, otherwise its most important function is hampered, while for lack of mechanical stimulus the intestines become stagnated into almost helpless inactivity. Hence it is easy to see how the experiments failed, and the victims paid the penalty of outraged physiological laws. So far, at least, there is not sufficient reason, because a man becomes a soldier, that his stomach should be puckered around a desiccated soup tablet, or that it should wrestle alone, in some dark corner of an accommodating fold, with some soggy and glazed albuminoid.

Horseless Carriages are used by the country physicians in France.

QUESTION OF PRIORITY IN SERO-THERAPY.

THERE are many names honorably associated with recent discoveries concerning the immunizing and curative properties of the blood of immunized animals, and the future alone will determine, if it is possible ever to know with certainty, who was actually the first to state the doctrine of artificial immunity with an appreciation of its stupendous bearing upon modern medical science. But while the future will render the final judgment, the documents and the evidence must be presented now while the chief actors are still on the scene. One of the claimants to this honor is Professor Victor Babes, of Bucharest, who presented his side of the controversy in a communication addressed to the Academy of Medicine of Paris, early in the present year.

While Behring and Kitasato, he said, published their first communication on tetanus in the *Deutsche Medicinische Wochenschrift*, No. 49, 1890, the writer, in collaboration with Lepp, had established the same principle in relation to rabies in a paper published in the *Annales de l'Institut Pasteur* for July, 1889. He thought at the time that Richet and Hericourt were the first to immunize animals by means of serum from animals already immunized, but on reading again the works of these authors, he found that they had made no such claim. They inoculated rabbits with septicæmia and then treated them with the blood-serum of non-immunized dogs, and also of dogs which had recovered from a previous attack. They apparently, however, did not appreciate the significance of this experiment, remarking simply that the blood of these last dogs seemed to be more efficacious than that of the others. If, then, the claim of these authors to priority be disproved by their own writings, Babes holds that his must be conceded.

He quotes from his paper to show that he employed the serum of an immunized animal with a curative aim. His experiments were thus described in the article above mentioned. Four dogs with shaven heads were put into a cage with a mad dog, which bit them. Two of these dogs were untreated, the other two had received an injection of five grammes of blood from an immunized dog every day for a week. The two control animals were attacked with hydrophobia sixteen and seventy-eight days, respectively, after being bitten. One of the vaccinated dogs died a month after being bitten, but without having exhibited any symptoms whatever of rabies, and experiments showed that its brain substance was not virulent. The second dog lived many years free from disease.

We think the objection might hold that this was only a preventive inoculation and not an attempt at cure—a distinction with a difference when it comes to deciding a question of priority or determining whether the significance of a discovery was appreciated at the time it was made, in other words, whether it really was a discovery. Vaccination was employed solely as a preventive of small-pox for a long time before its value as a curative agent in the early stages of the disease was recognized. However, that Dr. Babes did soon recognize the actual curative value of the serum of immunized animals is evidenced by the fact that he used it the following year—in 1890—as a curative agent in man.

The discoveries which Professor Babes claims as his own, and upon which he bases his contention of priority, are the following :

1. That immunity against infectious disease, in this particular instance rabies, may be transmitted to susceptible animals by means of the blood of animals previously rendered in high degree immune to this disease.

2. That this method will effectively prevent the development of the disease even in animals that have been inoculated with the virus prior to the beginning of treatment.

The writer expressly disclaims, however, the assumption that Behring had based his work upon the discoveries made by himself in Pasteur's laboratory, which Behring might possibly never have heard of ; and he desires in no way to belittle the epoch-making labors of Kitasato, Ehrlich, Roux, and others, for without the researches made by them, he admits, his own discovery might have remained hidden and barren of results. But he contends that, in the recording of the part taken by individual workers in laying the foundations of sero-therapy, the future medical historian cannot in justice omit all reference to the part he himself has taken in it.

THE DENVER HEALER.

A MOST extraordinary social and psychological phenomenon has been exciting the population of Denver and the great Divide. A certain person, known as "Schlatter the Healer," has been the principal figure in it. The facts in the history of this man and his works have been published in the daily papers, and are probably pretty well known to our readers. This man, it seems, became possessed with the idea that he was a second Messiah, and that he was sent to the earth with healing powers. He passed a long period of solitude and deprivation in the Arizona deserts, and then came to Denver, where he announced his mission. He talked, dressed, and acted in a curious and eccentric fashion, so that public attention was soon called to him, and he was helped to carry out his work of healing by the assistance of an enthusiastic friend. Schlatter's fame as a "healer" soon spread throughout the West, and people flocked to him from distant regions, with the result that the business of the railroad companies running into Denver was distinctly increased. It is reported that he saw and treated many thousands of people daily. The Denver "healer's" methods were very simple. He stood at one side of a fence which enclosed the house where he lived, while the people who came to be healed passed slowly by in a row on the other side. He took each one by the hand and uttered some words of promise, direction, and encouragement. Schlatter's views as to his powers were very ingeniously adapted to this kind of treatment, for he did not claim to cure at once, but told the people that they would get well after a few days or a few weeks or a few months. Naturally, among many thousands of people who went through this curious ordeal, a certain per cent. would get well, either by mental influence or the natural course of events. The peculiar mysticism of the man, his apparent unselfishness, for there seemed to be no money-making in connection with the work,

lent a somewhat additional credence to his claims, and his popularity and fame were growing steadily, up to within a few days from the time of the present writing, when he suddenly disappeared, leaving the message that his work was finished. Nothing could have been more dramatic or better timed than this sudden breaking-off in the very height of his popularity. So far as reports go, it seems that Schlatter would very soon have far out-done the healing springs of the waters of Lourdes, and there is, in the history of this curious man, something quite as surprising and interesting as that connected with the French faith-curing resort. As to the reality of his cures, however, or the percentage of them, we are told by the Rev. Mr. Heisler, of Denver, who has investigated the matter, that very few real cures, even of fanciful ailments, have taken place, and Mr. Heisler is of the opinion that Schlatter is by no means what he represents to be. Most people, however, we believe, take the view that he is a self-deluded enthusiast, and more or less insane. From the accounts that reach us, it would be fair to conclude that Schlatter's is a case of what is known to alienists as "paranoia religiosa," and the pictures that are given of him represent quite distinctly the degenerative physical characteristics of a well-marked paranoiac.

THE MORTALITY OF MEDICAL MEN.

Dr. Cortright, in the Brooklyn *Medical Journal*, has written a paper on the "Mortality and Causes of Death in Medical Men." This paper is based on the records of four hundred and fifty physicians who died in New York and Brooklyn during the past eight years. The average age of death was 54.6 years, and the mortality was about 25.23 as compared with a mortality of 15.93 in clergymen and 20.23 in lawyers. There is a considerable mortality from the self-administration of drugs; that from consumption is about half the general rate, while that from typhoid fever is very high. There is a high death-rate due to arterial sclerosis and other degenerative changes.

The practical conclusion deduced from Dr. Cortright's statistics, says the *British Medical Journal*, is that doctors should take at least three weeks' complete rest and change yearly, should be extremely moderate in the use of stimulants, should be regular in their meals, never worry and never hurry. This is the kind of advice that doctors give, but do not take. The further suggestion, however, that they all join some medical sickness and life assurance society, is a wise one.

STIMULANTS FOR ATHLETES.

The alert mind of the modern drug manufacturer has not failed to take note of the extraordinary interest and widespread indulgence in athletics and sports of every kind. The bicycle, field and track athletics, foot-ball, golf—all these things have increased enormously the number of contests in which the person who has the greatest physical vigor and endurance wins. It has occurred naturally to the pharmaceutist, therefore, that some substance which would make the competitor in athletic sports keep his wind and his strength a little longer would be eagerly seized upon. We hear already of bicyclists who use various coca and kola compounds in order to help them in their work. It is even rumored that preparations of cocaine are consumed to some extent. We feel sure that all true athletes would disdain any such injurious and adventitious aids, but there is a vast number of persons who take such things thoughtlessly and injury is done thereby. The announcements which are made in advertisements of various stimulants, in which it is claimed that they save the strength and promote the endurance of bicyclers and athletes generally, are very much to be deprecated. There are no drugs which will help one to win a game that could not be won without them, and the general effect of drug-taking, and especially of the use of drugs belonging to the caffein and cocaine class, is distinctly bad. We believe that the medical profession ought seriously to warn those with whom they come in contact professionally, against the use of such things.

"THE PASSING OF HYPNOTISM."

The *Journal of the American Medical Association* has an editorial, the general trend of which is to show that hypnotism has had its day, and is practically being laid upon the shelf, or, at least, its use confined to irregulars outside of the recognized school of medicine. This is a rather curious statement to make, at least, if one measures the interest of a medical topic by the number of articles written about it. There are few subjects about which German physicians are writing more monographs at present, or in which they seem to take a more active interest. The sensational side of hypnotism is certainly dying out, but a certain practical side, which is represented by the word "suggestion," has undoubtedly come to stay, and to be used in therapeutics.

GREEK AS THE LANGUAGE OF MODERN MEDICINE.

Dr. Achilles Rose is to be congratulated on having won over another adherent to his cause. The *Post-Graduate* devotes a page of editorial to pleading for the use of modern Greek as an international language. "What a start medical science would take," it says, "if we could have a congregation of doctors from various sections of the earth who could address us in a language known to all."

Fibroids Cured by Extract of Thyroid Gland.—Jouin (*Bulletins et Mémoires de la Soc. Obst. et Gynéc. de Paris*, No. 8, 1895) states that he has successfully treated several cases of myoma of the uterus by doses of Nielsen's dry extract of sheep's thyroid gland. He gives four to eight tablets daily, equivalent to half a thyroid gland. Out of five cases, the two which have been fairly long under treatment have distinctly improved in health. In the first case the tumor has distinctly diminished in size. Menorrhagia is much diminished by this treatment. In other classes of patients, hæmorrhoids present in at least one case were greatly relieved.

News of the Week.

Prostatic Catheter.—Shove me little, shove me long.

Influenza in London.—Influenza has reappeared in London and is becoming daily more prevalent. In this city there is not yet any special development of the disease.

A Freak of Nature.—A young woman living in Paris recently gave birth to a child whose eyes were placed on the top of its head. The infant seems to be doing well and crowds of people have tried to satisfy their curiosity by visiting the house.

Death of Dr. Richmond Lennox, of Brooklyn.—Dr. Richmond Lennox died on November 14th, aged thirty-four. He was a graduate of the Polytechnic Institute and of the College of Physicians and Surgeons of New York City.

Medical Mission Work in China.—Referring to the recent Szchuan riots and massacre, the *China Medical Missionary Journal* says: "Foolish and exaggerated statements of the esteem in which the foreign doctor is held in China, a too exclusive dwelling upon successes and their impression on the populace, has caused people to forget that there are two sides to this shield. While on the one side it is undeniable that medical work operates powerfully to remove prejudice and hostility, yet on the other side it must never be forgotten that it gives, and must give, however cautious one may be, abounding opportunities to ignorant and superstitious and malignant people to spread all sorts of evil stories. The removal of an eye to arrest sympathetic ophthalmia, or the amputation of a leg for a compound comminuted fracture, are deeds which, though they may be absolutely necessary, are powerful for either good or evil, and one can never be sure in which direction they will operate. This is true not only of hospitals conducted by missionary medical men, but also of those benevolent establishments to which so many port doctors freely give their services. Now, there can be no question that in Szchuan ugly stories were afloat about the hospitals and the doctors."

The New York State Association of Railway Surgeons.—This Association held its annual meeting in New York City on November 12th, Dr. R. S. Hardin presiding. The president, in his address, advocated strongly a co-operative system between railway managers and employees, whereby hospitals may be erected along the railroads, and medical services rendered to injured passengers, as well as the employees themselves. A tax of one cent on each dollar of an employee's monthly salary, and a contribution of the railway management, would be sufficient to put up hospitals, sustain them and pay funeral expenses, provide expert service, and furnish a relief fund. The association indorsed the views of the president. Another point considered by the president was the transportation of persons suffering from infectious and contagious diseases. Instances were given of the loss of life resulting from passengers contracting scarlet fever and other diseases during railroad travel. The hangings and furnishings of the American sleeping-cars were criticised as being liable to become infected with the germs of tuberculosis and other diseases. It was suggested that there be isolation cars, and that certain compartments might be arranged like those of the quarantine or operating wards in a hospital—compartments which could be thoroughly cleansed and disinfected, and in which infectious cases could be transported. A paper was read by Dr. W. L. Estes, of South Bethlehem, on "Multiple Synchronous Amputation." The writer advocated immediate amputation in all cases where the injured person is not too weak. The subject of "Shock" was discussed, and the use of strychnia recommended, some preferring that to the administration of whiskey and brandy.

Judge Dailey, of Brooklyn, read a paper which did not seem to meet the sympathetic approval of his audience. He cited instances in which railway surgeons had overstepped their professional duties in order to adjust claims and accidents advantageously to their employers. He stated that this practice of taking notes for the benefit of their employers, and to be used against the injured persons in prospective trials, was illegal as well as immoral, and that railway surgeons rendered themselves liable to criminal prosecution thereby. Dr. George Chaffee agreed with the speaker that the railway surgeon had no right to perform any legal functions. The officers elected for the ensuing year were as follows: *President*, Dr. C. S. Parkhill, of the Erie Railroad; *First Vice-President*, Dr. J. F. Valentine, of the Long Island Railroad; *Second Vice-President*, Dr. J. K. Stockwell, of the Ontario and Western; *Secretary*, Dr. C. B. Herrick, of the Delaware and Hudson Railroad; *Treasurer*, Dr. Theodore S. Mills, of the Ontario and Western; *Chairman of the Executive Board*, Dr. George Chaffee.

Death from Sin and Fear.—The papers report the case of a child living in Anderson, Ind., who was attacked with diphtheria. During the course of the disease the child was attended by a Christian Scientist. The patient died and the Scientist made out a death return, "Died from sin and fear." The authorities made an investigation and found that the child had died of diphtheria. It was also found that the "doctor" and the parents had relied upon faith entirely in the treatment of the disease. Warrants have been issued for the arrest of both the parents and the "doctor."

Dr. John Ridlon has been appointed orthopedic surgeon to Michael Reese Hospital, Chicago.

The Moscow Congress.—Dr. A. Jabobi writes that it has been decided to hold the International Medical Congress in Moscow, August 7 to 14, 1897, instead of in 1896, as was originally announced.

The New Orleans Polyclinic.—Dr. Isadore Dyer writes that a statement in the prospectus of a newly established school, that there is no post-graduate medical school south of Philadelphia, is incorrect, for the New Orleans Polyclinic is a flourishing institution that has been in existence for eight years.

The Alert Managers of Certain Mineral Springs in France have already discovered that the new elements argon and helium exist dissolved in the healing waters which they sell.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in Washington, D. C., November 12, 13, and 14, 1895.

THE Association met in the banquet hall of the Hotel Shoreham, at 10 A.M. Tuesday, November 11th, and was called to order by the President, DR. L. MCLANE TIFFANY, of Baltimore, Md.

Address of Welcome.—DR. H. C. BUSEY, of Washington, delivered an address of welcome on behalf of the medical profession of the District of Columbia. In his closing remarks, Dr. Busey said: I solicit your aid and co-operation in our effort to secure the protection of our people from the horde of impostors and charlatans which you have driven from your borders by the enactment and enforcement of medical-practice laws, and which has made the District of Columbia a common rendezvous, where the most atrocious methods of the charlatan and mercenary impositions are openly and flagrantly committed to the wrong, injury, and robbery of its citizens. You represent the most influential and intelligent class of suffragists, for whose aid on the hustings and at the polls we plead.

To state the deplorable condition of this District fully and broadly, there are five medical schools and several medical societies chartered by acts of Congress, or under the general incorporation law authorized and empowered to license persons to practise the art and science of medicine, without any uniform, and, by some, without any standard of qualification beyond the ability and willingness of the applicant to pay the required fees or give promissory notes for such payment; and, under the provisions of the general incorporation law, any dozen of persons can obtain a charter upon payment of the fee for recording the same, authorizing them as a body corporate to confer the degree of M.D. at their pleasure and will. Such is the status of this Federal territory, which is under the exclusive jurisdiction of the highest tribunal of legislation in the land, made up of the representatives and Senators from forty-nine States and Territories, which have enacted medical practice laws for the protection and welfare of their citizens. Take these facts home with you, and re-echo them throughout the length and breadth of the land, that such criminal neglect, not less disgraceful and scandalous than the slums of vice, may not continue to afflict the citizens of the Federal territory.

PRESIDENT TIFFANY responded to the address of welcome for the Association.

After some announcements had been made by DR. JOSEPH TABER JOHNSON, of Washington, Chairman of the Committee of Arrangements, the reading of papers was taken up.

Personal Experience in the Treatment of Stab Wounds of the Intestines and Peritoneum.—DR. ALFRED BROWN, of Alexandria, Va., read a paper on this subject. At the outset the author stated that about one hundred and thirty cases of stab wounds of the peritoneum and intestines had come under his care during his entire professional experience in both private and military practice. In less than one-third of the cases the intestines were wounded. It is a little remarkable, said the author, that there should be such a disproportion in the number of intestinal wounds in these cases; in other words, it is a singular fact that in a large majority of abdominal wounds the intestines escape injury, even when such wounds are extensive. Transverse and longitudinal stab wounds of the intestines were then considered at length. Dr. Brown regards the sabre wound as one of the most dangerous in its immediate and remote results. If the edge and point of the sabre are sharp, the wound inflicted is large and deep. The weapon, cutting through the intestines and mesentery, usually passing through the abdomen, severs large blood vessels and causes frightful hemorrhage, which is speedily fatal. He had only seen three sabre wounds of the abdomen, and they ended fatally in a brief time. The stiletto is a dangerous instrument, as it almost invariably enters an intestine or other organ. It does not kill by hemorrhage usually, but makes an opening in the intestine sufficiently large to permit the escape of a small quantity of fecal matter, causing septic inflammation. It is one of the most difficult of all intestinal wounds to detect.

The diagnosis of intestinal wounds was then dwelt upon, reference being made to Senn's hydrogen-gas test to detect wounds of the intestine. While he considered it a useful test, in remote sections of the country, far from large cities and towns, it is not practicable because of the impossibility of procuring the apparatus and generating the gas. In all abdominal stab wounds the author's rule has been, after cleansing the hands and thoroughly disinfecting them to insert the index finger and explore the intestine, to ascertain if there is an opening. In certain cases a wound may exist in the intestine, but it may be so small as to escape detection. But if the intestine is wounded, whether we can insert the finger or not, there is always more or less extravasation of fecal matter and gases, and if the finger comes in contact with this matter, it is certain to retain for a length of time the peculiar odor of human fæces. This will always afford positive evidence of an intestinal wound.

In treating simple wounds of the peritoneum, the author's rule has been to close them with silver-wire sutures after thorough disinfection. Formerly he closed these wounds without regard to antiseptic measures, except that the wound was washed with hot water and soap. On the battle-field and in field hospitals, wounds were washed with any water that was convenient, and were not washed at all when water could not be obtained. Previous to the introduction of antiseptic treatment in dressing wounds but little attention was paid to the condition of instruments, sutures, sponges or dressings, except the practice of ordinary cleanliness, and the percentage of cases of healing by first intention of simple wounds of the peritoneum was large. In dressing simple wounds of the peritoneum scrupulous attention should be paid to the laws of cleanliness. In treating wounds of the intestines two vital procedures are necessary, one is a complete and thorough closure of the intestinal wound; the other is to cleanse the peritoneal cavity of all fecal matter, blood, and gases escaping from the intestine.

Dr. Brown then described a simple method of reducing a protruded intestine in stab wounds. He takes two long slender curved needles, threaded each with a silken cord ten or twelve inches long. One of these needles is passed midway through the margin of the wound, the other needle is passed through the opposite margin and then each cord is tied in a separate loop. These cords are drawn in opposite directions by two assistants, upward and outward, firmly and tightly. By this means the wound is made to expand or gape widely and at the same time the walls of the abdomen for a large area around the wound are very considerably elevated above the intestines, while the patient reclines in the dorsal position, and a considerable vacuum is in this way created and the intestines will glide back without force or manipulation to fill this newly created vacuum.

DR. RICHARD DOUGLAS, of Nashville, said that in peritoneal wounds we always have a mixed infection, which is more serious than an infection from the colon bacillus. Peritonitis, whether local, adhesive, general or septic, should be considered of germicidal origin. In closing the abdominal wound, he thinks it is proper to always approximate the peritoneum, as by so doing we lessen the danger of hernia.

Dr. C. A. L. Reed, of Cincinnati, expressed himself as being apprehensive about mere exploration with the finger to detect stab wounds of the intestines. However erudite the tactile sense of the surgeon may be, at times it would prove misleading, and therefore in certain cases it was exceedingly important to enlarge the original incision or wound, and that part of the viscera lying immediately beneath it should be brought out and carefully inspected. He believes with Dr. Douglas that the peritoneal margins should be carefully approximated.

Dr. James Evans, of Florence, S. C., related an instance where nine men had received chest wounds by the bayonet during the war, the bayonets having been previously stuck in the ground, and yet all of the men recovered. He attributes their recovery to the form of wound made by the bayonet. In another case, a man had been shot within half an inch of the navel. He had no rise of temperature, yet when he saw the patient the omentum had extruded to the size of both his hands. He applied a double ligature, then put a piece of adhesive plaster over the surface, and the man recovered. He had frequently seen gunshot wounds of the abdomen during the war in which there was extravasation of fecal matter through the wound, but unaccompanied by shock.

Dr. A. Vander Veer, of Albany, had always made it a practice to first inquire carefully as to the kind of weapon by which the wound is made. He had seen several of the wounds inflicted by bayonets during the war, but does not remember of having seen the intestines or stomach penetrated by them. There should be no delay in treating stab wounds. The surgeon should act promptly and not wait for symptoms to present themselves. Just as a case of perforative appendicitis will terminate fatally in a short time, so will stab wounds of the intestinal tract, unless timely interference is resorted to.

Dr. Hugh T. Nelson, of Charlottesville, Va., said the necessity of enlarging the abdominal wound, under all circumstances, was an imperative one. Four years ago he saw a case in which the small bowel was wounded by a knife and the patient refused operation for twenty-four hours, believing that this viscus was not cut. Symptoms became alarming, and the patient finally consented to have an operation performed. Dr. Nelson opened the abdomen by a long incision, finding it impossible to remove from the peritoneal cavity the extruded contents of the bowel, owing to the fact that an adhesive inflammation had taken place and had agglutinated them to the bowel so firmly that he could not wash them away. He attempted to resect the peritoneum into the pelvic cavity where the fecal matter had burrowed, but could not do so. Peritonitis became general and the patient died. The sooner the abdominal incision is enlarged in stab wounds the better.

Dr. George Ross, of Richmond, asked whether there was any way of distinguishing between the symptoms of nervous shock and shock due to hemorrhage.

Dr. Brown replied that one of the most unerring symptoms was rapid reduction of temperature, but there was no symptom that would enable the practitioner to distinguish accurately between the different forms of shock except the gravity of the condition.

Dr. W. E. B. Davis, of Birmingham, desired to speak of the point in reference to injuries of the gall-bladder. The essayist referred to the fact that injury to this viscus would produce a septic peritonitis. An injury that would produce peritonitis would result in death very soon if there is a large escape of bile into the peritoneal cavity, but Dr. Davis does not believe it is a septic peritonitis. He believes that in the majority of cases the shock following abdominal injuries is due to hemorrhage, and that hemorrhage plays an important rôle in the production of symptoms in these injuries. It was the hemorrhage from these wounds that frequently caused death.

Dr. John D. S. Davis, of Birmingham, expressed himself in regard to the diagnosis of intestinal wounds, as having very little confidence either in Senn's hydrogen-gas test or the flushing method spoken of by the essayist. He had seen perforative wounds of the abdominal viscera where it was impossible from their character and location to flush the abdominal cavity through the opening sufficiently to thoroughly clean it. In addition to the three forms of shock mentioned by the essayist there should be added the shock of sepsis.

Dr. Brown, in closing, agreed with Dr. W. E. B. Davis, that all cases of violent or dangerous shock were due to hemorrhage. In regard to approximating the peritoneum, he had always left it untouched in closing simple wounds in the abdominal wall, and had found it good practice.

Report of Seven Cases of Abdominal Surgery in which the Murphy Button was Applied.—This paper was read by Dr. A. Vander Veer, of Albany, N. Y. The author stated that the seven cases he desired to present had a bearing upon the use of the Murphy button, which is now receiving attention both in this country and abroad, and as a method of intestinal anastomosis is being placed thoroughly on its merits. It is difficult to understand some of the unfavorable reports made by English and German surgeons, when we contrast the very successful results indicated by so many of our American operators, in the practical application of this mechanical device. Perhaps there is no part of surgery that within the past quarter of a century has presented so much in theory, and in which there has been so much disappointment, when practical use has been made of the suggestions, as in the field of abdominal work with all its complications. In other words, how much we have changed from time to time our methods of treatment of many complications, and yet withal there have come certain reliable advances that have met all requirements for which they were indicated, leaving permanently in our possession the comforting thought that a grand progress in the sum total has been made; that we can treat all manner of pathological conditions, traumatisms, malformations, etc., of the intestinal tract and abdominal cavity with less embarrassment than perhaps in any other part of the body, and yet there are very few portions of the human system upon which we operate where more rapid thought and best judgment are to be employed than in abdominal work.

Case I.—The first case was one in which gastro-intestinal anastomosis was made for carcinoma of the pyloric end of the stomach by means of the medium-sized Murphy button, between the upper end of the jejunum and greater curvature of the stomach. Patient was comfortable after the operation, but died from exhaustion on the third day.

Case II.—Case II. was carcinoma of the sigmoid flexure, removal, and end-to-end anastomosis. Operation consisted of removing a mass in connection with the sigmoid flexure three inches in length and an anastomosis of the large intestine by means of the button. Cause of constriction was found to be carcinoma. Patient died from exhaustion on the eleventh day, but was much exhausted and emaciated previous to the operation.

Case III.—Removal of gall-stones from the gall-bladder, using the long drainage-tube button. Recovery.

Case IV.—Removal of eight inches of the small intestine with papillomatous ovarian cyst. End-to-end anastomosis by the button. Perfect recovery.

Case V.—Anastomosis of the gall-bladder with small intestine. Recovery.

Case VI.—Operation revealed a tumor the size of a cocoanut in the immediate vicinity of umbilicus, a portion the size of a silver dollar implicating the umbilicus and in a gangrenous condition. On making an incision there was found a strangulated hernia and many old and firm adhesions. Peritoneum intensely con-

gested; very dark in color. Loop of small intestines included in tumor and gangrenous for space of ten inches. Vessels in mesentery secured, and this portion of the intestines excised. Murphy button used for end-to-end anastomosis. Button passed thirteen days after operation, followed by a large movement of the bowels. Uninterrupted recovery.

Case VII.—A diagnosis of biliary calculi was made in this case. Dr. Vander Veer made the usual incision for exploration of the gall-bladder, found it containing about two ounces of bile, and through the walls and down into the cystic duct could be felt a number of small calculi. There were some adhesions. He made use of the long drainage-tube button to the fundus of the bladder, and closed the wound, after a careful examination for any possible cancerous mass, which was not found to be the case, then placed the patient in bed. He regarded the use of the button in this instance as a saving of time, leaving the patient in good condition for removal of the gall-stones later. Several days after he had made the exploratory incision the attending physician removed five irregularly shaped calculi, which Dr. Vander Veer exhibited. At this time the patient began to show marked symptoms of cerebral anæmia, with delirium, which continued, patient finally passing into a comatose state and died, temperature just before death reaching 105.5° F.

Dr. Vander Veer said that although the cases he had reported were not many, yet they covered a field in which the Murphy button might be made use of so readily and easily, and the result so satisfactory, that he had considered them worthy of attention as having a bearing upon statistics. He believes he had given a just criticism of the accumulation of facts, so that we could reach and determine definitely as to the value and usefulness of this contrivance. The Murphy button will not answer for every lesion about the intestinal tract, but surely has its sphere of usefulness, being clean, easily handled, and saves the patient from a much longer operation, when time alone is the great desideratum, which cannot be secured by some of the other methods.

Intestinal Resection and Anastomosis.—Dr. H. H. Grant, of Louisville, said there had always been a division of judgment upon the question of immediate suture in acute obstruction or injury requiring resection of the intestine, which even the improvements in technique and means of aid in operative work have not adjusted. The members were all familiar with the Murphy button, and doubtless many had employed it. What it is intended to do, it does well; but too often it does what is not intended, and disaster and death result. There is abundant evidence that it becomes a foreign body; that it occasions spreading necrosis, which involves the peritoneal coat; that recontraction takes place after lateral anastomosis; that fatal results are frequently directly attributable to its use, besides other less important objections.

Lateral anastomosis is now beyond all question the most acceptable method of resection of the continuity of the bowel, if we exclude the button. It is best to accomplish by direct suture, and direct suture is of difficult execution except in very skilled hands. In order to facilitate this suture, Dr. Grant presented a device for clamping opposing surfaces of the bowel, cutting off fenestra between them, and retaining them so opposed until the suture can be completed. He then demonstrated the *modus operandi* of his device.

He had experimentally used the clamp sixteen times, with fourteen consecutive recoveries, but had had but one opportunity to use it in practice. On May 25th he operated on Mrs. E——, aged fifty-three, who had a fecal fistula at the right femoral opening, the result of a strangulated hernia, operated on eight months ago. An incision was made just above Poupart's ligament, near the fistulous opening. The fingers easily liberated the intestine, which presented an opening occupying half its lateral surface and as large as a quarter of a dollar. The mesentery was greatly thickened; the distal segment of the bowel was reduced in size, the proximal dilated at the site of the fistula. About four inches of the intestine was resected; the blades of the clamp were applied opposite the mesenteric borders of each segment, and the anastomosis made as above described. After suturing, the communication between the opposing surfaces was found ample. The cut ends were then invaginated and the anastomosis returned; the abdominal wall closed with silkworm-gut sutures; the site of the fistula curetted and filled with iodoform gauze, and the patient put back to bed in forty-two minutes. There was very little shock. At the present time the patient is well.

The advantages of this method over the other aids, except the button, are manifest. Not only does it do away with the foreign body, but cuts an opening three or four inches long at the fenestra. It is fully as easily accomplished and takes less time. It is no more difficult to use than is the button, but the operation cannot be so quickly completed, as the invagination of the ends is not necessary after the end-to-end approximation by the button. The clamp merely makes direct suture easy to any ordinarily skilled hand.

Dr. C. A. L. Reed said experience would establish the fact that the Murphy button ought not to be used in approximation of the large intestine, for the reason that the intestinal contents were not sufficiently liquid to pass through the small opening in the button. In the small intestine it is different. There we have liquid contents that will pass through the opening in the button and the approximation is satisfactorily accomplished. Dr. Reed reported a case of resection of the sigmoid for malignant disease (which terminated fatally) in substantiation of the above remarks, the anastomosis being made by means of the Murphy button. He commended the device presented by Dr. Grant, and although he preferred the end-to-end procedure, he would try the device in the next case in which he performed lateral anastomosis. Cholecystenterostomy by means of the Murphy button was one of the easiest, neatest, and altogether most satisfactory operations known to surgery.

Dr. Joseph M. Mathews, of Louisville, said he had taken occasion more than once to call attention to the difficulty that attends diagnosticating tumor of any kind in the sigmoid flexure. Time and again he had been mistaken, as he believed others had, in supposing that he had malignant tumor of the sigmoid when he had not, and supposing, on the other hand, that he did not have when he really did. A few years ago a patient was brought to him from an adjoining State, and from evidence outside of palpation he believed that the man had malignant trouble of the sigmoid flexure. A few days thereafter he was taken to Chicago, was examined by a very eminent surgeon, who positively stated that there was no tumor of any kind in the flexure, and advised the patient to go home and go to work. In less than a week the man was dead. Autopsy revealed carcinoma of the sigmoid flexure. His reasons for opposing resection of the sigmoid and making anastomosis by the Murphy button were in substance the same as Dr. Reed's. Cancer in the sigmoid flexure was not only usually attended by systemic infection, but there is an involvement of other organs and tissues of the body. He would therefore ask, could a man live any longer after a surgeon had removed the tumor than he would if it was left untouched? Granting that there is total obstruction, would it not be better to perform colotomy and let the man live out his allotted days with cancer in a more pleasant way than he would if an operation were done? In lieu of this, it had occurred to him that the plan suggested by Dr. Bacon, of Chicago, of anastomosing the colon to the rectum, leaving the growth there, would be a more favorable operation than extirpation of the carcinoma.

Dr. A. M. Cartledge, of Louisville, said in doing a cholecystenterostomy there was not much time saved by using the Murphy button, and it was not as useful as the ordinary method of suturing. He thought this was well illustrated in one of the cases reported by Dr. Vander Veer, in which there was a passage of stones after the operation, and where it was necessary on account of the extremely feeble condition of his patient. In cases with numerous small calculi extending into the cystic and common ducts, he had made a comparatively large incision in the gall-bladder and sutured it to the peritoneum, where the stones could not be removed, and they would then pass for days externally through the drainage-tube. The orifice in the button is too small to permit the stones to pass, whereas they would escape through a drain and come out. He expressed himself in favor of Dr. Grant's device, and considered it an excellent one for lateral anastomosis.

Dr. W. E. B. Davis believes the Murphy button can be used to advantage in intestinal work where it is necessary to do operations quickly; otherwise the method of stitching, similar to that practised by Abbe, is better, is more certain, and accidents are not so likely to follow it as by the use of a mechanical appliance which is non-absorbable. Cholecystenterostomy by the button should be resorted to only in those cases where it is impossible to remove the obstruction in the common duct. The old method, as pointed out by Dr. Cartledge, is decidedly better in the other class of operations.

Dr. Vander Veer, in closing, was satisfied that end-to-end anastomosis with the button in the large intestine was not likely to be a satisfactory procedure, inasmuch as the calibre of the button was such as not to permit of the passage of hardened fæces through it, while in the small intestine the fæces would easily pass through the orifice in the button. He believed Dr. Grant had presented an appliance that would be of value to the profession. The fact that new devices were being presented from time to time before medical gatherings for intestinal anastomosis was ample evidence that we had not yet reached an ideal method. The Murphy button is an excellent device in the performance of cholecystenterostomy and other operations.

Dr. Grant believes that any surgeon of ordinary skill with his device, after having the two surfaces of the bowel directly opposed, can suture them without soiling the peritoneum or letting them slip away.

Surgical Interference in Rectal Disorders.—Dr. J. McFadden Gaston, of Atlanta, Ga., read a paper on this subject. After outlining the anatomy of the rectum, the author said it is a mooted point in regard to the practicability of eradicating rectal troubles of syphilitic origin by medication, and with the present light on the subject it seems justifiable to resort to such a surgical measure as the condition indicates, while constitutional treatment is being carried out in the case. There are instances of supposed development of specific disease in the form of stricture of the rectum, after the lapse of many years subsequent to any syphilitic contamination, and some authors claim their ability to diagnosticate specific stricture even without a previous history of primary syphilis. Strictures of the rectum from fibrinous depositions in its walls call for division or excision of the structures involved. When carcinomatous induration of the rectal tissues is detected early, there is encouragement to undertake an operation, but after the breaking down of the neoplasm with infiltration of surrounding structures, no benefit is derived from excision of the parts involved. The rectum affords material for surgical work of the most important character, and it should not be relegated to those professing to deal with so-called orificial surgery. Dr. Gaston is fully impressed with the conviction that many cases find their way into the hands of quacks which ought to be treated by members of the regular medical profession, and preferably by those who have made a special study of rectal diseases and are prepared to treat properly all the surgical disorders of the rectum. Reference was then made to a paper by Dr. Gerster, read before the American Surgical Association, upon the surgery of the rectum, in 1893.

The burning and urgent appeal to the surgeon today is for a definite settlement of the issue as to active interference in cases of pronounced cancer of the rectum. Shall we content ourselves with the mere palliative measure of inguinal colotomy and leave the diseased structures untouched, as urged by Dr. Mathews in his paper before the American Medical Association, or shall we endeavor to remove all the tissues involved by extirpation, as recommended by Dr. Gerster? The full statistics of results in the hands of skilled operators ought to be collected and a fair analysis made before a final adjudication of the question can be reached. The materials for such a comparison should be obtained from cancer hospitals in this and other countries, as well as from general hospitals receiving and treating this class of patients, and being grouped together a fair inference may be drawn as to the feasiblity of active interference in any case of carcinoma of the rectum.

Dr. J. M. Mathews said the essayist incidentally alluded to fissure of the rectum giving rise to reflexes. He was glad he mentioned this simply to emphasize the point, that to have reflexes from the rectum we must have a pathological condition. The so-called orificial surgeons had run wild with reflexes from the normal rectum, and as a consequence many respectable citizens in his own city had lost healthy rectums. In regard to stricture of the rectum, his observation has been that benign rectal stricture is very seldom met with. There were cases, however, mentioned by authorities, but Dr. Mathews had failed to find them. If he does find it, it is simply an annular constriction of the mucous membrane, which is easily dissipated. It does not require excision. When the surgeon introduces his finger into the rectum and finds stricture there, it betokens one of three serious diseases—syphilis, tuberculosis, or cancer, and the patient should not be turned aside with a jesting remark that he has a rectal stricture. It is a serious thing. He maintains that sixty per cent. of the cases of stricture of the rectum arise from syphilis, or are the result of it. He had asked his professional friends to investigate this matter and make known their investigations. The responses he had received were nearly all in the affirmative. He regards stricture of the rectum as more frequent than either cancer or tubercle.

With reference to excision of the rectum for a cancer that has blocked the rectum to the sigmoid flexure, in nearly every instance we have systemic infection. This being the case, can the man be cured by surgical interference? He wished, like Dr. Gaston, we could successfully remove the rectum for cancer, but he doubts it.

Dr. H. M. Nash, of Norfolk, Va., had seen a number of cases of ulcer of the rectum cured by dilatation of the sphincters and topical applications. He uses the Sims speculum, placing the patient in the exaggerated Sims position, which gives the operator all the room he wants for manipulation in the rectum.

Dr. Gaston, in closing, congratulated Dr. Mathews on his attitude of masterly inactivity in a great many cases of carcinoma of the rectum.

Surgery of the Biliary Ducts.—Dr. W. E. B. Davis, of Birmingham, Ala., contributed a paper with this title. He reviewed the operative procedures practised on the biliary passages, and recommended for cases of obstruction from stone in the common and hepatic ducts that the obstruction should be removed, and that no attempt be made to suture the incision in the duct or ducts. His experiments with animals had demonstrated that the field of operation will be walled off, and that

no general inflammation will occur after this treatment. He had tested the value of gauze in draining bile in injuries of the gall-bladder and ducts, and reported cases where he had removed the gall-bladder without tying the duct by packing with iodoform gauze. The animals got well. In other instances where he incised the gall-bladder and ducts and packed with gauze around the openings, no stitches being used, the animals recovered. Complete walling off of the general cavity was noted when the abdomen of the animals was reopened. The experiments of Dr. Davis demonstrate conclusively that the peritoneum is capable of taking care of a small amount of bile, but that large quantities or the constant extravasation of it will produce a fatal peritonitis usually in from twenty four to forty-eight hours.

Management of Cases which have Recovered from Appendiceal Abscess in which the Appendix was not Removed.—Dr. John D. S. Davis, of Birmingham, Ala., read a paper on this subject. The practice of dealing with appendiceal abscess by simply evacuating the pus and draining the cavity thoroughly without any very extensive search, or the breaking up of adhesions in order to find the appendix, has been adopted by a large number of the leading operators for some time. More recently some of the leading surgeons have advocated, in all cases, that the operation should be made complete; that all adhesions should be freed and the appendix removed. One leading abdominal surgeon, who has, perhaps, done more work in pelvic surgery than any other man in this country, has advocated this plan of treatment in most vigorous terms. In a large proportion of cases of pus in the tubes and ovaries gonorrhœa has been an important factor in its production. Such pus is not septic and is not calculated to give rise to so dangerous a general inflammation as infection from an appendicitis or an appendiceal abscess. It is a notable fact that a ruptured tube or ovary will usually be followed by a circumscribed inflammation. It is the exception that a fatal general peritonitis results from such an accident. The most fatal forms of peritonitis are due to a ruptured appendiceal abscess. In fact, but few cases are saved when such an abscess ruptures into the general cavity.

An operation on an appendiceal abscess is usually one of the simplest of procedures and is attended with almost no danger. Where the inflammation is circumscribed and the drainage is thorough, nearly all cases recover. The records of operations for appendiceal abscess show that the great majority of cases are cured after evacuation and complete drainage. Recurrence of the disease in such cases is rare. The appendix, in a large proportion of cases, having ruptured before the abscess formation, is completely drained through the abscess and permanently cured. In others the appendix is destroyed by the inflammation and there is nothing left of it when the abscess is operated upon. To make an extensive search for the appendix is liable to break up adhesions and then allow escape of septic fluid into the general cavity. Thus a very simple condition may be converted into one of the most serious that could happen to the peritoneal cavity. Dr. Davis believes that there cannot be much need of breaking up adhesions, for they give way in a short time after the abscess is relieved. In breaking up these adhesions, in addition to the danger mentioned, the surgeon prepares a favorable condition for fresh adhesions, with the possibility of the bowel being fastened in a position that will produce pain and often obstruction. After the abscess is thoroughly cleaned out, gauze packed into the abscess cavity and between the abscess and abdominal wall will completely shut it off, and the chances for recovery will be good in such cases. Dr. Davis does not favor the breaking up of adhesions and searching for the appendix in cases of appendiceal abscess.

Memorial Address.—Dr. John A. Wyeth, of New York City, delivered a memorial address on "Dr. J. Marion Sims and His Work" (see p. 694).

At the close of Dr. Wyeth's address, remarks were made by Drs. Robinson, Wilson, Nelson, Marcy, Engelmann, Kollock, Vander Veer, Gaston, Tiffany, and Westmoreland, eulogizing Sims, most of whom were personally acquainted with him.

Comparative Frequency of Stone in the Bladder in the White and Negro Races.—Dr. George Ben Johnston, of Richmond, Va., read a paper on this subject. It is commonly stated by writers on urinary diseases that stone in the bladder is of rare occurrence in the negro race. This is so at variance with his own experience that he has instituted an investigation either to prove the statement or to correct the fallacy. He selected the Southern States of Virginia, North Carolina, South Carolina, Alabama, Georgia, Tennessee, Kentucky, Florida, Louisiana, Mississippi, Arkansas, and Texas as the field of inquiry. He selected four hundred representative practitioners to correspond with in order to procure the necessary data. He received three hundred and thirty-eight responses, ninety-four of which contained information, and the remainder were negative. He succeeded in collecting 1,068 cases of stone in the bladder. Of these, 952 were in white subjects and 116 in negroes. It is at once observed that the negro cases represent 9 55 per cent of all cases reported. This showing is quite sufficient to disprove the idea of immunity which the negro is supposed to enjoy.

Geographically these stones were distributed as follows: Alabama, 10; Arkansas, 11; Florida, 28; Georgia, 90; Kentucky, 56; Louisiana, 19; Mississippi, 99; North Carolina, 126; South Carolina, 66; Tennessee, 128; Texas, 98; Virginia, 430.

Sex is specified in 780 cases, and not stated in 280. Of those in which the sex is indicated there were 691 in males and 97 in females, or about seven times oftener in males than in females.

There were 182 cases not subjected to operation, and 584 in which the stones were removed by the following methods: Lateral perineal, 249; medial perineal, 100; suprapubic, 138; vaginal incision, 32; dilatation of female urethra, 28; crushing, 35, and operation not given, 5.

Of those operated on, 541 recovered and 43 died. No report of operation in 304 cases. Dr. Johnston's own cases are incorporated in the foregoing statistics. During his twenty years' practice he has made notes in 41 cases, which is the third largest list furnished by any reporter, and what seemed to him the enormous number of cases in the negro in the face of its supposed rarity, caused him to set on foot the inquiries leading up to this paper. Of his 41 cases, there were 35 in whites, 6 in blacks, 39 in males, and 2 in females. Thirty-nine were operated on and 2 were refused operation on account of advanced kidney disease. Both died.

In 25 cases lateral perineal lithotomy was done, in 12 suprapubic, and in the cases of the two females the urethra was dilated and fragmentation practised. He had no deaths following operation.

President's Address.—This was delivered by Dr. L. McLane Tiffany, of Baltimore. He said the aim of the Association is twofold: first, to do advanced work, and second, to bring it to the notice of and aid other members of the profession. The one complementary to the other, neither complete alone, yet attaining full fruition when associated. The fellowship of the Association is a very extended one, embracing a territory of many degrees of latitude by many degrees of longitude, with infinite varieties of soil, temperature, environment, etc., yet the transactions did not show those exact local records from which facts may be generalized, applicable to the whole area, or a large part of the area, from which the fellowship is drawn. It did not seem reason-

able to him to suppose that a surgical operation done among the mountains of Western North Carolina was going to behave quite the same way that a similar operation would if done on the Gulf coast of Texas. It did not seem reasonable that similar surgical operations on the bank of the Mississippi and the central plateau of Tennessee would behave the same way. Accurately kept charts, with exact and careful notes, would unquestionably show difference not yet put on record by anyone, from which much clinical information could be learned. Again, he questioned whether surgical operations undertaken during the great heat of summer, or after the long continuance of summer heat, would show similar charts or give like results when compared with operations upon patients not subjected to high atmospheric temperature, either temporary or of long continuance. No association has a membership better situated or more competent to carry on a series of such investigations.

Cystotomy for Stone.—Dr. Willis F. Westmoreland, of Atlanta, Ga., said that any surgeon of the present day who had had a long and extensive experience in operating for stone must acknowledge that the upper operation of cystotomy is better and safer. Unless there is a pathological condition of the blood or infection of the bladder, as recognized by chemical or microscopic examination, the surgeon could decide before operation what course to pursue. The anatomy of this region, as laid down by the investigations of Strong and Peterson upon the cadaver and frozen sections, leads the surgeon astray, and the observation of the practitioner is more to be depended upon than any literature we have thus far relative to the subject. In operations for stone, the author said he cares not whether he sees the base of the bladder; that he depends upon touch, and that therefore rectal distention might be dispensed with. Instead of rectal distention, he recommends that a vessel of water be suspended three or more feet above the patient, according to the amount of distention necessary. Where the surgeon desires to effect distention of the bladder by a vessel, if the bladder is ulcerated at any point, with a thickening here or thinness there, it could be done without sudden force, and if the patient, during the operation, should sneeze or cough, or contraction of the bladder take place, instead of contracting upon a solid mass of fluid, the fluid is forced back into the vessel and there is practically no increase in pressure.

Abdominal Pregnancy.—Dr. Cornelius Kollock, of Cheraw, S. C., read on this subject. After referring to the pathology of extra-uterine fœtation and the classification of its varieties by early writers, he reported the following case:

October 18, 1894, he saw for the first time a dark mulatto, thirty-four years of age, the mother of three children, whose general health had been good until within the last fifteen months. The abdomen was very much distended, measuring at the umbilicus sixty-three inches. Fluctuation was evident and wave-tap very distinct. The patient affirmed that she was pregnant, and that she had gone four months beyond the actual period of gestation. After a thorough examination laparotomy was decided upon, and an incision was made four inches in length below the umbilicus. The walls were so thin that the instrument penetrated the cavity before it was certain that the abdominal muscles were divided. There was a sudden and copious discharge of offensive matter. An immense fibroid was removed from the anterior portion of the sac. The cavity also contained a fœtus weighing ten pounds. The placenta had undergone fibroid degeneration, with only a small part of the placental tissue remaining. The patient was extremely weak when operated on. She lived comfortably for five or six weeks after operation, and the doctor thinks she would be alive to-day were it not for the unfortunate intervention of intestinal obstruction.

Extra uterine Pregnancy.—Dr. J. T. Henry, of Chester, S. C., followed with a paper in which he reported a case of extra-uterine pregnancy. In this case the abdomen was freely opened and a large dark mass, nearly as large as the head of an adult, came into view. The uterus was crowded very much forward. The mass lay posterior to it, and was very much adherent to the fundus posteriorly and to the promontory of the sacrum. The fimbria of the right tube spread out over the covering of the mass. This mass was with some difficulty freed from its attachments, except that portion to the fundus of the uterus, and it was thought best to remove the uterus with it, which was done after tying and cutting the broad ligaments. The fœtus was five inches long and lay between the placenta and the uterus, the cord being attached to the left margin of the placenta. The abdomen was thoroughly washed out with sterilized water and closed without drainage. Patient sat up on the fourteenth day after operation, and was out of bed in twenty-five days. She has gained twenty-five pounds in weight since operation.

The Technique of the Buried Suture.—Dr. Henry O. Marcy, of Boston, read the paper. The constant receipt of letters from all parts of the country, containing inquiries concerning the method for the safe application of the buried animal suture, prompted the author to write this contribution. At the risk of seeming dogmatism, he would venture to assert that aseptic wounds, with very few exceptions, should be primarily closed by buried tendon sutures and hermetically sealed with iodoform collodion. Carefully selected tendons are to be preferred for buried sutures, since primarily their anatomical construction makes them stronger, more compact, and, as a consequence, more resistant to the softening processes which must ensue when buried in the living structures. When properly preserved, they have not been subject to bacterial decomposition, and hence may be sterilized without detriment to their ultimate elements. When tendon has been chromicized, it is best preserved in a sterilized oily fluid. Experience has shown that by far the best preserving fluid is linseed oil sterilized by heat, to which carbolic acid has been added. Tendon improves so much when thus kept that he rarely uses it until it has been in carbolic acid from three to six months. A method far too common has been to preserve chromicized catgut and tendon in absolute alcohol, boiled under pressure. There is no question but that such material is absolutely sterile, but the important factor has been singularly overlooked, that by this process the chromic acid is dissolved out of the tendon, leaving it really less valuable than if chromic acid had not been used.

The infection of wounds may never be absolutely prevented, but the experience of surgeons teaches us daily to what a marvellous extent it can be minimized, reduced in aseptic wounds, he confidently believes even in hospital practice, to less than five per cent. Indeed, not long ago, he examined his own personal experience, reviewing six hundred operations, with only two per cent. of septic cases, evidence ample to show the safety of the coaptation of wounds by means of the buried animal suture.

One of the interesting features of the meeting was the presentation of a gavel made from the leg of the operating-table used by Dr. J. Marion Sims in his office for twelve years preceding his death. It was the gift of his son, Dr. H. Marion Sims.

Election of Officers.—The following officers were elected: *President*, Dr. E. S. Lewis, of New Orleans, La.; *First Vice-President*, Dr. Joseph Taber Johnson, of Washington, D. C.; *Second Vice-President*, Dr. Richard Douglas, of Nashville, Tenn.; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*, Dr. A. M. Cartledge, of Louisville, Ky. Place of meeting—Nashville, second Tuesday in November, 1896. *Chairman of Committee of Arrangements*, Dr. W. D. Haggard, of Nashville, Tenn.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 7, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Benefactor of the Academy.—At the recommendation of the council, it was voted to place the name of the late Dr. Alfred L. Loomis on the list of benefactors of the Academy.

Some Observations on the Effects of Horse Serum Injections.—DR. HENRY D. CHAPIN read the paper (see p. 721.)

Pathological Changes Resulting from Serum Injections.—DR. WILLIAM VISSMAN in this paper quoted several authorities to show that the injection of blood serum was not altogether harmless, and so far as antitoxin serum was concerned he should judge, from the reports made, that its effect was far from indifferent. But since antitoxin was used almost exclusively in diphtheria, it was almost impossible to determine what anatomical lesions it produced, especially since nearly every one of the changes caused by antitoxin or blood serum when injected into healthy animals were also found in persons dying of diphtheria without antitoxin treatment. A few changes, however, had been observed in man, brought about by this agent independently of diphtheria. Horse serum caused a rise of temperature of one to three degrees, acceleration of the circulation, often followed by heart weakness and variable pulse. The exanthema observed after antitoxin treatment had also followed injection of simple horse serum.

Among the disagreeable effects observed after the injection of antitoxin were erythema, hemorrhages into the skin, heart weakness, pain in the joints, with or without swelling; some had observed albuminuria more frequently, others less frequently, than usual for diphtheria. Inasmuch as healthy man was not available for experiments, Dr. Vissman had used rabbits, and gave a résumé of his work. The number experimented upon was eighteen, and a like number was used for control purposes. The changes produced were nearly the same in all that were injected. A nodule developed, with a radius of one inch from the needle, slightly painful on pressure, beginning to disappear on the second day. It was sterile. Little attention was paid other organs than the kidneys, except to note that the liver and spleen were somewhat swollen. In all cases there was injection of the blood-vessels of the kidneys and cloudy swelling. The animals which received more than one dose had slight hemorrhages into the tubules, but fatty metamorphosis of the epithelial cells was not noticed. It was reasonable to assume that since antitoxin produced these changes in healthy rabbits, it produced similar changes in children.

In conclusion he said that, since the injection of serum into rabbits had been shown by himself and others to cause acute nephritis, it had probably had a similar effect in many persons, who had only problematically received any benefit from its influence on diphtheria. If all persons having diphtheritic bacilli in the fauces were treated with antitoxin, many would be injured for an uncertain benefit, for not all would have developed diphtheria. If the disease had gone sufficiently long for a diagnosis to be made independent of the bacillus, the antitoxin (it had been admitted) would have little influence. It was probable, therefore, judging by experiments upon animals, that the antitoxin treatment of diphtheria had increased rather than diminished the death-rate.

Physiological Action of Serum Injections.—DR. W. H. PORTER read this paper. Two theories had been advanced to explain the action of serum therapy, the chemical and the so-called vital theory. The chemical theory assumed that the serum, or some of its constituents, directly neutralized the toxins which were essential to the disease process. But this theory had already been about conclusively disproved, and it could be discarded as of no practical value. The so-called vital theory assumed that the serum or some of its constituents acted upon the living cells of the body, either rendering them insusceptible to the toxic agents, or enhancing their power to dispose of them as substances foreign to the normal economy. Dr. Porter presented his conception of the function of the living cell, of the chemical physiology of the animal body, and on this basis proceeded to study the effects of serum, or modified serum, when injected into the circulation.

In using horse serum we had no means of determining exactly the nature of the fluid injected, but we could assume that it was mixed proteids. It was equivalent to introducing a foreign body, just as when one employed an inorganic substance of any kind for hypodermic injection. It had been shown that blood serum or its contained constituents was not inert, since transference of considerable volumes from one animal to another caused rapid destruction of the red blood-cells. Whether this change was brought about by direct action upon the blood-cells, or as a foreign body which had to be taken up by the living cell and split into simpler compounds, had not been accurately determined. It was highly probable, in the author's opinion, that the chemical properties of the living cells were overtaxed in their attempt to destroy and eliminate the serums, and this caused general decrease of activity of the cells throughout the body. This view had been, it seemed, substantiated by the experiments of the previous speakers. To establish the value of serum therapy, it must be shown that, instead of having the effect just named, it stimulated the living cell and caused it to assume a higher state of nutrition and chemical resistance against toxic agents; further, to justify the treatment it must be shown that serum therapy accomplished this purpose more thoroughly than other modes of treatment.

The facts were recalled that in man diphtheria was likely to be of mixed infection; that antitoxin was expected to act only in the pure form, and early in the disease. Yet, in the face of these statements and those which had preceded them, innumerable statistics were being published which appeared to prove that the mortality from diphtheria had been reduced by antitoxin. The real facts, however, seemed to him to be as follows: The diagnosis of diphtheria had been based upon the presence of the Klebs-Loeffler bacillus in the throat. The presence of the bacillus, even in the absence of clinical phenomena, had constituted the case one of diphtheria. This naturally swelled the total cases of mild diphtheria which would get well under almost any rational treatment. This factor had increased the total number of cases, while it had decreased the mortality rate. Further, the severe cases, not amenable to the antitoxin treatment, were eliminated, which again helped lower the mortality. Again, a large number of cases had pseudo-membrane, but examination showed no Klebs-Loeffler bacilli, and these being excluded also lowered the mortality.

Allowing for these facts, Dr. Porter thought the true mortality for diphtheria had not been lowered. On the contrary, he thought it had probably been raised since the introduction of the antitoxin treatment. Until all these differences of opinion could be scientifically adjusted, it was quite impossible to state exactly what was the true status of serum therapy, but the weight of evidence pointed strongly to failure along the whole line. Not but what serum might have its place in medicine, but it would have to assume the position of other compounds, which had value in some instances but were not specifics.

Serum in Health.—DR. W. H. PARK, in opening the general discussion, said he would keep closely to the effect of serum, perhaps also serum antitoxin, in health, and not touch upon its influence in disease. First, in animals, as Dr. Chapin had shown, we found moderate

reduction of the red blood-cells, the number increasing to the normal again within one or two weeks. There were no broken-down cells. From serum alone there was almost no reduction of the leucocytes, perhaps a slight, very temporary reduction from antitoxin.

As to the influence on the kidneys, Dr. Van Arsdale had told him that he could see hardly any difference in the kidneys of three rabbits, one having received injections of serum, the other of serum antitoxin, the third no injection. In the case in which he thought there was slight injection, another pathologist, examining independently, expressed the opinion that there was less change than in the other two cases.

But we had, fortunately, not to depend upon the changes found in animals so far as the clinical symptoms went, for in New York alone eight hundred and twelve children had been immunized by antitoxin against diphtheria. In a few there was rise of temperature; in a few, a rash; in about one-fifth there was albumin in the urine, but this lasted only a few days, usually only forty-eight hours. None of the children had shown permanent ill effects. Only the slight change in the number of the blood-cells, mentioned as occurring in animals, was seen in children.

It appeared, then, that the dangers of serum injections were very slight, and were much more than counter-balanced by the beneficial influence of antitoxin treatment of diphtheria.

Dr. J. S. Billings, Jr., said he had examined the blood in over twenty cases of diphtheria treated by antitoxin, and in a minority of the cases had found slight reduction in the number of the red blood-cells, no other change; in only a very few was the reduction in the red cells above half a million in a cubic millimetre. There was even a greater reduction in the control tests, cases of diphtheria treated outside the hospitals, without antitoxin. According to these observations it would appear that antitoxin did no harm to the red blood-cells, and caused no degeneration of the blood.

Dr. J. Ewing had seen some reduction of the number of leucocytes in diphtheria treated by antitoxin, and a similar reduction in healthy rabbits in which considerable serum was injected, and while the observations were not conclusive, he wished to call attention to this as one of the possible dangers in using antitoxin. He had not seen harm result from antitoxin treatment of diphtheria at Willard Parker, but, on the contrary, it had seemed to him to do good.

Dr. J. Lewis Smith gave results of antitoxin treatment of diphtheria at the Foundling Asylum. The conclusion arrived at was that it had proven beneficial in the cases of unmixed diphtheria, while apparent failures were attributed to mixed infection. An unusual proportion of the latter cases occurred there.

Dr. Vissman said the changes observed in his experimental rabbits were not present in the control rabbits, and therefore they must be attributed to the injections.

The Health of New York.—Dr. H. M. Biggs delivered the Wesley M. Carpenter lecture, choosing for his subject "The Health of New York." Extensive tabulated statistics of the morbidity and mortality of New York and large European cities were shown. The author presented not only the figures, but analyzed them, and explained their significance in relation to the public health, which was his main purpose in writing the paper. Formerly the mortality rate of New York per thousand was, in round numbers, 37; tracing the decrease by successive decades, it had fallen to 28, and finally for the past year to 22.7. While this was the real mortality rate of New York, the corrected rate was about 26.5 as made out in London. The death-rate for rural districts was less usually than in the cities, and, it might be said, was less avoidable, or depended less upon the art of man. The reduced mortality of the present over that of the past in New York and other cities, showed that the past greater mortality was due to preventable diseases. The mortality rate for London was at present considerably less than that for New York, and while climatic influences which were unavoidable might account for this in part, yet there could be no doubt but that causes were acting here which, with improved sanitary knowledge and appliances, would disappear. Liverpool and Manchester had a much higher mortality than New York, while Surrey had a smaller mortality than London. No city had as great a population for the same area as New York below the Harlem River, and to a certain extent the denser the population, the more difficult it was to avoid certain morbific influences. This rule, however, was not absolute even in different districts for New York. In the Tenth Ward, for instance, the mortality rate was only 20.5, while in some other wards with a much less dense population the rate was much higher. It was a significant fact that where the mortality was greatest there was also, as a rule, an unusually large proportion of cases of preventable diseases, such as tuberculosis, diarrhœal diseases, bronchitis, pneumonia. There was reason to hope that the death rate from these diseases, at least, might be reduced one-third during the next ten years. He had the most sanguine hope that New York, which had once been regarded as an extremely unhealthy city, would soon come to be noted for its unusual degree of healthfulness.

Therapeutic Hints.

Cannabis Sativa.—My greatest experience has been in the treatment of phthisis pulmonalis, and here I cannot speak of it too highly, for, while it most perceptibly relieves the cough, it aids the patient by its stimulating and exhilarating qualities, supplying a remedial agent in a manner which in my opinion no other drug can so beneficially do.—Lees.

Pruritus.—Itching must be treated empirically, by the employment of electricity, atropia subcutaneously, or the coal-tar derivatives, such as antipyrin and phenacetin, in gradually increasing doses.

McCall-Anderson.

The external causes of pruritus include local skin diseases and parasitic skin diseases, as well as the pruritus due to changes in temperature and alterations in blood-pressure. These are frequently the causes of irritation of the skin. Its treatment can be properly undertaken only when the underlying causes are taken into account.—Brooke.

Water.—When judiciously taken in half-pint doses as a laxative in the morning, as a sedative at night, as a diuretic with a cool skin, or a diaphoretic when the skin is warm, as an expectorant or a refrigerant, its value is remarkable. It makes no difference whether sulphates are taken in mineral waters at Epsom, or Carlsbad, or dissolved in water by a druggist and sold in eight-ounce bottles.—Pye-Smith.

Psoriasis.—Salicylate of soda, grains fifteen, three times daily, after or between meals. Stop it if epigastric pain is occasioned.—Crocker.

Arsenic is absolutely useless in eczema.—Jamieson.

The Pyrexia of pneumonia is brief, normal to the disease, unfavorable to microbic activity, and inasmuch as the growth of this germ was checked by a temperature of 104°, it was not advisable to reduce it when not excessive, and then not below 102.°—R. Douglas Powell.

Antitoxin in Diphtheria.—The report on antitoxin treatment in Germany, obtained by collective investigation, on a total of 10,312 cases occurring in a period of six months from October 1, 1894, gives very striking

results. Of the whole number 5,833 were treated with serum and 4,479 without it. The proportion of deaths in the former group was 9.6 in contrast to 14.7 per cent. in the latter. In 401 cases of children under the age of two years, in which the serum treatment was used on the first and second day, the mortality rate was 11.8, in contrast with 39.7 where under similar conditions it was not used. Of 2,556 children between two and ten years of age, the death-rate was four per cent. after antitoxin treatment, instead of 15.2 per cent. in the other group.

A New Method of Treating Pulmonary Tuberculosis.—It seems evident that the beneficial influence of beech creosote is due to an indirect action explained by the stimulation of cellular activity. It has seemed to me that the association of the essential oil of peppermint by inhalation with the administration of creosote or of its derivatives, combined with a good diet, ought to be a rational method of treating phthisis. In 1888 I began experiments in continuous inhalations. The inspiration should be deep and held for a moment, so that the vapors of the oil remain in contact with the respiratory tracts and their contents. A given proportion of the essential oil can be added to the creosote and, absorbed by the stomach, may prevent secondary infection of the digestive tract. In 43 cases there were 37 cures. The bacilli of Koch always disappeared from the sputa. Several cases of cure extend over five or six years. The inhalation apparatus is very simple, consisting in a linen bag five centimetres long and two wide, held under the nose by two bands passing over the head or attached to the ears. This is wet every three or four hours with four or five drops of the oil. It is to be worn day and night. For patients not far advanced a tube or quill with the oil upon a bit of sponge in one end, can be given to carry in the mouth, as the patient goes about. When inhaling by the nostrils for the first time irritant local effect can be prevented by the application of vaseline. —Dr. Carasso, *Director of Military Hospital of Gênes.*

Evaporated Milk for those on a milk diet who cannot take the required quantity. Heat the milk rapidly over a flame easily regulated. Diminish the heat before the boiling point is reached, stirring all the time even after the flame is extinguished. Thirty centilitres can be reduced one-half in half an hour.—Thin.

Endocarditis.—As soon as the heart-sounds in acute articular rheumatism begin to grow muffled, or a *bruit* is detected, give in addition to the salicylate, iodide of potassium 0.60 centigram three times daily. Also flying blisters over the apex and along the course of the fourth, fifth, and sixth intercostal nerves.—Caton, *Sem. Méd.*

Sycosis.—Apply two or three times daily as a wash with a cotton tampon, a one per cent. solution of corrosive sublimate in ninety-five per cent. alcohol. To allay the irritation which may be produced, cover at night with an occlusive ointment such as that of Hebra. —Tilé, *Bul. Méd.*

Nutritive Enema.—

Water	150 grams.
Dry peptone	10 grams.
Yellow of one egg.	
Glucose	20 grams.
Sydenham's laudanum	gtt. iv.

—Tournier.

Acute Articular Rheumatism.—I use the salicylic acid by inunction. The formula used by me was that of Bourget, viz., salicylic acid ten parts, lanolin ten parts, lard one hundred parts. Two drachms of the pomade were rubbed into several areas on the trunk and extremities every four hours, the total daily inunctions representing sixty grains of salicylic acid. The absorption was very rapid, requiring no more than ten minutes for the single inunction, and it was unattended with any irritation of the skin. No covering was employed.—Kinnicutt.

Iodine in Dermatology.—Good results are obtained from its topical use in ringworm, alopecia circumscripta, and tinea versicolor. In ulcerative stomatitis fungous gums, and various chronic anginas, painting with tincture iodine is an efficacious procedure attended by no inconvenience.—Comby.

Dropsy.—

R. Diuretini	gr. ex.
Aquæ menthæ pip.	℥ ij.
Spirit gallici	℥ j.
Eucalyptoli	gtt. xxv.

M. Sig.: To be taken during 24 hours.

—Best.

Nephritis.—I advise the treatment of nephritis by inunction of an ointment of pilocarpine nitrate—a procedure advised by me in joint disease in 1882. I in this way secured a purely local diaphoresis with a minimum dose of the alkaloid, and without the inconveniences and dangers which sometimes attend its subcutaneous injection.—Mollière.

Flatulence.—For the violent spasmodic attacks, with great distention of the stomach and bowels, to which some sufferers from flatulence are liable, the following is nearly always efficacious:

R. Sp. cajuput	℥ ij.
Sp. ammon. aromat.	℥ ij.
Sp. chloroform.	℥ ij.

M. Sig.: The antispasmodic mixture. One teaspoonful in a glass of water every half hour or every quarter-hour until relief is obtained.

When flatulence is associated with pain after food and coated tongue, indicating gastritis, the following prescription should be given:

R. Potassii bicarb. vel sodii bicar.	℥ ij.
Sp. ammon. arom.	℥ jss.
Liq. strychninæ	♏ ss.
Sp. armoraciæ co. vel sp. caju	℥ jss. ℥ ij.
Sp. chloroformi	℥ j.
Infus. calumbæ vel gentianæ co.	℥ xlviij.

M. Ft. mist. Sig.: A sixth part three times a day between meals.

—Stephen Mackenzie.

Alopecia after Fevers.—

R. Alcohol	℥ vjss.
Veratrini	gr. vijss.
Tinct. benzoin	gtt. xv.
Acid salicyl	gr. vjss.

M. S.: Apply locally.

—Kaposi.

Pruritus from Jaundice.—

R. Ichthyol	pts. 10.
Spts. vin. rect. dil.	pts. 40.
Ether	pts. 40.

M. S.: Apply locally.

Menstruation, which occurs in all erect animals, is simply a shedding of the superficial layers of the endometrium, and is a kindred process to the moult in birds, to the dropping of the horns and hair in deer, and to the loss of dermal structures which occur periodically in so many animals.—Johnston.

Acne Rosacea.—

R. Sulphur precip.	℥ j.
Calaminæ præpar.	℥ ij.
Zinci oxidi.	
Glycerini	ad ℥ j.
Aquæ destil.	ad ℥ iv.

M. Sig.: Ft lotio. The lotion is to be shaken, then painted on with a camel's-hair brush at night.

In morning face is washed with a little warm water (no soap) and powdered over with the following:

R. Acidi borici	pts. 10.
Talci	pts. 15.

M. Sig.: Ft. pulv. To be applied every morning.

—Jamison.

Gall-stones.—Statistics show that ten per cent. of men, twenty-five per cent. of women, and thirty-six per cent. of the insane have gall-stones. Of all these only one per cent. experience any symptoms therefrom. For such patients medicines are useless, and an early diagnosis of their condition is imperative, for they more often need reference to a surgical clinic than a trip to Carlsbad. They may be divided into two classes: 1. Those with stones in the cystic or gall-bladder. 2. Those with stones impacted in the common bile-duct. In the former, jaundice is the exception, while in the latter it is present and persistent.—WEBSTER.

Anasarca.—

℞. Sodium borate..... pts. 4·2.
Distilled water..... pts. 60.
Pot. bitartrate..... pts. 1·2.
A tablespoonful every two hours.

Psoriasis.—

℞. Ichthyol,
Salicylic acid,
Pyrogallic acid,
Aristol.....āā gr. xl.
Vaselin,
Lard,
Lanolin.....āā ʒ j.
A powerful ointment to be used in small quantities.

Menorrhagia and Metrorrhagia.—

℞. Extracti hydrastis fluidi..... ʒ ss.
Extracti ergotæ fluidi..... ʒ j.
Strychninæ sulphatis..... gr. ij.
Tincturæ ferri chloridi..... ♏ jss.
Sirupi simplicis.....q.s. ad ʒ viij.
M. Sig.: ʒ j. t.i.d. after meals.

Biliousness.—

℞. Fellis bovini purif..... ʒ j.
Manganesii sulph. exsiccat..... scr. ij.
Resinæ podophylli..... gr. v.
M. et ft. pil. no. xx. Sig. . One pill three times a day.

—DA COSTA, *in Dominion Medical Monthly.*

Tobacco Cure.—

℞. Chloride of gold and sodium..... gr. $\frac{1}{4}$.
Strychnine nitrate..... gr. $\frac{1}{60}$.
Nitroglycerin..... gr. $\frac{1}{600}$.
Atropine sulphate..... gr. $\frac{1}{600}$.
Tincture digitalis..... 3 minims.
Capsicum..... gr. $\frac{1}{4}$.
Salicin..... gr. i.
Cinchonidia sulphate..... gr. i.
For one pill, to be taken three times daily.

—KEMPF.

Tic Douloureux.—Treatment consists in making subcutaneous injections of the following solution into the affected side of the face: Distilled water, 10 grammes (2½ fluid drachms); antipyrin, 4 grammes (1 drachm); hydrochlorate of cocaine, 0.03 gramme (½ grain). The face sometimes became much swollen, but soon resumed its normal appearance.—GRANDCLÉMENT.

Phthisis.—The following combination reduces fever, cough, and sweating, and exerts a tonic influence:

℞. Phenacetini..... gr. xl.
Strychninæ sulphatis..... gr. j.
Ammonii chloridi..... ʒ j.
Quininæ sulphatis..... gr. xxxij.
Pulvis capsici..... gr. x.
Pulvis digitalis..... gr. vj.
Ferri sulphatis..... gr. xx.
Atropinæ sulphatis..... gr. i–130
M. ft. capsulæ no. xxxij.
Sig. One capsule four times a day.

—MAYES.

A Tonic Aphrodisiac.—

℞. Strychniæ sulph..... grs. 1–32
Acid. phosphorici dil..... ʒ j.
Aquæ destil..... ʒ j.
M. To be taken in water four times daily.

Cimicifuga.—Ten drop doses of the fluid extract frequently repeated are said to cure the headache attending menstruation.

Lumbricoids.—

℞. Santonin..... 20 grs.
Podophyllin..... 5 grs.
Sugar..... 30 grs.
M. Sig.: Divide into five powders; give one every four hours until it acts freely on the bowels. The dose of podophyllum can be varied according to the age of the child.

—DERAY.

Pulmonary Tuberculosis.—

℞. Creosoti..... f ʒ ij.
Alcohol. rectifical..... f ʒ xvij.
Glycerin. pur..... f ʒ viij.
Chloroform..... f ʒ v.
Ol. menth. pip..... f ʒ ij.
M. Sig.: Tablespoonful in sweetened water before each meal.

—CAROSSO, *in La Médecine Moderne.*

Asthma.—

Ammon. chlor..... ʒ jss.
Tinct. lobeliæ..... f ʒ iij.
Spir. æth. comp..... f ʒ j.
Sir. acaciæ.....ad f ʒ iv.
M. Sig.: Dessertspoonful in water every hour or two during paroxysms.

—PEPPER.

Too True.—We can give the novitiates at the shrine o Æsculapius no better greeting than that of Abernethy, "God help you all."

Goitre.—Good results have been obtained from the parenchymatous injection of ¼ to 1 drachm of a mixture thus composed:

℞. Iodoform..... 1 part.
Sulphuric ether,
Olive oil.....āā 7 parts.
M.

—GALEE, *in Revue de Laryngologie.*

Lavage.—When any obstruction is felt, one should cease for the moment to push the tube onward, and the obstruction, which is, of course, merely spasmodic contraction of the pharynx or œsophagus, will relax and the procedure can be continued without difficulty. To attempt to push the tube onward against the spasmodic obstruction causes the patient to gag, and may induce violent retching, so that the operation is frustrated. The greatest difficulty under which to attempt the introduction of the tube, is when a bed-ridden patient, who, for any reason, is unable to sit erect, is the subject. It is then better to turn the patient slightly upon the side, so that if there should be vomiting the fluids may readily run out of the mouth. The tube should never be retained in position while the patient is vomiting, as it may cause the entrance of the vomited material into the larynx. However, very little experience is needed to teach one the manipulation, and great skill is soon acquired.—*The Physician and Surgeon.*

Pneumonia.—In pneumonia we have the field where digitalis is the remedy *par excellence*. That recoveries from this disease will and do occur in greater numbers when it is treated by large and persistent dosage of digitalis, than occur without its use, seems to be the growing belief in medical practice to-day. In conjunction with strychnine, given in physiologic doses, digitalis is administered until the pulse comes down to 90 a minute. If it can be kept there, recovery will ensue in a shorter time, as a rule, than by the use of other methods of treatment.—FOSTER.

Fowler's Solution.—Fowler's solution, either in aqueous form or in the more convenient tablet, has been found to be an agent of great therapeutic value in cases where the mucous membrane seems to lack tonicity in the nose as well as in the lower respiratory tract.—HICKEY.

Lumbago and Strain from Muscular Exertion.—Tinct. iodini, liq. ammoniæ; collodion, p. e., painted on with camel's-hair brush.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

YESTERDAY'S MEETING OF ROYAL COLLEGE SURGEONS—THE REPORT—THE WOMEN'S QUESTION—HOSPITAL STAFFS—RADCLIFFE INFIRMARY—GUY'S HOSPITAL—MR. DELMAR'S BEQUEST—PUBLIC HEALTH.

LONDON, November 8, 1895.

YESTERDAY afternoon the annual meeting of the fellows and members of the Royal College of Surgeons was held. The report was presented and a motion made to thank the Council. To this the previous question was offered as an amendment, on the ground that the Council had done nothing for members calling for gratitude. This, on being put to the meeting, was carried by 17 votes to 5. Then came on a motion for certain reforms, advocated chiefly from the members' point of view. On the suggestion of the President the paragraphs were moved separately. The first demanded that no alterations in the constitution should be made without the consent of the body corporate (fellows and members) convened to discuss them. This was carried *nem. con.* The second provided that the annual general meetings should be made statutory, and no longer depend on the consent of the Council. This was carried with one dissentient. The third proposed to increase the number of councillors from twenty-four to thirty-two, the eight additional ones to be elected by the members. This was carried with two dissentients.

The way being thus cleared, the question of the admission of women to the examinations for the college diplomas was brought forward. The President said it was a very important question, and the Council desired the opinion of the meeting before coming to a decision. He further stated that, under the existing arrangements, no one could be a member without at the same time becoming a licentiate of the College of Physicians, though of course this was not finality, and the agreement between the colleges might be altered. It was moved that, as many portals are open to women, it is not expedient for this college to admit them. An amendment that they be admitted was made. This after discussion was defeated by 58 to 48, and the original motion carried. Thus for the present the women are excluded from both colleges, but as there are good qualifications open to them, this is really no great hardship, for the number of women students is small compared with that of men. The question excites considerable controversy now, but not so much as formerly, when it was rather whether women should be prevented following a medical career. Now they have gained that point, and the two parties take a different stand. The one advocating the claims of the women affect to believe they must carry every point; the other, more conservative, look upon the movement as a passing craze which will die out of itself. With such a change of position in the question it is obvious the heart is taken out of discussion. Looking at the numbers voting, we see how languid is the interest in college politics compared with what it was at the early meetings, when the theatre was crowded with indignant and eloquent orators demanding reforms. The Council then listened, offered no reply, and went on its way—a method of postponing the reforms which has succeeded and will probably be continued. Neither the fellows nor the members have any control over the Council. The fellows would like the members to help them gain certain points, but then, what would they do for members? Nothing. I am sorry to see that the *Medical Press*, which was once the stanch advocate of justice to members, came out on Wednesday with a "wobbly" leader recommending members to trust to the fellows for the future and help them in the present. I suppose the "wobble" comes from the gentleman who forgot to send in his nomination paper and so disappointed his party by his dilatoriness, for he is understood to control your contemporary on London college politics. He had better wake up, unless he thinks editorial responsibilities may be met by dreams.

The question to what extent the medical staff should participate in the management of a hospital is not always so easy to determine as many imagine; circumstances alter cases. I have many years of experience under different plans. At some hospitals all members of the staff are *ex-officio* members of the committee, and I have seen this plan work well even in small institutions. When, however, the staff is rather large, and the attendance at committees not more numerous, there may arise a difficulty. At other hospitals representatives of the staff have a seat on the committee. Lately an attempt was made, at the Radcliffe Infirmary, Oxford, to change to this plan from the former, on the ground that the committee was too unwieldly. I cannot admit such a plea, for I know that the most common difficulty is to maintain the regular attendance of committeemen. Some very large hospital committees, however, only admit one or two members of the honorary staff. A clergyman at Oxford declared he was afraid to point out the obvious dangers which might result if the staff could carry anything they liked. I have known no danger from such a position, though I have seen great evils arise from the staff being unable to persuade the lay members to adopt the best course. The proposal at Oxford was rejected by 23 to 4, so it must be presumed that the staff continue to enjoy the confidence they well deserve.

Guy's Hospital is losing about £20,000 a year through the falling of rents of its landed property. The agricultural depression is therefore seen to be affecting the sick poor in our cities as well as the laborers on the land. The founder directed his endowment to be invested in land, and at that time nothing seemed so safe or so little likely to depreciate. The lands produced about £40,000 a year up to 1880, since which the depreciation has continued, increasing to such an extent that at present half the income is swept away.

In these circumstances an appeal has been issued to the public for help, and Mr. Gladstone has written a letter for circulation with the appeal. In a matter of this kind Mr. Gladstone's recommendation will have great weight even with those who are politically opposed to him, and, as you may suppose, when he says he has inquired into the circumstances, he pleads with persuasiveness. Though the committee have lithographed his letter for circulation, they have done well to enclose a printed copy, for his manuscript is none of the easiest to decipher. London's boundless want is side by side with her boundless wealth, which must therefore come to the rescue. Mr. Gladstone, who is great at figures, vouches for the economy of administration which distinguishes Guy's.

Mr. F. O. T. Delmar died on October 14th, and in his will left £90,000 in trust, the interest of which is to be divided among such charities as his trustees select from time to time. Mr. Delmar expressed a special desire as to institutions for epileptic or cancerous patients, as well as for the Royal Society for Preventing Cruelty to Animals. The Middlesex Hospital Cancer Department was founded in 1792, and has greatly benefited sufferers. As the oldest and chief charity of the kind it is supposed a considerable share of the amount will fall to it, and no institution can be named which would better discharge the duty imposed by this munificent legacy.

Diphtheria is still prevalent, and some local outbreaks have been sudden and rapidly extending. The number of deaths registered from it last week rose to

72, being 34 in excess of the corrected decennial average for that week of the year.

Influenza has been threatening, and at Willarden many persons are its victims. The out-patient physicians at the hospitals are having a heavy time, and cases in the profession and society are under my notice.

OUR PARIS LETTER.

(From our Special Correspondent.)

SEROPATHIE—EXPERIMENTS AS A PROPHYLACTIC OF TETANUS—TREATMENT OF CANCER BY—TYPHOID FEVER AND CHOLERA.

PARIS, November 5, 1895.

THE treatment of disease by injections of serum seems to be engrossing scientific and professional attention more than ever on this side of the ocean. We know that, up to the present day, all efforts to cure tetanus by injections of antitoxic serum have failed. These failures are due to the fact that the injections can only be carried out at a period when intoxication has long since taken place, and if the quantity of toxin is sufficient, or if the toxin is sufficiently active, nothing can annul the effects of an intoxication that has been going on insidiously and rapidly for some days. We must therefore give up, at least for the present, all hope of curing a tetanus once declared, but we may diminish the number of cases of that disease by having recourse to the preventive treatment. That is what Dr. Nocard has tried to do, and with what success we shall now see.

During the first six months of 1895, Dr. Nocard distributed to the veterinary surgeons of Paris, 1,800 bottles containing each 10 c.c., or about one-third of an ounce of anti-tetanic serum.

He recommended them to inject into each animal threatened with tetanus consecutive to an operatory or accidental wound, 10 c.c., or about one-third of an ounce, of the serum as soon as possible after the traumatism; twelve or fifteen days after a second injection of the same quantity should be made. The results that I have been able to obtain were upon a total of three hundred and seventy-five animals, each animal having received two injections at intervals of fifteen days. In every case the serum proved innocuous and no single animal treated took tetanus. It is true that some will consider 375 cases very few to determine the efficacy of a preventive treatment, especially when it is a question of a disease as rare as tetanus. That objection cannot, however, stand against the facts that all the animals treated belonged to stables in which tetanus had destroyed animals a few days or a few months before, and many of them were in stalls adjoining others that had tetanus; moreover, in some cases the traumatism was produced at the same time and under the same conditions as in others that, without treatment, became tetanic. Finally, in the six months during which the treatment lasted, Dr. Nocard's twenty-six correspondents, who did not lose a single animal of the three hundred and seventy-five treated, observed fifty-five cases of tetanus among those not treated.

From this brief résumé of Dr. Nocard's work, we may at least conclude that if the curative treatment of tetanus remains still to be found, we may at least reduce in great measure the number of victims to that terrible disease, thanks to the preventive injections of antitoxic serum.

Treatment of Cancer.—Having personally had opportunity of testing the value of injections of serum in the treatment of intra-thoracic cancer, we are able to add our own testimony to that of Professors Richet and Hericourt, whose personal observations, coupled with others communicated to them, have enabled them to formulate some general conclusions taken from a large number of cancerous patients.

In the first place, there is a very marked diminution of the pain so frequent in those affected with malignant neoplasms; and this effect was entirely unexpected. In the second place, cancerous ulcerations become detergent, take on the appearance of a granulating wound, and cicaterization may take place over considerable of the affected area. A third effect of the injections of anticancerous serum consists in a notable diminution not only of the tissues surrounding the tumor, and of the lymphatic ganglia adjacent to the neoplasm, but also of the tumor itself. Finally, in some cases the evolution of the disease is retarded and at the same time there is a decided amelioration of the general condition. En résumé, in four-fifths of the cases of cancer it is impossible to deny a real improvement; unfortunately the effects of the serum stop short of curing, and after a certain time—one month, a month and a half, two months—the general health remains stationary and then retrogrades to the starting-point; new cancerous deposits appear and the disease progresses toward a fatal termination.

The question naturally suggests itself, is the serum a specific or not? It is difficult to reply with certainty; nevertheless, two of the cases observed and treated by Professors Richet and Hericourt caused them to incline to the opinion that it is a specific and that the serum from animals immunized is much more active than that taken from healthy animals. Our own experience in the case of intra throracic cancer above mentioned, coincided with that of the learned gentlemen. The pains, which had been so intense as to cause the diagnosis of tumor compressing the sensitive roots of the spinal nerves to be made, entirely disappeared after the treatment by injections of anticancerous serum was begun and there was a marked general improvement, accompanied by a disappearance of the swelling of the axillary glands.

In conclusion, it must be now admitted that if the seropathic treatment is not yet apt to cure neoplasms radically, it at least ameliorates them more than any other known method; perhaps by combining this treatment with operative measures, still more favorable results may be obtained.

Injections of artificial blood-serum in typhoid fever and cholera have given results equally as satisfactory.

THE ISTHMUS OF THE AORTA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: While reading the English edition of Ziegler's "Pathology" (p. 107), I noticed the translator's note, and after investigating the subject believe his explanation of "isthmus" is not quite correct.

Lancereaux, in his "Traité d'Anat," Part ii., p. 839, says: "At one period of embryonal life, the true aorta, or ascending aorta, distributes the blood to the head and to the superior extremities, while the pulmonary artery, after having furnished two branches to the lungs, continues with the descending aorta by a prolongation which later will be the arterial canal. A narrow conduit connects the two halves of the aortic tree; this is the isthmus of the aorta, habitual seat of stenoses of congenital origin," etc.

Again, Professor Knox, in his "Manual of Human Anatomy," p. 337, states: "The third or descending portion of the arch is remarkable for occasionally presenting a slight contraction (connected with fœtal structures); it is here that the aorta has been known to become spontaneously obliterated."

So also, we find in Macalister's "Text-book of Human Anatomy," p. 346: "This portion of the aorta (descending arch) measures 46 mm. in length and is 24 mm. in diameter, contracting suddenly to 22 mm. at its termination (*gretnus aortæ*) immediately beyond the ductus arteriosus, etc.

A search through a considerable number of other

authorities, including Meckel, Cruveilhier, Cloquet, Delierre, Gegenbauer, Sappey, Todd and Bowman, Soemmerring, and others failed to reveal any other references.

Yours faithfully,

Dr. X——.

THE CLIMATE OF COLORADO.

To the Editor of the Medical Record.

Sir: Residence of something over a year in Colorado serves to impress upon me very forcibly the fact that patients coming here with pulmonary tuberculosis are much in need of competent medical supervision after their arrival. It is needless to say that the atmospheric conditions differ very materially from those at the sea-level, and I am certain that these differences are not appreciated by many of the physicians in the East. A considerable number of patients with pulmonary tuberculosis who come to Colorado, think that it is simply necessary for them to live in this climate, and feel that they may pursue such life as seems fitting to them. They feel the stimulus of the clear, dry air and sunshine, they are invigorated by the tonic qualities of the atmosphere, and are easily led to commit grave indiscretions in undue exercise, unsuitable food, and the like. These indiscretions only too often result disastrously. These facts are well known by the physicians here, but, as I have said, I am sure that they are not duly appreciated by many physicians in other parts of the country. I feel that I can speak of this with good grace in the columns of the Medical Record, as I do not myself treat pulmonary tuberculosis.

The climate of Colorado is a most valuable therapeutic agent which requires careful medical supervision in its employment. All who come here agree that it is the best climate for permanent residence which the average consumptive can obtain. Throughout the State are found careful, painstaking, conscientious physicians who have devoted many years to the study of tuberculosis, and who are well able to bring to bear upon the invalid every condition which can aid in effecting a cure; and it is because I see from month to month such a considerable number of patients coming from the East who do not feel it necessary to place themselves under medical supervision, that I feel impelled to again bring the subject before the profession in this way.

Very truly yours,

Charles A. Powers, M.D.

Denver, Col., November 15, 1895.

A LONG SURVIVAL OF A TERRIBLE WOUND, AND A STRANGE COINCIDENCE CONNECTED THEREWITH.

To the Editor of the Medical Record.

Sir: About five years ago I received a letter from a man living in Pontotoc, Miss., giving me a history of the condition in which he found himself at that date, as a result of a wound received at the battle of Chickamauga, September 19, 1863.

John N. Sloan, captain of a company in one of the Mississippi regiments engaged in that bloody battle (said to have been the bloodiest since the invention of gunpowder), was struck by a cannon-ball, which completely tore away his chin and lower jaw, tongue, and some of the upper teeth. His wound being considered necessarily fatal, when he fell he was dragged a few feet behind a tree, and no further attention was paid to him. He was not even carried to the rear to a place of comparative safety. From that day to this he has lived upon liquid food, his nourishment being carried into the upper end of the exposed œsophagus by means of a rubber tube. Naturally, I became interested in the condition of this man, and made careful inquiry in regard to the information I had received, especially through members of my own profession living near him.

On the thirty-second anniversary of the battle of Chickamauga, there was a dedication of the National Park, to which all the survivors of both armies were invited. I had not visited the battle-field since the fight in 1863, and, of course, felt some curiosity to go over the ground again. It was very interesting, and, to me, a memorable occasion. The Government has macadamized the old country roads that traversed that section, not changing their routes in any particular, simply bettering their condition.

The line of battle was nearly eight miles long, and as we drove or walked over it, it was certainly unusual to see the men of both sides in that terrible struggle, wandering together about the various points where their commands had fought, and discussing incidents which were so indelibly impressed upon their mind; for when a man has stood face to face with death, it has occurred to me that a profound impression is made upon his memory, and it needs but the occasion to have it clearly recalled.

A doctor friend, who lives in Chattanooga, kindly devoted his horse and buggy and his time to me on this excursion. We found ourselves about one o'clock, taking luncheon at Crawfish Spring (now known as Chickamauga Spring), one of the most wonderful springs of pure, cold water gushing out of the earth I have ever seen. As we had a generous basket of luncheon, and seeing four or five ex-Federal soldiers who looked hungry, I invited them to share our basket, which invitation they accepted with avidity. As we were chatting about things in general, one of the Union soldiers, a Mr. S. S. Rich, who is now living at Moberly, Mo., and who was then serving in a Kentucky regiment, said that in this battle he had seen the most horrible wound that had ever come under his observation. (As he was an infantryman and had been engaged in all the great battles in the West in a regiment that made a fine record for gallantry, I am sure he had ample opportunity to see a great many ghastly wounds.) I asked him on what part of the line he was, and he indicated it by the known position in which his division fought on that day. He said that it was a Confederate soldier he had come upon in a charge in which they were engaged; and that this man was lying at the root of a tree, with his whole chin, lower jaw, and upper part of his throat blown away, seemingly by a shell, but that he was still living. He added that he knew he must have died, because no man could have recovered from such a wound.

I knew that this Mississippi regiment had fought just there, and that the man of whom he was speaking was my patient. I had written to the old captain in Mississippi to be sure to get to the Chickamauga reunion, and that we would go over the field and find out the place at which he was shot. I had then a letter in my pocket from him, saying that he would be there if his health would permit. I said to Mr. Rich, the ex-Union soldier, "You will be surprised to know that the man did not die, and that this letter is from that same individual. I expect him at any moment to meet me in Chattanooga or somewhere on the field."

You may imagine his surprise on finding that this man had survived such a horrible wound. As soon as I handed him the letter and said that the man was expected there, one of the other ex-Union soldiers of our party, who was from Indiana, but whose name I unfortunately failed to put down at the time and have since forgotten, exclaimed, "I'll bet anything that I saw that same man in the train coming down to the Park this morning!" A number of old soldiers had gathered around him and he showed them the rubber tube through which he was fed by sticking it through a hole in his throat."

I unfortunately could not find my old friend in the tremendous crowd that was there, but I wrote to him on my return to New York, and received a letter stating that he had been there and had found the place where he was shot, and was very sorry he had missed me.

Naturally, this patient is aging rapidly, and now, although only a little over sixty years of age, by reason of the fact that he is compelled to live upon a fluid diet, his strength is failing him. He does not belong to that great army of pensioners which draw regularly upon the United States Treasury, but he is on the pension list of his old comrades throughout the South, who since the war, in all her poverty, take care that no incapacitated ex-Confederate soldier shall suffer for the necessaries of life.

JOHN A. WYETH, M.D.

NEW YORK, November 20, 1895.

New Instruments.

A RUBBER BAND FOR SECURING THE UMBILICAL CORD.

BY J. H. GREENE, M.D.,

DUBUQUE, IA.

I NOTE in a medical journal an advertisement of an instrument to secure the umbilical cord. For the past five or six years I have used a simple device, original, so far as I know, with myself. It is so effectual for its intended purpose, so cleanly, and easy of application, that I deem it worthy of mention. It is the ordinary rubber band of small size; and its utility lies in its manner of application. I use the "No. 8" Faber band, approximatively three-fourths inch in length. Passing it around the umbilical cord, it is given two or more turns upon itself. One of the loops at either end is then passed through its fellow and the band drawn taut by the finger through the free loop. The cord is then cut and the free loop passed over the end of the cord. Its effectiveness is so self-evident, further comment is unnecessary.

A NEW PUMP AND CAUTERY.

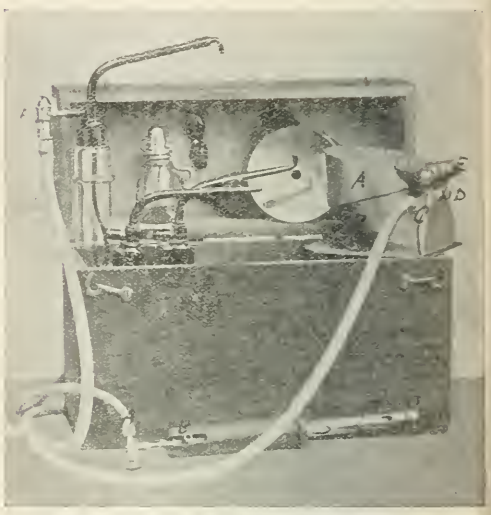
BY CHARLES GRAEFE, M.D.,

SANDUSKY, O.

FORMERLY ASSISTANT AT THE SURGICAL CLINIC OF PROFESSOR CZERNY AND THE CLINIC FOR DISEASES OF THE THROAT AND NOSE OF PROFESSOR JURASZ, HEIDELBERG; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; ASSISTANT SECRETARY OF THE OHIO STATE MEDICAL SOCIETY; SECRETARY OF THE NORTHWESTERN OHIO MEDICAL ASSOCIATION; AND PRESIDENT OF THE ERIE COUNTY MEDICAL SOCIETY.

IN modern therapeutics the application of sprays and powders in diseases of the throat, lungs, and ears makes it most indispensable for the specialist as well as the general practitioner who keeps abreast of the times, to have some means by which he can at all times and places fulfil these indications. The large pumps and reservoirs are not portable, the hand-bulbs always unsatisfactory, and such foot-power pumps as are on the market have not withstood criticism.

After some years of study, about a year ago, with the help of Mr. Waldkirscher, an expert in pump-making, I had a portable air-pump and reservoir combined made, which he had dubbed the "Graefe." It is made of brass, is four inches long and three inches in its other dimensions, and weighs less than two pounds. *A*, as will be seen by the cut, is the cylinder of the pump, roughened on its upper surface to keep the foot from slipping. *B* is the reservoir for compressed air, giving an equal pressure and when controlled by a valve cut-off as shown in the illustration, giving force enough for blowing powders, inflating the middle ear, etc. *C* represents the nipple to which the tubing is fastened for connection with the atomizer, and *D* a similar nipple to which an air-filter can be attached, or tubing, so that the air can be drawn from any source desired, avoiding dust, disease germs, etc. *E* represents the hinge and spring upon which the pump works.



In front of the case which I had made for the instruments, will be seen a gas cautery, which I invented a number of years ago but have never brought before the profession, because the rubber bulbs heretofore used for supplying compressed air have been unsatisfactory. *A* represents the point for the gas connection. *B* that for the air, *C* the platinum bulb, and *D* the opening for lighting the gas. It works perfectly with a slight pressure of gas and air, and can be handled by the operator without assistance. It does away with benzine and its dangers, the alcohol lamp, and the clogging of the Paquelin burners, as the platinum is hollow and has no meshes in its interior.

I claim many advantages for these instruments, which will suggest themselves to the profession, and think they will be as indispensable to others as they have been in my practice, if once used.

They are made by the Waldkirscher Pump Co., of this city, and are for sale by Meyrowitz, New York City, and Sharp & Smith, Chicago.

A Pathological Medical Club has been organized by the junior class of the Medical Department of the University of Worcester. The club is organized for the purpose of securing pathological journals and literature, and not literature and journals which are pathological, as the title might imply. The object is to have the members make translations and abstracts of important articles dealing with pathology and bacteriology. These are to be read and discussed before the club at stated intervals. The idea is in harmony with a suggestion made by Dr. Bayard Holmes, of Chicago, that there be established medical libraries and library clubs in connection with undergraduate medical study. The venture is a novel one, but will certainly prove useful if the students have time to pursue it as they should.

None in His.—"No!" exclaimed the fox, loftily; "I don't care for the grapes at all. Appendicitis? Not on your life!"—*Detroit Tribune.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 23, 1895.

	Cases	Deaths.
Tuberculosis	119	118
Typhoid fever	32	7
Scarlet fever	71	3
Cerebro-spinal meningitis	2	3
Measles	168	10
Diphtheria	201	22

Syphilitic Headache.—Fournier points out that pain in the head is one of the most frequent manifestations of secondary syphilis, while the prodromal headache of tertiary encephalopathies is universally recognized and described. It is, however, unfortunate that the term specific cephalalgia conveys to many minds the impression of a single pathological process, when, as a matter of clinical fact, the lesions may be, and often are, widely diverse in their nature. The single symptom common to all is pain in the head. Thus, this pain may be due to specific neuralgia, affecting one or more of the cranial nerves, constituting what is called neuralgic headache. Or it may be due to a lesion in the cranial bone, such as periostosis, gummatous osteoma, causing bone pain. Or it may develop as neuralgia without bone lesion, in which case it is often impossible to locate it. In many respects it differs not at all from headaches due to causes other than syphilis. Finally, there is a headache which, though dependent on syphilis, is not syphilitic in its nature ; in other words, it is a parasyphilitic neurosis. Syphilitic neuralgias are not headaches in the true sense of the word ; the pain is located in the trunk or distribution of a given nerve, and is aggravated by pressure upon certain portions of this nerve, particularly points of emergence. The supraorbital is most frequently affected, extreme tenderness being elicited on pressure over the supraorbital notch. This pain may affect the upper branches of the fifth pair, or the auricular and mastoid filaments of the cervical plexus, or the occipital nerve, but it is most frequently observed attacking the fifth pair, and has for its type the supraorbital neuralgia. This affection is observed during the early stage of the secondary period—that is, in the first six or eight months of the disease. It is impossible to state whether or not it is dependent upon organic lesions. When it occurs during the tertiary period, it is nearly always due to a distinct lesion ; often the pressure of a gumma or bony outgrowth. These specific neuralgias are characterized by almost identically the same symptoms, dependent on neuritis from other causes. They have, however, a tendency to become worse at night, and yield promptly to specific treatment. Indeed, the therapeutic test is the only means of making a positive diagnosis.

Pain due to bone lesions may occur in the early stages, during the height of the disease, or at a late tertiary period. It is most frequent in the tertiary period, and is readily recognized, since the lesions are gross, producing considerable deformity. Secondary lesions are slight, circumscribed, and readily overlooked, especially when they develop in the hairy scalp. They occur during this early period as periostitis, periostosis, or as ostealgias characterized by circumscribed areas of hyperæsthesia without appreciable lesion. These lesions are very common, especially in women, and are usually overlooked. The periostites produce slight circumscribed swelling of the bone, particularly in the parietal, temporal, and frontal regions. The involved areas are small—about the size of a ten-cent piece, sometimes as large as a fifty-cent piece—very slightly raised, sometimes obscurely fluctuating. They are painful and extremely sensitive. This excessive sensibility is a characteristic sign. Periostoses offer the same symptoms and are even more painful. They are, however, more dense and resistant and last longer. There is true bony proliferation on the surface of the bone. The ostealgias are characterized solely by pain. There is no swelling and no appreciable alteration of any kind. The pathological alteration occasioning this symptom is absolutely unknown. The pain of these bone affections is sometimes agonizing, and often radiates over a very large surface. The diagnosis is founded upon careful and thorough palpation of the entire cranium.

Headaches due to syphilitic affections of the brain or its envelopes are more diffuse and more deeply placed than those dependent upon bony lesions or upon neuralgia. It is impossible from the symptoms to decide whether they are dependent upon lesions of the meninges, the cerebrum, the blood-vessels, or whether all these structures are involved. Clinically, three varieties are recognized : Secondary encephalalgia, headache symptomatic of cephalic lesions, parasyphilitic headache due to hysteria or neurasthenia. By all odds the most important variety is the migraine preceding grosser symptoms of cerebral syphilis. In certainly two-thirds of all the cases of hemiplegia, amnesia, aphasia, epilepsy, coma, pseudo-paralysis, etc., dependent upon syphilis, there is this prodromal headache. A large percentage of these cases could have been saved from these grave accidents by vigorous treatment instituted during the period of prodromal headache. This headache differs from other cephalalgias, as, for instance, those due to neuralgia or epicranial rheumatism, from the fact that it is felt to be deep within the head. The character of the pain varies ; there may be simply a sense of weight and mental hebetude, or there may be a constrictive pain, as though the head were screwed in a vice ; or, finally, the sensation may resemble that produced by blows of a hammer, the suffering being very intense and the pain being deeply placed. These three types may be associated, or may succeed each other. The pain may be sharply circumscribed to an area not larger than a half-dollar. In this case it frequently indicates the formation of a gumma. Sometimes it is diffuse, occupying a general region, as the frontal, or temporal, or parietal, or occipital, or spread over two or more of these regions. Exceptionally it seems to involve the whole head. The fronto-parietal region is the one most frequently subject to this pain. This pain has three characteristics which should at least strongly suggest its nature. There is an habitual intensity, sometimes extraordinary severity, of pain. It is persistent, tenacious, long-lasting ; there are nocturnal exacerbations. Even in mild cases the pain is less bearable than the ordinary headache : it harasses the sufferers, making them despondent, morose, excitable, sleepless, and interfering with general nutrition ; or it may be so severe as to completely prostrate them. Exceptionally the pain amounts to a veritable anguish, comparable in intensity to that of hepatic or nephritic colic. Nocturnal exacerbations of pain, though the rule, are by no means invariable. In the secondary period this characteristic is most pronounced ; in the tertiary period it may be wanting entirely ; indeed, it may happen that there are nocturnal remissions. As a rule, syphilitic cephalalgia precedes the grave developments of brain syphilis by an interval of three to six weeks ; it is, however, not uncommon for this pain to last three to six months ; exceptionally the pain may exhibit remissions and exacerbations for two or three years. Under the influence of intermittent, mild, specific treatment, the headache may be temporarily cured, to recur time after time, till symptoms such as hemiplegia or epilepsy show that irreparable damage has been

done. The prodromal headache is a sign of inestimable value, enabling a treatment to be instituted in time to prevent grave lesions. This treatment should be instituted early, should be vigorous, should be long continued. It is not sufficient to cure the headache; the underlying constitutional taint must be eradicated in so far as this is possible.

This treatment should combine mercury and potassium iodide, each given in the most active form and manner possible. Every ten days an injection of a grain and a half of calomel should be given, repeated as often as is required. Internally, the iodide of potassium is to be administered, to a woman, one to one and one-half drachm a day; to a man, nearly twice this dose. This treatment should be long continued, with appropriate short intervals of rest, until there is good reason to believe that there is no likelihood of further recurrence.

Among the parasyphilitic affections causing headache may be mentioned the neuralgic migraine and the crises of pain often observed in tabes. The most important affection, and by far the most common, is neurasthenia. This is an ordinary sequence of syphilis, and among its multitudinous symptoms none is more troublesome or more frequent than headache. This parasyphilitic neurasthenic headache is characterized by very moderate intensity; it is not really a pain, but rather a sensation of weight or constriction, of dulled or imperfect cerebral action. As to duration, it usually lasts several years. It is present in the morning on rising; is sometimes better after meals, but shortly returns with its original intensity, or even with a slight excess of this; it is better at night, so that sleep is not disturbed. It is not benefited by specific treatment; it is usually located in the occipital region; and, finally, it is usually associated with other signs of neurasthenia. These are characteristics which sufficiently distinguish the cephalalgia from pain prodromal to the recognized cephalopathies; indeed, a headache which has lasted for several years almost certainly does not belong to the latter class, since apoplexy or some one of the serious symptoms denoting irreparable lesion is quite certain to develop long before the expiration of this period. Yet it may well happen that a differential diagnosis cannot be made. In this case the mixed specific treatment should be given one thorough trial. Should it fail, there should be no further effort in the direction of attempting cure by this treatment. Where the diagnosis of parasyphilitic neurasthenia is firmly established, minute attention to general hygiene, a thorough hydrotherapy, especially with douches of brief duration, or warm-bath treatment, massage, and change of surroundings represent the best methods of ultimately accomplishing a cure. The only drug which is of the least service, aside from the tonics and nutritives, is bromide of potassium; this sometimes relieves the headache.—*Therapeutic Gazette.*

Professor König, of Göttingen, has been chosen to fill the post of the late Professor Bardeleben, Professor of Surgery at Berlin.

Horse Meat in Germany.—It is said that nearly one-half of the flesh consumed by the people of Germany, in the larger cities, is horse meat. The German butchers used to buy worn-out horses at five dollars to ten dollars apiece, but they now have to pay from forty to fifty dollars. Even at this price, they are able to furnish meat at about seven cents a pound. The flesh is consumed salted and smoked, as well as fresh.

Infant Stomach Trouble.—About seven times more children, says Douglas, die from stomach and bowel affections during the first year of their birth than during the second year.

Dr. Smith.—The name "Smith" is the popular monosyllabic appellation of 1,284 practising physicians in the United States.

Sick or Ill.—Mr. W. D. Howells discusses, in a humorous way, the fact that there is a tendency in America to use the word "ill" in place of the word "sick," following the English fashion. To the Englishman, the word sick implies, as we understand, a morbid state especially connected with the stomach and with nausea. The American uses the word sick to indicate all kinds of morbid states. The word sick is a good, honest Anglo-Saxon term, and has answered the purpose very well during these last two hundred years. But Mr. Howells seems to think that it has got to go, and that in time there will be no sick people in America, but only persons who are ill.

The Dangers of Thyroid Feeding.—It has come to the notice of physicians, that the thyroid tablets are being used somewhat by the laity, and especially by women who are desirous of ridding themselves of superfluous fat. Some dangerous symptoms have been observed, we are told, as the result of this treatment. Dr. A. Eulenberg, of Berlin, reports a case in which the patient took six tablets a day, with severe nervous and cardiac symptoms as the result. There can be no doubt that the use of the thyroid tablets is dangerous, and should only be employed under careful supervision.

NEW BOOKS RECEIVED.

THE PROGRESS OF MEDICINE.[1]

BY EDWARD G. JANEWAY, M.D.,

NEW YORK.

MR. PRESIDENT, MEMBERS OF THE ACADEMY, LADIES, AND GENTLEMEN: It is my privilege to address you this evening, and while I have felt that some one with more oratorical power might have been chosen, yet it was not possible to refuse the request of the President, who put it in the light of an unavoidable duty. In going over the ground for a subject which might be of general interest, and yet more, one from which lessons of importance to the welfare of the Academy might be drawn, the speaker has selected the progress of medicine. It is not the intention to pass in review the gradual advances of medical science, but to limit our theme to a time sufficiently recent to be within the memory of a number, and the knowledge of all—that of the last thirty years. The theme will be somewhat discursively considered, in order to touch on a number of points.

If we commence with the study of medicine as now conducted in this city, and compare it with that which obtained thirty years ago, we will notice a marked improvement, which, however, is not perfection, because of certain limitations of time, and of number of students to be instructed within that period. Thirty years ago the time required for the study of medicine was three years, comprising two courses of lectures in a medical school, the last of which was to be in that institution which issued the diploma. A considerable part of the study and of the practical work was supposed to be done in the office of a practitioner with whom the student entered, and who was usually too busy to give more than a very slight oversight on the progress of the aspirant for medical honors. Much of the work in those days, far more than at present, when there is yet too considerable, was in the direction of what is called teaching, cramming, etc., consisting in making the student memorize facts from books and lectures, and not education in its truest sense. The idea of the difference between a true educator and a teacher in the ordinary acceptation of the word, does not enter into the conception of many medical students, and is possibly absent from the sphere of some teachers of medicine. In the coming era the demand will more and more be for educators, not for the ordinary teacher, who will simply cram the student with facts, theories of disease acceptable to himself, and plans of treatment of which he approves, as the only possible things which the student must remember. The facts may not all exist, the theories be false, and the plan of treatment one which is but the fad of the present, or possibly even of a past, to be discarded later; nevertheless the student is obliged to learn these things. How many a student in after-life has wondered at the difficulty of shaking off false conceptions of disease because of the thoroughness with which they had been ingrafted during the stage of pupillage! How different this plan of dealing with the youthful medical mind from that which should obtain if the best growth of which each is capable is to be obtained. The true educator takes the student (speaking now of one branch as illustrative) to the disease as it exists in the living patients, showing him the different aspects in which it may present itself, letting the student note the condition of the mind in delirium, scan the state of the eye and pupil, and of the expression of the features, see the variation of temperature, feel the different characters of the pulse, note the phases of eruption, listen to the varying sounds to be heard in the heart and lungs, and palpate the conditions capable of such method of demonstration in the different parts of the body. Moreover, as he trains the student to observe he will try also to impress upon him the importance of these observations by applying them to diagnosis and to treatment. But here we can discern the great and radical difference between a teacher and an educator. The former will strive to impress upon the student that such and such is the case because I say so, or it is my way of doing, the ego being ever so large as to obscure the true object of teaching, viz., to develop the student into a correct thinker, not a dwarfed reproduction of the teacher. On the other hand, the educator will go over the varied manifestations, striving to make the student think out first the conditions, and next the method of combating these, so that with each case seen he may ever be a better reasoner, and be more capable of recognizing such subtile differences as may determine this or that to be the preferable plan of procedure.

In the death of your late President, Dr. Alfred L. Loomis, one of the prominent teachers and educators has been removed. The curriculum of each of the medical colleges of this city (speaking for our branch of the profession) has been lengthened, until now, in one, it consists of a compulsory four years' graded course, extending over eight months of the year, with a large portion of the time devoted to laboratory work and to practical study of disease. In the other two colleges for men the compulsory course is of three years' duration, for six months of each year, with an addition of two months of permissory study under the direction of the faculty. The medical college for women has as rigid requirements as those for men.

In all the colleges much of the practical teaching for which formerly an extra charge was made is now a part of the regular course. In by-gone times students were at times given diplomas entitling them to practise medicine, when they had never heard the morbid sounds of disease, applied a bandage, or helped at the introduction of a new life, but had only crammed the theory of these things from books. Each decade has witnessed a striking improvement in this direction. Some may say that there were clinical lectures given in all the colleges, but what did those students learn, who were on the back seats in a crowded amphitheatre, of many of the subjects presented. It should be added here that the medical colleges of other cities have also advanced in their requirements and plan of study, or have, as the Johns Hopkins, only had that method of medical instruction *ab initio*. Most of you, moreover, realize the additional burdens which have been placed upon medical students in the newer and the more extended branches of study, compared with what obtained thirty years ago. At the present

[1] An anniversary address delivered before the New York Academy of Medicine, November 21, 1895.

time more or less of histology, normal and pathological, is required in all our colleges, and in considerable degree this is a practical course. In one school compulsory laboratory study of bacteriology has been added. Thirty years ago the former may have been in a measure permissible, were the student so mindful and could get the opportunity; of the latter practically nothing was known. Now, moreover, each of the colleges has laboratories and microscopes, the former the gift in each case of some citizen (of this city), who should ever have pleasure in the contemplation of having done his share in placing our medical colleges in the position of truer educational centres. Volumes are now written upon the subject of bacteriology in each language, where formerly none existed, and the importance of this new branch constantly increases. Yet there is a singular confession of our ignorance to be made here. We are as yet unable to teach the student the name, or to know ourselves the organism productive of some of the most contagious of diseases.

With the growth of knowledge in different directions there has come more or less of a necessity of separating the teaching faculty of our colleges into those devoting themselves to the scientific subjects and those who teach what are called the practical branches. Formerly a professor might teach physiology or pathology, and at the same time practise medicine; but, owing to the rapid and widening growth in these branches, some of the colleges have the professors of these chairs devote themselves to the study of the subject and not engage in practice, in consequence of the inability to do their best work under the distractions incidental to the practice of medicine. The growth of physiological chemistry is so considerable, and the study of pathology, and especially of bacteriology, is so time-robbing, that in case the professor desires to be an educator he must devote himself to the subject. My object in thus briefly bringing before you this matter, its importance, and the necessity which exists or will exist in all our medical schools of having men devote their time to the consideration and teaching of these scientific subjects, instead of making them accessory to the practice of medicine, is to call attention to the necessity of urging the endowment of these chairs on scientific subjects in such colleges as have not the means of properly remunerating these chairs. The professor of what is called a practical subject is enabled to improve his position and to increase the pecuniary return from the work and time he bestows on teaching.

Hence the necessity exists, and the question comes from whence are the colleges to obtain their endowment fund? In Germany the government provides, but in our country we must look to our wealthy citizens not alone to build colleges and laboratories, but also, what is of more importance, to endow chairs in these institutions, at least those of a scientific nature. At a recent meeting of the American Academy of Medicine resolutions were adopted which looked toward the discouraging the building of any more hospitals and dispensaries, on the ground that enough, or more than enough, already existed, and that their effect was to interfere with the returns which the number of physicians now in this country should obtain from the practice of their profession. It may well be asked also if there are not too many medical colleges, especially those in small cities, turning out too many physicians, some of them poorly equipped for their work, but yet competitors with the better educated for a livelihood.

However, the establishment in different States of the requirement of a license from a body of examiners appointed directly or indirectly by the State, and issued only after an examination, has acted in some degree as a safety-valve, for a fair percentage of candidates fall short of the requirements. The practice of medicine, moreover, owing to a license being required in most of our neighboring States from its own board, is hedged with more restrictions than formerly, and it is a matter for consideration whether some inter-State courtesy or reciprocity will not be a necessity. New Jersey, I am told, will allow a licentiate of New York to file his certificate from the latter State and practise thereon, but he must pay double the fee over what would be required if he passed an examination.

It behooves me to speak with emphasis upon the benefit the medical profession has received from the employment of efficient trained nurses. The Bellevue Hospital training-school is the parent institution, and only twenty odd years old.

Two schools now exist for the teaching of those graduates of medicine who wish to avail themselves of the rich clinical material in New York City in a short space of time. Few of us appreciate the immense strides in our knowledge of some departments of medicine. In no branch have greater achievements been reached than in neurology. Numerous systematic treatises now exist upon the subject, several authors being members of the Academy, and it is taught as a special course instead of, as formerly, being grouped with general medicine.

Thirty years ago multiple neuritis was unknown, the most astute observers considering the manifestations as indicating a subacute general spinal paralysis, and writing the methods of diagnosis of this complaint. To-day a medical student is readily taught the means of discrimination, and in that bygone time not a few cases of cured progressive muscular atrophy and locomotor ataxia were to be referred not to the cure of these latter conditions, but to a mistake between those conditions and a disease not then recognized. Gradually, too, in these years the term neurasthenia, first employed by a member of this Academy, has come into general use. The monotony of having only malaria for obscure states of the system has been wonderfully relieved by the complex of conditions comprised under this head, and with lithæmia they divide the debatable ground.

I fear that a number of my hearers have never read the book upon spinal-cord troubles which was much resorted to in those days, the brochure of the lamented and brilliant Brown-Séquard. In this work we were taught to distinguish between meningitis, myelitis, congestion of the cord, and reflex paralysis. This was a very simple matter compared with the terms and the diseases of the spinal cord which the student must to-day comprehend. I shall not weary such of my auditors as may not be familiar with the long list. We are indebted for the progress to many workers, each adding something to the structure, though no name stands out so prominently in the whole field as that of the late distinguished French physician, Professor Charcot. So much has he been identified, both by writing and teaching, with diseases of the nervous system, that many are unaware that he contributed articles on the diseases of the liver and kidneys; and, in fact, after Moneret, was the next to employ the term fever intermittent hepatic of biliary obstruction, years before lectures were delivered and articles written about this condition in English; at a time, in fact, when most of our text-books were teaching that fever did not occur with biliary colic and pointed to some other condition. Pardon me for the digression, but I thought that this brief notice might be of interest.

In no direction have greater advances occurred, moreover, than in the ability to locate the area of disturbance in the brain. The fight for localization was a long and arduous one, whose beginnings date beyond this era, in the discovery of the connection between aphasia and disease of the third frontal convolution of the left side. Yet he who reads an article on aphasia of to-day, and such a masterly one as that contained in Trousseau's clinical lectures, will note the growth of our knowledge on this subject. The writer recalls the amazement of a friend well versed in neurological knowledge at the time, on noticing the

record of an autopsy in a case of aphasia, in which the lesion was found in the left temporo-sphenoidal lobe, and his insistance that a mistake had been made in not noticing some connection of the disease with the third frontal. This is an illustration of the importance of paying great attention to such cases as deviate from the general type and the ordinary phenomena of a recognized disease; for he who carefully scans all the features of such a case with sufficient knowledge may discern a new law or bring to light a subdivision of importance. We now understand word-deafness and its relation to disease of the temporo-sphenoidal lobe. Had my friend, who made the autopsy in that case, also been possessed of all the facts in the ante-mortem history, he might have been one of the earliest describers of word-deafness. Moreover, we have been very considerably indebted to vivisection for the advance in this direction. Without this method of investigation the writer cannot see how the increase of knowledge which has occurred would have been possible. Undoubtedly it has required the careful and painstaking research of numerous autopsies on those dying of disease of the brain, to confirm in the human being the observations made on the lower animals; but these alone would not have sufficed to place the theory upon a firm foundation. The brain surgery of to day is in consequence a very different affair from that which obtained in the sixties. In certain instances we feel that it has led enthusiasts too far, and that a certain proportion of such operative interferences might far better not have been attempted. Our distinguished ex-president, Dr. Jacobi, has drawn attention to this in his address "Non nocere." Yet the outcome has been that lives have been saved by the ablation of tumors, by the opening of abscesses, and by the removal of clot, whose location was only recognizable by study of rules growing out of the work of Hitzig, Ferrier, Munk, and others.

The railroad spine, or concussion, has also been a product of these last thirty years, Erichsen having launched the term greatly to the regret of numerous railroad companies and corporations, who have been in many cases mulcted of large sums owing to the elasticity of the term. A disease indeed with varied symptoms, but having in one respect a close resemblance to dipsomania, viz., in that a certain proportion of the cases are best treated and restored by the gold cure. So, too, in this connection there was recorded unfortunately that first instance of abnormally high temperature in the case of the young lady thrown from her horse, and while the temperatures recorded in her case, and some more remarkable of subsequent dates, have always puzzled the writer and many of his friends, they believe them only explainable by juggling with the thermometer.

Not alone has the list of diseases of the spinal cord been increased by our expanding knowledge, but many of supposed functional character have been found to be of organic nature; the difficulty earlier having been the lack of autopsies in appropriate cases, and in addition the want of accurate methods of investigation in such a structure as the spinal cord. Within this period also the choked disk became noted as a pathognomonic sign of tumor of the brain, and though it was soon discovered that tumor of the brain might occur without this, yet it took considerably longer to dispel the idea that tumor was the cause of trouble should a choked disk be found. So much was this the case that when one had been noted, and the subsequent course of events demonstrated the inaccuracy of the statement, attempts were made to draw a distinction between the appearances in the two conditions. Now we know that the condition is not pathognomonic. However, later on we will allude to this same sort of error in disease of another organ. The first observer draws attention to the existence of a certain state in some disease, others note the same thing, and soon an enthusiast, or better, a dogmatist, announces such a condition is a sign of such a disease, and years are spent in undoing the evil.

The term myxœdema has also come into use, indicative of a disorder not dreamed of thirty years ago, and it illustrates the method of discovery of relationship between an organ and a state of the system long overlooked, and for which a remedial measure has been found in the feeding of the sheep's thyroid. The names of Gull, Ord, Horsley, and Murray stand out prominently in the gradual description, recognition, understanding of the pathology, and treatment of this state.

It has been a matter of interest, too, to note how little of apparent notice our German friends took in a diseased condition worked up by English physicians; though Kocher, of Berne, in describing the results of the removal of the thyroid described myxœdema and helped to bring into relief the true cause of the complaint.

The method of mediate percussion introduced by Avenburger, and that of auscultation taught by Laënnec, gave, in addition to the other, though not so essential, means of examination, an early insight into the diseases of the heart and of the lungs long before the period of which I write. The chief additions to our knowledge during this period have been by the explanations bacteriology has given as to the etiology of disease. Of course, pathological examinations have gradually increased our comprehension of the intimate changes of disease, but no such marked increase as has been noted in the case of the nervous system has occurred.

Actinomycosis has been made out. Explorations with needle and syringe have enabled us to tell at an early date the nature of fluids in the chest and pericardium. Moreover, I believe that this method was more employed in New York at an early period than abroad, and though liable to abuse by careless use of unclean instruments, or by lack of forethought as to the nature of the process for which used, it has proved of marked benefit. The introduction of aspiration by Dieulafoy has simplified the withdrawal of fluid from the pleura and from the pericardium, while free drainage has gradually helped to cure cases of empyema in a shortened period of time. We understand, moreover, ulcerative endocarditis, have had the terms tachycardia and bradycardia replace the simple names of rapid and slow heart. Moreover, it seems to the speaker that at the present time greater attention is given to a consideration of the condition of the heart muscle, and the importance of the study of this as contrasted with that of the adventitious sounds or murmurs which were formerly so apt to monopolize attention, or else receive too considerable thought.

The use of the stomach-tube for investigation and for treatment of disorders of this viscus has been the means of widening our knowledge of stomach disorders, and also of proving a very important aid in bringing about cure or amelioration of its diseases. This is sufficiently familiar to you, as is no doubt that other production of erroneous diagnostic rules based upon its employment. For no sooner was it found that free hydrochloric acid was absent from the stomach in cases of carcinoma, than it was assumed that the absence of free hydrochloric acid meant carcinoma. The dogmatist laid down the law on an insufficient basis, only to discover later that the methods were at times inaccurate, and that other conditions could at times produce the same result.

Perhaps no greater improvement in our consideration of abdominal disorders has taken place than in the recognition of appendicitis as a diseased condition of frequent occurrence, and that a very large proportion of what had been formerly termed perityphlitis in a loose way, was in reality periappendicitis, and that the exudate in the majority of these cases was intra-peritoneal. Moreover, it has proved the means of lessening largely the cases of so-called idiopathic peritonitis, the ma-

jority of them being dependent upon perforations or disease of this apparently unnecessary (unless to the surgeon) portion of our anatomy. A former member of this Academy, Dr. Willard Parker, laid down the rules of guidance for perityphlitic abscess—and it was reserved for another, Dr. McBurney, to urge the importance of the early operation in the cases of appendicitis. Moreover, from what has come to my knowledge here, compared with that of which I have information on this subject abroad, I believe that the surgeons and physicians of New York City and of the United States have had a much truer conception of the process and of its proper treatment than have those of other countries. In fact they have only within a recent period waked up to a just realization of this matter. It has hardly been necessary to remind you of this advance in view of the number of times that you have been addressed upon it. So, again, the recovery from tubercular peritonitis as a result of a simple laparotomy is a progress whose real explanation eludes us as yet.

When we come to consider the etiology of disease, and particularly of the infectious disorders, we at once appreciate our true conception of these conditions. Thirty years ago we were still as those who see through a glass, darkly, in this matter, though in the past there had ever been those who felt the need of some organized body with life and capability of division, to explain this infectiousness and contagion. Any who will look up the literature of influenza will be struck by the soundness of reasoning of some of the observers of epidemics of this disease in the last century—a soundness of reasoning that ought to put the blush on the cheek of some writers on influenza, who indulged in speculations as to the cause of the disease when it made its first reappearance some five years ago. For this purpose I can commend Symes Thompson's historical survey, and particularly the extracts from Gray and Haygarth, and the statement of Heberdeen about Haygarth's communication in reference to the outbreak of 1782. It would take too long to reproduce here Haygarth's method of reasoning in his own words, but it is of particular interest to note that his communication in regard to the outbreak of 1782 was not published until 1803, on the occasion of another epidemic.

Haygarth gives the following interesting reason for the publication of his communication, after twenty years, regarding the influenza of 1782, and his reasons for considering the influenza to be due to contagion: "The contagious nature of the influenza had, as I thought, been sufficiently proved by many physicians. . . . But a contrary and, as I think, a very pernicious opinion, has lately been supported by physicians of great respectability, and authors of the highest reputation, not indeed in this, but in other enlightened nations, have ascribed not only this, but many other epidemics, even the plague itself, to a morbid constitution of the atmosphere, independent of contagion. To determine whether this doctrine be true or false is of the highest importance to mankind. Knowledge in this instance is power. So far as it can be proved that a disease is produced by contagion, human wisdom can prevent the mischief. But the morbid constitution of the atmosphere cannot possibly be corrected or controlled by man."

The younger members of the Academy will not remember the long controversy regarding the possible infectious character of tuberculosis, including phthisis. There was only a small minority of physicians who admitted this prior to 1882, when Koch announced his discovery of the germ of tubercular affections. As often happens, not a few of the laity, judging from what came under their observation from time to time, had accepted the theory; moreover, there was a strange superstition, or perhaps fancy would be a better word, in different parts of the country, that in case an invalid with the disease could give the malady to an animal he might recover. This idea was undoubtedly founded upon the observation that at times one of the lower animals, in contact with a person suffering with phthisis, contracted the disease. Moreover, even after Koch had announced his discovery, and even after its confirmation by many different observers, it required still much controversy to cause its more general acceptance. As so often happens, those physicians who made a special study of the disease were found in certain instances the most difficult to convert. Especially were such arguments used as, that we have had charge of a hospital for the disease (Brompton Hospital), or a hospital in which the disease was treated, and neither our house staff, our nurses, nor our attendants, nor other inmates, were affected in any such manner as to prove the idea. This is the argument always used by those who dislike to admit the force of reasoning relating to improving conditions dependent upon acceptance of a theory adverse to business interests, or to theories previously taught and held. As a theory it has proved dangerous, because those who have become ill in this way are not to be looked for among the present workers in places of nuisance, nor in the case cited in hospitals and wards for consumptives. They have either given up their places or have been laid where alone the tombstone will speak. The writer had in his earlier practice collected a number of instances pointing toward the dissemination of phthisis from sick to the well in families, in houses, in institutions, and in one case from one patient to four successive dogs. In coming to the conclusion some years before he published his conviction that there was a contagious element in phthisis, he found very few among the leaders of medical thought in this city who accepted the idea. And even after Koch promulgated his proofs about the tubercle bacillus, the statement was that this germ found favorable soil in the diseased parts, was not cause, but simply concomitant — the same argument which had been used years before by some dermatologists to prove that the parasite in parasitic skin diseases was not cause, but only an outcome of a favorable nidus.

At the present time but few deny the infectiousness of tubercle. Thirty years ago there was still much argument as to the unity of tubercle and of varied tubercular affections, and much question existed as to the relationship between miliary tubercle and tubercular pneumonia, or, as it was called, tubercular infiltration. Anatomical differences were drawn, by means of which we should discriminate. How simple it seems to the student of to-day, as contrasted with that one of thirty years ago. The attempt was made by this and that reason to make plain what the professor himself was not assured of. Moreover, this discovery of Koch's has, by assigning a definite cause for the tubercular affections, drawn attention to the necessity of preventive measures in dealing with the excreta which contain the bacilli. The prevalence of phthisis is so great, the apathy as regards careful attention to this matter on the part of some of our profession is still so considerable, and the numbers of those ill adapted to resist the inroads of so prevailing and insidious an enemy, owing to inherited or acquired weak frames, is so great, that we do not wonder that, notwithstanding our knowledge of the bacillus is thirteen years old, at the death-rate from this cause. The writer calculated that there must be nearly fifteen thousand cases of the disease in New York City, and that a very considerable portion of these are peripatetic. Yet in preparing a paper on overcrowding, for the County Association, two years ago, he was gratified to find that both in New York and in Philadelphia the number of deaths from phthisis had diminished instead of increasing during the last ten years, as contrasted with those gone before. Nor could this diminution be ascribed satisfactorily to other causes. We hope to see a careful statistical table on this subject at no distant date, which shall comprise most of the large cities, in order that we may be better

able to judge as to this improvement. And it is hoped by the writer that each member of the Academy will do all in his power to teach those suffering with the malady, or their friends, the importance of destroying the secretion from the affected parts, and thus aid the efforts made in this direction by the Board of Health. We do not expect to see the disease completely eradicated, but we feel that with medical insistance and the increase of popular knowledge in this regard, that we shall witness a much more considerable check to the ravages of this fell destroyer.

We cannot believe that the density of population permitted in New York City, twenty or twenty-four families on a twenty-five by one hundred foot lot, betokens medical progress, nor does it point to as successful an issue in the struggle with tuberculosis and other infectious diseases as may be the case in less crowded places, providing that equal vigorous measures are adopted looking to the destruction of the bacillus. The fifteen, twenty, and more story high office buildings are also fraught with danger in the same direction. So many people are brought together in confined areas that one tubercular invalid, if careless, has much greater chance of spreading the disease. The papers point at these lofty structures, attempting to compel tribute from the sky, with civic pride, but we feel that they are an added source of detriment to health and cannot be considered as medical progress.

Koch may justly be proud of his position in aiding in the progress of medicine. A practising country physician outside of the university, studying carefully with Cohn microscopic botany, he discovered first the link which was sought to complete the life-history of the bacillus of anthrax, a matter which was needed to throw light upon its method of entrance into the system. This was the existence of "dauer sporen." Then he worked out much about septicæmia, and later cholera as well as tuberculosis yielded up to his search the cause of their being. Moreover he, more than any other, taught the true method of bacteriological research. Many names admit of honor in this regard. Pasteur, his predecessor, for his long work in the same direction; Eberth, discoverer of typhoid germ; Fehleisen, of the erysipelas coccus; Laveran, of the malarial plasmodium; Obermeer, of the relapsing fever spirachele; Nicolaier, of the tetanus bacillus; Hansen, of leprosy bacillus; Loeffler and Klebs, of the diphtheria bacillus; Fränkel, of the pneumococcus; and Friedländer, of the first variety superseded in great measure by Fränkel. Moreover, a variety of germs capable of exciting suppuration have been made out by different observers, Ogston, Rosenbach, Passet, and others. Finally, it has been reserved for Kitasato, the Japanese bacteriologist who had worked with Koch and who had with Nicolaier studied the tetanus bacillus, to work out the bacillus of the plague. He went to China to engage in those studies, which resulted in the discovery, conducting them according to the rules laid down by Koch. This certainly betokens medical progress, and how gratified would Haygarth be, were he living, to know that this argument was correct, though the finding of the organism had occurred over one hundred years after his utterance. More surprised he would be to know that the discoverer was a Japanese, for the plague organism, while Pfieffer had unravelled the secret of influenza in finding a bacillus as cause.

If, without going into detail with each of these, we ask whence the gain from this knowledge, we may well answer, much in every way. The discovery of the cholera spirillum has put in the hands of sanitary authorities a means of distinguishing the disease at an early period, and of taking precautions in consequence of certain knowledge that formerly would have required time and the development of additional cases. In this way, aside from the value attaching to knowledge in the abstract, it has proved of immense importance and will gain in this respect, should the immunization experiments meet continued success.

With reference to typhoid fever we are enabled to know more accurately the conditions favorable to the life of its causative organism, and thus to increase our means of preventing its spread. This knowledge, alas! has robbed us of some of the satisfaction with which we eat raw oysters in the fall of the year, when typhoid germs are being discharged from sewers whose openings in rivers may be near the floats on which the oyster is being fattened or freshened. Medical progress may demand that oysters shall be freshened only in such places as shall be free from liability to typhoid contamination. Previous to the discovery of this organism much of what we now know had been adduced by careful and painstaking study of the method of origin of the disease; and it has served to direct attention away from sewer-pipes, defective traps, etc., to what was eaten and more particularly drunk, water and milk as the main sources of etiological importance. As far as the writer can see, our knowledge of the pneumococcus is as yet of scientific interest more particularly, though it serves to prove the right of those who, as my former distinguished and revered colleague, the late Professor Austin Flint, claimed pneumonia as an infectious disease prior to the discovery of an organism —and also for possible antitoxin production. The proof of the existence of germs causative of suppuration has in part helped to revolutionize surgery. We say in part, because prior to the proof such far-seeing men as Lister had reasoned out the probability, and laid down rules for the prevention of their entrance in operations, etc. Rules which are now discarded, because the surgeon has learned the value of cleanliness. Cleanliness is next to godliness is the motto, but alas! in bygone times the lack of cleanliness on the part of the surgeon led many a poor soul to learn the mysteries of another world. The writer dreads to think of the number who have succumbed in this city, prior to the era of aseptic and antiseptic surgery.

The treatment of internal diseases has not apparently made so considerable an advance as has the surgical. This is entirely owing to the fact that asepsis has allowed the surgeon to achieve results impossible previously. Yet, when we come to consider that the physician aims at two entirely different results as the issue of his increased knowledge of the etiology and course of disease, we will be struck by the progress which has occurred. He aims, in the first place, to prevent the spread of contagious and infectious disorders, and through foresight, so far as may be, to forestall the influence of deteriorating conditions in individual cases. On the other hand, his duty is to carry the individual patient through his sickness, whatever it may be.

Though much of the work of protecting the community has been placed upon boards of health, yet it must be recognized that these owe their origin, development, and efficient activity to medical men. A large measure of advice has still to be given by the practitioner to the families under his care, as to the proper methods of procedure against contagion. We have not been able as yet to secure so effective a protection against the other dangerous contagious disorders as vaccination has achieved against small-pox. In this city, during the last thirty years, a study of the statistics will show a remarkable gain in this regard by the establishment of a permanent corps of vaccinators under the control of the Board of Health. Previously to 1875, when an epidemic of small-pox occurred, then a corps of physicians was assigned to the work of gratuitous vaccination among the poor of the city. Since that date a permanent corps has been maintained, and it can be proven by the results to be the only wise course in a large city. The epidemic of 1874 died out in 1876, and while since outbreaks occur from time to time, when enough unprotected people exist to form a chain after the exposure of the first to the exciting

cause, yet these have not attained the magnitude formerly possible. A careful study of the statistics of small-pox in New York City will convince any reasonable person, not alone of the immense value of vaccination, but also that a permanent corps of vaccinators employed by the city is as essential for the control of the disease. Fortunately, the vaccination law is not compulsory in this city, and hence the anti-vaccination cranks have never been able to reach any considerable number nor obtain any marked influence. They are like the smut on the corn in a field with a large crop, here and there a dark spot, in the wonderful progress of prevention in this disease achieved in this city during the past twenty years. But this era has been marked by the attempt to control other diseases by a protective influence not like vaccination. Pasteur, who had obtained successful results in dealing with animals by the use of attenuated virus, succeeded in his attempts to find a means of immunizing animals against the hydrophobia by the use of attenuated poison derived from the desiccated spinal cord of rabbits. He also applied this method to human beings, with a result which has given him world-wide fame. Insomuch as in both vaccination and in inoculation for small-pox the germ itself is introduced, grows, and by producing on the one hand vaccinia and on the other a mild attack of small-pox, we may question whether in these protective vaccinations against hydrophobia, with gradually increasing strength of virus, it is not a gradual toxin introduction rather than of the germ of hydrophobia which has not so far been isolated.

Since this time numerous workers have endeavored to solve the question of immunity. The results of vaccination, the fact that human beings and animals recover from infectious diseases, and that one attack of some infectious diseases protects for more or less of a lifetime against subsequent exposures, and in other diseases against a speedy return, led to the search for the method of cure and of a means of immunization against diseases of this nature. It was reserved for Behring to study out and bring to public notice the demonstration that the blood serum contained in tetanus and in diphtheria a substance which has been termed antitoxin, which in each of these diseases had the property to so far antagonize the toxin of disease as if injected previously, with or very shortly after the toxin in sufficient quantity and strength, to prevent the poisoning of the system by the toxin. Kitasato worked with him in the study of the tetanus immunity. Thus was laid the foundation for the serum therapy of diphtheria and of tetanus. In the case of diphtheria, because of the frequent occurrence of the disease, because of its severity and of the number of deaths due to it, this method of treatment has acquired world-wide attention. When we consider the number of deaths from diphtheria, including croup, occurring in New York each year, this city has a vital interest in the matter. The Board of Health, at the suggestion of Dr. Biggs, and with the co-operation of Dr. Prudden and the work of Dr. W. H. Park, his assistant, began and continue the production of this antitoxin gratuitously for the poor. At the meeting of this Academy on April 3d of this year the subject was presented to the members, and the results then achieved at the Willard Parker Hospital and in the city detailed. Such arguments as could be urged in opposition were presented by Dr. Winters. Since that time the use of antitoxin has continued, and the speaker said he could not allow this opportunity to pass by without stating the reasons why, when asked, he advocates its use. The statistics of the death-rate from diphtheria and croup in Paris prior to and since the use of antitoxin serum, which is there prepared by Roux, who, after Behring, principally drew the attention of the profession to its value, are so strikingly favorable that, till disproved, no other should be needed. So again, the statistics on the same subject furnished by institutions and physicians in Germany in the great majority are arguments for its use. A very able paper by Professor William H. Welch, of Johns Hopkins University, embodies his views, and is based upon a careful study of seven thousand cases treated by this means. The result is decidedly confirmatory of its merits. Moreover, a number of physicians, in whose judgment and ability the speaker has confidence, have stated to him its favorable effect in extremely severe individual cases of the disease. The papers presented at the meeting of the Academy on April 3d are arguments for its employment. More recent statistics than these in journals of recent date confirm me as an advocate for its employment. The occurrence of forty-three deaths from diphtheria and croup in this city during the week ending November 9th make the speaker fear that this method is not receiving a prompt and fair trial. Moreover, previous to this date the deaths from the disease have not decreased as have those in Paris.

We would not be understood as stating that there are never any disagreeable sides to this treatment. These the advocates of the method admit, but the speaker does not believe that all the evils which follow the use of antitoxin are of necessity due to the antitoxin. When we consider that the horses used for the production of antitoxin are of a very different constitution, though young and free from disease so far as can be made out, yet the fact that some serums far more than others are attended by urticaria, and by joint pain or rheumatic-like attacks, suggest the idea that if one set of observers find results at variance with those of the rest or many of the rest, we have a right to conclude that some of the differences are dependent upon the horse from which the serum has been obtained. The possibility that some of the horses had rheumatism is suggested. Neither should such distresses as are to be fairly attributed to it be allowed to outweigh the advantages, when employed early.

Tetanus is fortunately a comparatively rare disease, so that the same interest does not attach to the use of the serum therapy for the possible cure of this disease. Yet the results obtained by animal experimentation stand on the same footing of success as is the case with the diphtheria antitoxin. However, there is the difference that the amount required is larger and greater the longer the symptoms have existed. The cases so far treated in tetanus give a hope that, early and promptly employed, success may at times be obtained to a greater degree than would otherwise be the case. Yet it will require a very careful gathering of statistics to inform us of the absolute value of the remedy.

Experiments in animals have also been made with the organism and toxin of cholera, and recently experiments made in India seem to show that Hafkeine has succeeded in proving a probability that he has immunized those exposed against this disease.

Claims are now being made for the success of this method for other infectious diseases—pneumonia, typhoid—and more recently for the pus-exciting organisms. There is undoubtedly much of promise in this field, but a liability also to allow our enthusiasm, due to the success in one or more directions, to lead us astray in claiming too much or against a process for which it is not calculated to prove serviceable.

For the last few years, associated with the struggle to prove that carcinoma and sarcoma are not simply outcomes of the bodily development, as a result of unused embryonal tissue stored up in some nook of the body, but are due to the influence of a parasite, animalicular or vegetable, there has gone on an attempt to check its growth by the use of toxins of erysipelas, etc., or the serum of animals treated with such toxin. Our colleague, Dr. Cooley, has been an enthusiastic worker in this direction, and feels confident of some success from his work. The writer has not personally been able to witness a case which has turned out successfully, though he has had them subjected to the trial. In view of the fact that successes have occurred,

it seems that we will be obliged to assume in these cases a difference of structure or of etiological substratum, such as does not reveal itself to the microscopist. The writer trusts that either by the means now used, or by the intervention of some additional agencies, we may be enabled to add to the progress of medicine in other directions that of having achieved a victory over the malignant tumors.

The attempt to cure consumption (tuberculosis) has been oft repeated, and in view of the prevalence of the disease, which kills five thousand people annually in round numbers in New York City alone, no wonder is excited by the frequent appearance of a new method for which great promise is made. Thus, of late years especially, the hot-air inhalation, the Bourgeron carbonic-acid and sulphuretted-hydrogen injection, and last the tuberculin plan, have come successively before the medical and lay public with great pretensions. The two former quickly sank to their proper level of inefficacy; but the latter came heralded by the name of one who has done so much for the medical progress of the last twenty years that it was not alone the hope for a cure of this dreaded disease, but interest that the discoverer of the germ of origin of the disease might also be the finder of the means of its destruction, that gave intensification to the announcement. We must regret the eager striving to be the first to use this new remedy, product of difficult and prolonged research on the part of its renowned projector, which rather marred its introduction. At present it is but little used, though there are those who, like my friend, Dr. Trudeau, are making continued tests in those who desire to make trial of it; and I am told that Professor Koch is himself still at work endeavoring to secure some method by which it may be employed with success. The writer, and I have no doubt all his auditors, wish him Godspeed in his efforts. As it is, we find no better method for the cure so far than the effort to develop the patient's internal powers of resistance by suitable climate, air as free as possible from the germs of suppuration, improved nutrition, and appropriate medication in such better atmosphere where as much as possible an out-door life may be led.

A visit to the sanitarium at Saranac Lake would well repay each of my auditors. The cottage plan has been adopted except in the oldest structures, each holding four inmates, with a common living-room and a separate bed-room. The outlook is over an unbroken forest, save a hill, to protect from the worst winds, situated behind. Here eighty patients receive treatment and board for a price which has to be supplemented by the gifts of the charitably disposed. Moreover, in his laboratory there Dr. Trudeau continues his experimentations upon tuberculosis. This laboratory is a surprise to those who have not seen it before; it is the gift of the late Mr. George Cooper to replace one which had been burned.

Not alone has the present era witnessed the introduction of these new agencies, of which our fathers in medicine did not even dream, and at which they would have stood aghast, but it has largely increased the number of agencies to be used in disease. It has become a habit to decry the use of the coal-tar series in the treatment of febrile disorders, but the writer has found them, judiciously used in appropriate cases, of service, and he does not hesitate to say that he still sanctions their employment under these conditions. How can we admit the claim of those who formerly saw great results from their use, and now say that they have no value? Many undoubtedly have employed excessive doses, and have attempted their employment in such doses unguarded, in unsuitable cases, with at times unfavorable results, but this is no argument against the statement made above, nor to their own previous claims. No one method of treatment can be at all times applicable to all cases. While this is true, the very general trend of medical work in fevers has been to substitute the use of cold water in one or another way for the medicinal agencies in bringing about a reduction of temperature. First, sponging and use of the coil, then the pack, and now more than formerly the use of the tub-bath is the plan adopted. The use of the tub-bath is not alone for reduction of temperature, which does not of necessity occur, but as much for its effect on the circulation, nervous system, and with a view to prevent the ill effects brought about by the stagnation of the circulation in the lungs and limbs. But in this connection how much better would the ounce of prevention be than the pound of cure. Certainly we must urge that boards of health, so far as is possible, shall have the power to inspect the water-supply, of all communities, and also of every kind, of each dairy furnishing milk for consumption in their towns or cities—and in case there is a suspicion that the conditions are liable to be dangerous as regards any water-supply, whether used for washing milk cans or otherwise, that they prohibit such dairy from supplying milk so long as such danger exists. If such inspection had been effective with a law of the above nature, the outbreaks of typhoid fever in Stamford and New Milford, Conn., and in Montclair, N. J., and Watertown, N. Y., would have been prevented. These were all due to water-contamination of milk, said only to have come about by washing cans.

It would require too much of time and impose on your indulgence should I go over the list of new remedies of a strictly medicinal nature which have come into use, as strophanthus, iodoform, sulphonal, trional, ichthyol, cocaine, etc., not to speak of the change which has in particular resulted from the success of the thyroid feeding to make up for the deficiency of the normal secretion from the gland, as bone marrow in anæmia, suprarenal capsules in Addison's disease, the use of extracts of certain organs in diseases of those organs, further than to say that our credulity is largely borrowed on at times by the reports which are in circulation and also in print. If some of these remedies are so efficacious, why not resort to the raw egg, from which certainly the whole system of the chicken is built up—bones, blood, brain, spinal cord, muscles, etc. The old-fashioned egg-nog had a virtue evidently based upon a theory of which our grandmothers were ignorant, when they would administer this to a convalescent. Moreover, those who ascribe such dangerous bilious-producing properties to the yolk of egg, in many cases the result of this syllogism, bile is yellow, yolk of egg is yellow, hence yolk of egg is liable to induce biliousness, must beware how they slander so powerful a food. The growth of specialism has undoubtedly tended to medical progress, and this has been largely an affair in certain directions during these past thirty years. There are some parts of the body which more than others call for special treatment, because the dexterity acquired by constant practice makes one largely excel another who is more occasional in his work. The eye, the ear, the nose, and throat claim attention, and gynecology and andrology have come to be branches of special study. Moreover, the field of internal medicine is split up into subdivisions under the control of specialists and especialists; hence we have neurologists, cardiologists, pneumologists, gastrologists, enterologists, hepatologists, hæmatologists; and not to lengthen this list of words, which are deserved if not applied, those who devote themselves to the latter end.

The writer does not believe, except in some of the fields to a certain extent, that a man can be a first-rate specialist who has not had a broad enough foundation of knowledge to appreciate the relationship between diseased states of organs and the secondary results of such states, both on the general economy and upon other organs, as well as the reverse of this. And it is also true that many specialists have been obliged to extend the sphere of their work because of this interdependence of parts. The aurist and oculist find that the brain will claim attention, and that the condition of the general health is of great importance. Moreover,

it is the writer's conviction that by considering too exclusively the disorders of one part all morbid phenomena are liable to be referred to errors of this part. The speaker would not advocate giving up specialties, but he would advise young medical men not to start as specialists until they have acquired a broad general knowledge of the effects of disease upon the body.

Along with the growth of specialism has come with the progress of our time the medical expert. He existed before, but not to the extent that he has of late years. The medical profession is at times surprised to find who are experts upon certain questions, and also to find what diametrically opposed opinions experts will express in regard to the same condition of affairs. One expert will swear that a man was insane because at such and such a time he did so and so, acted in such a way, spoke such words, saw perhaps hallucinations, or what were regarded as these; while another alienist or neurologist will explain these as compatible with sanity. In a trial some ten years ago three experts called for the defence in a case of nervous trouble due to an injury to the spinal column resulting from a fall, each swore that the man had a complaint different from what his associate had considered it, and all swore that he did not have what the speaker and Professor Sayre swore to, viz., that he had Pott's disease and subsequent pachymeningitis. Moreover, one of these medical expert neurologists wrote an article in which he took us to task for the character of our testimony. An autopsy in the case two years after the trial showed Pott's disease.

The patient won his suit and recovered $25,000 damages. It does not, however, do for the lawyers to rail at us in view of the court after court to which cases are taken and retaken, the judgments upset and confirmed, to be upset on appeal, and the court of highest resort not infrequently divided in its decision, and at times even practically deciding against the judicial soundness of an opinion previously promulgated. We may well say to the lawyer, don't point your hoary finger at us, but correct your own infirmities which are many, including the tendency to ever-recurring delay and postponement, the *bête noire* of the medical witness.

Whether in the future some plan can be devised which will avoid this conflict of testimony, by arranging for the selection of several physicians so chosen that they shall represent the best attainable medical intelligence upon the condition of the person about which there is a dispute, may be open to question, owing to the laws relating to trial by jury. There is, however, not the least doubt about the desirability of such a change. A medical expert who goes on the stand for a particular side, no matter how firm his intention of telling the truth, the whole truth, and nothing but the truth, is very apt to be biassed in favor of the view advocated by his attorney, and moreover, to be, in a measure, unwittingly antagonistic to the lawyer of the opposite side, who is to cross-examine him. Expecting an attack upon the opinions he has expressed, he mentally endeavors to foresee the method of meeting such attack.

In view of the facts which I have so briefly touched upon, showing the progress of medicine in so many directions, requiring of the busy practitioner, as well as of the medical student, increased effort to keep up with the ever-increasing mass of knowledge, and of which he may readily find the information in the books and journals belonging to the Academy of Medicine; it does seem as if this Academy might be able to give to its fellows, without encroaching in the least upon the provinces of the laboratories attached to our medical colleges—a laboratory in which there might be the means of investigation of the different pathological discharges, and in which there should be also exemplifications of the recent advances in scientific research. By reading, he is told what someone else has seen and done. I would have him part owner of property in which he could witness the thing itself. How extensive such a laboratory should be would become a matter for discussion after it had been decided to have a laboratory. The writer believes that upon a proper presentation of the advantages likely to accrue, not only to the physician himself but also to his patients, from his increased efficiency, funds could be secured from those of the members interested in the best welfare of the Academy, and also from those friends of the Academy who are neither members nor physicians—citizens of New York desirous that its medical institution shall be the best equipped for their work of any in the land or world.

Objection may be urged against this plan upon the ground that a debt exists at the present time, and that funds are needed for the library, which should be extinguished before any new enterprise is undertaken. Then let us endeavor to extinguish this debt, to secure our laboratory, if the members decide that they wish one, and to obtain as large a library fund as possible, even a library and laboratory building, if our friends will avail themselves of the opportunity of bestowing upon a hard-worked profession the means for its truest recreation.

A NEW AND ORIGINAL METHOD OF OBTAINING MATERIAL FOR SKIN-GRAFTING.[1]

By ZERA J. LUSK, M.D.,

WARSAW, N. Y.

Among the various methods of obtaining material for skin-grafting, none are so universally employed at the present time as those of Reverdin and Thiersch. The credit of healing raw granulating surfaces by the application of minute pieces of cutaneous epithelium is generally conceded to Reverdin,[2] who published his discovery and experience about twenty-six years ago. The subsequent methods reported, differ only in the manner and source of procuring epithelial tissue. Dr. C. B. Kibbler,[3] of Corry, Pa., reports having had excellent results with thin slices of calloused or indurated epithelial tissue taken from the palmar surface of the hands or plantar surface of feet, recording several cases successfully treated after this method. Especial emphasis was placed on its being easily obtained, causing no pain or discomfort to the donor.

Dr. John T. Hogden[4] claims to have successfully used "scrapings of epithelium and shavings of corns." The success of these methods has been frequently verified by published reports, all of which indicate that healthy granulating tissue, by some inherent power, imparts life to cuticular epithelium. The contemplation of this fact, under circumstances which I will hereafter describe, suggested an experiment which proved eminently successful in a recent case of mine, where nearly six hundred square inches of raw granulating surface was healed in less than six weeks by grafts furnished by patient.

On January 14th, Emile Silskey, native of Russia, twenty-three years of age, robust constitution, laborer at Hawley Salt Works, was trying to separate a salt crust adhering to the bottom of the pan, when the heavy iron bar, which they use, slid without the expected resistance under the crust and he lost his balance, falling head foremost into a pan of boiling brine. Those working near hurried to his assistance, and had nearly succeeded in getting him out when they lost their grip and he fell backward again into the boiling brine. By another effort they succeeded in getting him out.

I saw him very soon after the accident. He was

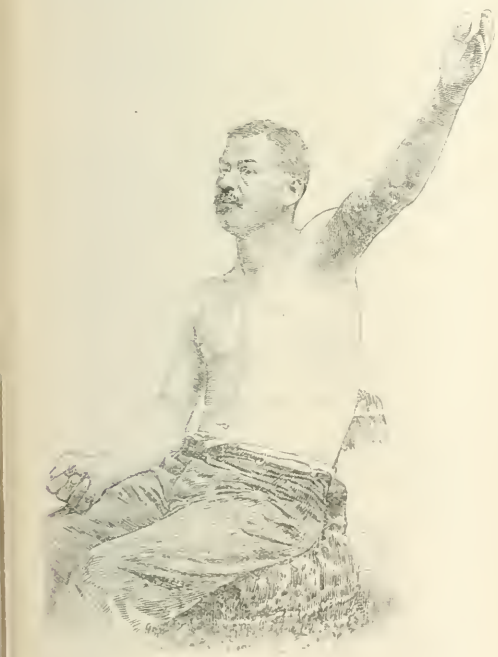
[4] International Cyclopedia of Surgery, vol. ii., p. 288.

lying on his back with no covering except a sheet loosely thrown over the lower part of the body. Great bags filled with serum hung from his sides and other parts of the body. Both arms were completely stripped of epithelium, which hung in shreds about the wrists, having been scraped down in his efforts to get out of the pan. The thick callousod skin of the palmar surface of both hands was torn and in shreds. The dorsal surfaces were covered with sacks full of serum. There was a raw, bleeding surface six inches wide extending from the left arm to the middle of the right scapulæ; one of the same character and size covered the lumbar regions. The buttocks were covered with large blisters, but more superficially. The skin on the lower extremities hung in shreds, bleeding in many places, especially about the knee and ankle joints. The genitals were very œdematous, and covered with bullæ. There were numerous small vesicles on the face and neck, and large erythematous patches over the chest and abdomen, but no vesication except in the right infra-clavicular region, where there was a blister four inches in diameter. It is unnecessary to state that there was profound constitutional disturbance, and that no hopes of his recovery were entertained.

However, after a liberal use of strychnine hypodermically, together with the application of artificial heat, his pulse became stronger, when dressings were hurriedly applied, and he was left in the care of competent nurses. The gravity of this case may be understood when we consider that the area of burned surface covered more than two-thirds of the body—indeed, there was no part where the blush of super-heat was absent; yet, contrary to expectation and precedent, recovery has taken place. His condition seemed



hopeless until February 11th, when favorable symptoms appeared, and for the first time I thought the man might possibly get well. He was extremely emaciated, with nearly one-fourth of his body a raw granulating surface. The only cutaneous covering on the left leg was seven inches wide at the trochanter major, narrowing to two inches at the knee, covering one-third of the leg to within two inches above the ankle. The right, eleven inches wide below the trochanter, narrowing to a point two inches above the right knee, commencing two and a half inches below, covered one-third of the leg, narrowing to one inch over the ankle. The right knee, from two and one-half inches below to two inches above, had no dermal covering; left the same, except two inches on the

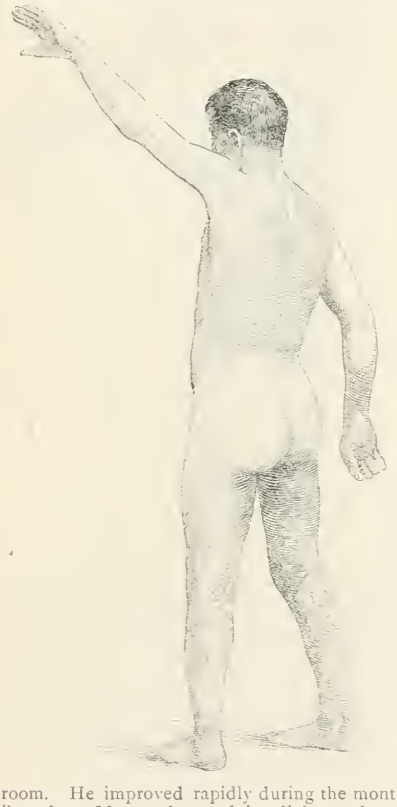
outer surface. The upper extremities were covered only by narrow strips on the outer aspect, except at the elbows, both of which were denuded of skin. An elliptical space over the lumbar region, five by nine inches, and one of about the same diameter over the left shoulder, were without dermal protection. There were in many places deep gangrenous sloughs, the underlying tissues resuming a more healthy appearance. The question now was, where could material be obtained sufficient to heal these large ulcerating surfaces. None could be provided by the patient. I could not utilize the Thiersch method, as no one could be found who would consent to give strips of skin.

I made a beginning on February 13th, by applying eight grafts taken from the indurated tissue on the palmar surface of the hand of an attendant. The next day, when I wanted to repeat the operation he declined, said his "hand was tender," that I had "cut too close, and though it did not bleed, was sore." As nothing more could be done, I concluded to await the results of the grafts made the day before.

In the meantime, while reviewing the various methods employed, an idea occurred to me, suggested by the following condition: There were numerous patches of exfoliated epithelium, the remains of vesication. They were hard, dry, and crisp, having for nearly five weeks been separated from the cutis. Why could not this material be utilized for skin-grafting? I had faith to believe that it could, and on February 16th, in the presence of attendants and others I made grafts, using the following material: Attached to the dorsum of the

right foot by one edge, the other being free and raised one-fourth inch, was a patch of dry exfoliated epithelium, extending nearly across over the surface, near the distal end of the metatarsal bones; the floating part was from one to one and a half inch wide. From this I clipped off a piece one inch square, softened and sterilized it in warm boric-acid water, and divided it into twelve grafts, which were applied to the anterior granulating surface of left thigh. The result was eminently satisfactory. Seven out of the twelve grafts took, and rapidly developed into vigorous islands of skin. The subsequent treatment consisted in using this dried epithelial tissue with which these large raw surfaces were covered with substantial skin, by April 1st.

The man began sitting up a few days prior to this date, and with the attendant's aid could walk about



the room. He improved rapidly during the month of April, and on May 1st began doing light work at the salt works.

The following experiments were made in the presence of my assistant and others: A little to the right and two inches below the trochanter major of the left leg, there was a raw surface three and one-half inches in diameter. At the proximal end of the great toe there was a dry, bleached patch of epithelium which had been thoroughly isolated from the body seven weeks, being held only by ends of hair. With this material this raw surface was completely healed in twenty-one days.

At the spring meeting of the Wyoming County Medical Association, I had the pleasure of exhibiting my case, and reporting the method of treatment. Dr. Roswell Park, of Buffalo, who was present as our guest, complimented me on my discovery, commenting particularly upon the integrity and firmness of skin, the perfect use of the joints, and the entire absence of cicatricial contraction.

In reporting my case I mentioned the difficulty experienced in properly shaving the skin in the Thiersch method, and how liable we are to snip too deep in that of Reverdin. I also made the following statement, which I have since verified, which was that the epidermis raised by vesication could be successfully employed in skin-grafting. By this method the cuticle is separated from the cutis, giving us the ideal material—indeed the same employed with successful results in the case reported. An opportunity of demonstrating practically this method occurred on August 3d, when I was consulted by Mrs. M——, married, aged fifty-two, housekeeper, who had a large varicose ulcer two and a half inches in diameter, three inches above the ankle on the outer surface of the left leg. She had worn elastic hose and tried all kinds of ointments for the last eight years. The granulations were unhealthy and bathed with a foul-smelling discharge. The treatment consisted first in thorough curettement, followed by stimulating applications, so that by August 13th the granulations appeared healthy. A surface on the left thigh near the anterior superior spinous process, was made aseptic, on which was applied a piece of emplastrum cantharides two inches long by one inch wide (it being first moistened with carbolized oil). Vesication was produced in six hours, when the plaster was carefully removed. The epithelium was detached at the edges of the blister, washed in boric-acid solution, after which all moisture was absorbed with sterilized cotton, and it was suspended in a four-ounce salt mouth bottle (aseptic cotton being used for a stopper), and kept at a temperature between 55° and 70° F. It was thoroughly dry in three days, when a piece one inch square was divided, making twelve grafts, which were applied in the usual way. The results were extremely gratifying. Nine of the twelve grafts took nicely and grew rapidly, so that by September 3d this ulcerated surface was healed, having a substantial epithelial covering.

A great many experiments have been made to ascertain the limit of vitality of the skin after its removal. Dr. J. H. Girdner[1] claims to have successfully used grafts removed six hours after death, from the body of a young man who died from hemorrhage. Dr. E. P. Brewer,[2] of Norwich, Conn., found that thirty-six hours was the limit of vitality, out of eight trials in which he used pieces of skin from amputated limbs. George S. Marten[3] experimented with grafts kept at different temperatures, claiming that grafts retained their vitality ninety-six hours, at a temperature just above 32° F.; that confined air gave better results than free air.

I can see no practical object of the first two experiments, for very soon after death chemical changes occur by which ptomaïnes are formed, which would destroy the vitality of the skin, even making it dangerous for experimental use. So far as the temperature is concerned in maintaining the vitality of grafts, if they are properly separated, sterilized, and dried, they can be kept almost indefinitely at a temperature between 40° and 90° F., and before using they should be softened and sterilized, preferably in warm boric-acid water; and when applied to a healthy granulating surface they will become revitalized, developing rapidly into substantial tissue coverings.

Just how these small epithelial grafts are revitalized when applied to granulating surfaces, has never been fully explained. In an article on "Leucocytes and Nuclein," under the head of "Nutrition," Dr. T. O. Summers,[4] of St. Louis, writes:

"The conversion into tissue, or imparting molecular activity to material lifeless in itself, is a wonderful phe-

[1] MEDICAL RECORD, vol. xx., p. 110
[2] Ibid., vol. xxi., p. 483.

[4] Journal of the American Medical Association, vol. xxiv., p. 963

nomenon. We cannot explain the affinities by which certain kinds of pabulum are accepted and rejected by the several tissue-cells of the body. We know this, however, that the change that goes on is the elaboration of a vitalized, cellulized substance which is capable of entering at once into tissue as soon as it meets the various cells which have this power of elective assimilation."

In briefly reviewing, I desire to report the following observations: 1. The best results were obtained from the thin transparent epithelial tissue. It made no difference, whether one or both edges were attached, just as satisfactory results followed the use of dried patches, with no attachment except at distal ends of hair. 2. The certainty of their attachment when properly applied, and rapid development. 3. The absence of cicatricial contraction, the skin being loose, and in many places, especially on back and thighs, so natural as to require close examination to discover its artificial nature.

THE TYPHOID-FEVER EPIDEMIC IN STAMFORD IN 1895—ORIGIN AND COURSE.[1]

By F. SCHAVOIR, M.D.,

CITY HEALTH OFFICER, STAMFORD, CT.

About the middle of April, 1895, when the general sanitary condition of Stamford seemed to be in a very satisfactory state, there were noticed by the physicians of the city a number of typhoid-fever cases, all arising at about the same time. A casual exchange of observations quickly disclosed the fact that there were a large number of cases existing, and the remarkable number of children affected led to the conclusion that an article of food consumed by children as well as adults must be the carrier for infection. Milk being such an article it was readily ascertained that these cases had been supplied almost without exception by one dealer named B——.

A meeting of the physicians was called at the office of the health officer, and an informal report on Sunday, April 21st, showed that there were eighty cases then existing. The origin of the infection being so forcibly suggested, the milk-dealer was at once directed to stop selling milk and an investigation was instituted. It was ascertained that B—— did not own a single cow, but purchased all his milk from three dairymen, who delivered their supply in cans furnished by B——, and kept at his place, where they were washed when empty and then sent to the dairymen. The premises where the empty cans were washed, and where the milk was kept until delivery, are located in a thickly inhabited, low, and poorly drained vicinity. The so-called dairy consisted of a small frame structure, containing a stable, wagon-shed, and a tank with a pump and well. The well is what is known as a dug well, walled up with stones not cemented, and covered with a loose board platform six inches above the ground. The well was thirteen and a half feet deep, and the water stood within one foot and nine inches of the surface of the ground. All the houses in the vicinity were provided with privies, one very foul one was situated twenty-five feet west of the well and on somewhat higher ground.

An inquiry into the conditions of the dairies from which the milk was supplied to dealer B—— showed them to be in good sanitary condition, and although no original case of typhoid fever could be traced, there is overwhelming presumptive evidence that the origin of the epidemic must have been in that well. By the middle of July, 1895, there were reported 406 cases, of these 352 occurred in families who received their milk-supply from B——. Twelve were known to have used it at the café supplied by him, 2 obtained milk at a bakery supplied by him, and 2 obtained B——'s milk in other indirect ways, making a total of 368 cases, or $95\frac{3}{10}$ per cent. of the total number of undoubted primary cases.

The ages of the affected persons were as follows:

Under 5	68	From 30 to 35	33
From 5 to 10	72	" 35 " 40	15
" 10 " 15	51	" 40 " 45	14
" 15 " 20	42	" 45 " 50	6
" 20 " 25	56	Over 50	10
" 25 " 30	36		

The number of males and females was about the same.

The number of cases reported as to date were:

From April 15th to 22d	72
" " 23d " 29th	78
" " 30th " May 6th	47
" May 7th " " 13th	164
" " 14th " " 28th	33
" " 28th " July 15th	12

Of the cases of children under ten years of age the reports were as follows:

April 15th to 22d	20
" 23d " 29th	21
" 30th " May 6th	18
May 7th " " 13th	56
" 14th " " 25th	8
" 29th " July 15th	17

The number of deaths from typhoid fever up to July 8th were 27: the ages of these fatal cases were as follows:

Under 5	1	From 20 to 30	13
From 5 to 10	1	" 30 " 40	9
" 10 " 15	0	" 40 " 50	0
" 15 " 20	1	" 50 and over	2

The dates of death were: April 27th, 2; May 1st, 2; May 3d, 1; May 4th, 1; May 5th, 1; May 9th, 1; May 10th, 1; May 12th, 2; May 13th, 1; May 14th, 2; May 15th, 1; May 16th, 1; May 23d, 1; May 26th, 1; May 28th, 1; June 2d, 2; June 3d, 1; June 4th, 1; June 9th, 2; June 12th, 1; June 14th, 1.

One child dying on May 15th, and another on May 26th.

It is a noteworthy fact that in some families every member was stricken down with the disease, and I have personal knowledge of one house where there existed nine cases, two households with seven each, and several with five cases.

When the extent of the epidemic was fully realized, a meeting of the Health Board was called, and a relief committee organized. The Hon. Edwin F. Scofield, Mayor of Stamford, was elected chairman of the relief committee; Dr. Samuel Pierson, secretary; and Mr. E. C. Willard, Superintendent of Schools, treasurer. An appeal to the citizens was issued, and within a very short time the sum of $5,000 was raised for the relief of the sufferers from the epidemic. With the fund a temporary hospital was established, about fifty trained nurses were engaged to take care of the sick in the hospital as well as in the families where it was otherwise impossible to procure proper care, and it is to the devotion and skill of these nurses that we must largely attribute the small death-rate of the epidemic.

The temporary hospital as well as the St. John's Hospital did noble work, and those in charge deserve the highest praise and the thanks of the community for their untiring devotion.

Medicines and articles of food were provided to the needy, and though a good deal of distress was caused by the epidemic the work of the relief committee did wonders to alleviate it. The physicians were notified by the health officer that disinfectants would be furnished free of charge to any person or family presenting a physician's order for the same. Instructions

[1] Read before the New York Academy of Medicine, Section on Pædiatrics, November 14, 1895.

were given to the people how to avoid infection, and every possible precaution was used to limit the disease.

After the cessation of the epidemic all the premises where cases had existed were systematically disinfected as far as feasible, and into the privy vaults, cess-pools, and drains were introduced disinfectants to destroy the germs wherever they could be reached. At the same time circulars were issued to all the inhabitants, cautioning them against the use of well-water without previous sterilization by boiling; besides this numerous wells were ordered closed.

It is a fact that since the epidemic not more than ten cases per month have been reported, although we have just passed through the period of the year when typhoid fever is most prevalent.

THE CLINICAL HISTORY OF THE STAMFORD TYPHOID-FEVER EPIDEMIC.[1]

By SAMUEL PIERSON, M.D.,

STAMFORD, CT.

In attempting a clinical history of the Stamford typhoid-fever epidemic, which would be of any value for its statistics, method of treatment and results, it is manifest that a history of each case, as reported by the attending physician, is necessary. To achieve this result the following plan has been adopted:

From the physician's reports to the Health Officer a list was made of all cases, together with the name of the attending physician. The different physicians were then personally seen, and each case was gone over in detail, noting all symptoms, complications, treatment, etc., and from these reports were tabulated the various results herein given. By this method the absolute reliability of the figures is assured.

From April 15th to May 6th, two weeks after the sale of the infected milk was stopped, 253 cases were reported; after this date the number rapidly decreased, showing that in the early cases the poison was much more active than in the later ones. During the next three weeks only 135 more cases were reported, and nearly all of these were of distinctly milder type.

From this time until the middle of June, 20 more cases were reported, and some of these were secondary cases, being nurses and members of the family having the care of the sick, making the total number of cases 406.

The differential diagnosis was at first somewhat difficult, as many cases had distinct chills, followed by fever and sweating, recurring daily. Malarial possibilities were eliminated by large doses of quinine, which usually had no effect upon the temperature; in nearly all the cases the diagnosis was not considered certain until the rash or diarrhœa appeared; so it is certain that no malarial cases are included among those reported as typhoid.

Ten cases were infected by drinking a single glass of milk; one of these, a very malignant case, was under my care in the hospital; the patient had high temperature, delirium, repeated hemorrhage, and finally died of perforation thirty days from the beginning of his disease. The autopsy showed perforation of the ileum about twelve inches from the ileo-cæcal valve, numerous ulcers of the lower part of the ileum, spleen much enlarged, general peritonitis. This case is interesting as showing virulent infection from very slight exposure.

Sixty-nine cases were under ten years, and 65 were under five. Statistics show that sporadic typhoid is almost unheard of in children under three years of age. The large number of children infected in this epidemic would show that where the poison is overwhelming they too succumb.

[1] Read before the New York Academy of Medicine, Section Pædiatrics, November 14, 1895.

The period of incubation was somewhat uncertain, but the majority were under fourteen days. The longest of which I have personal knowledge was twenty-eight days. Nose-bleed was not a very constant symptom, but was present in 117 cases, twenty-eight per cent. of all; it was more frequent in children than in adults. Diarrhœa was present in 364 cases, eighty-nine per cent. of all, and was usually followed by constipation in the second and third week. In some cases constipation was present from the start. Tympanites was noted in 297 cases, seventy-three per cent. of all, but rarely was it a very serious or troublesome symptom. The rash was very constant, and was present in 360 cases, eighty-eight per cent. of all, varying in amount from a few scattered spots on the trunk to hundreds of petechial spots all over the body; in the majority of cases the rash was only on the trunk. Delirium, more or less active, was present in 142 cases, thirty-five per cent. of all. Hemorrhage occurred in 73 cases, 17.9 per cent. of all. Of these cases 61 recovered and 12 died. This percentage is largely in excess of any reports that I have been able to find, and seems to have been due to the virulence of the poison; it occurred repeatedly in several cases, and 12 of the fatal cases had one or more attacks.

Bronchitis or pneumonia occurred in 40 cases, 9.8 per cent. of all, and a very annoying bronchial cough was present in many more.

Relapse and reinfection occurred in 26 cases, 6.4 per cent. of all. The majority of cases that recovered terminated by lysis rather than crisis. I can recall no typical text-book case in temperature range. Many ran a continuous high temperature for four or five weeks without complication, or apparent cause. A sudden fall in temperature was invariably the precursor of some complication, usually hemorrhage. In many cases, apparently convalescent, the temperature would suddenly shoot up and remain elevated for several days, and then slowly return to normal. This recrudescence was supposed to be due to reinfection. These cases were often given full doses of quinine without favorable results. In the severe cases the temperature ran high, from 104° to 106° F., with irregular remissions, and it was frequently noticed that the high temperature gave the patients no discomfort, nor did it seem to have any specially bad effect on heart or nervous system.

Acute nephritis occurred in 9 cases, 4 of which were fatal.

Delivery at term occurred in 2 cases; both died. One was delivered in the latter part of the second week of her typhoid; rash, diarrhœa and enlarged spleen were present at the time; the presentation was breech, but the labor was not severe; the lochia was normal, and involution good, but the patient died one week after delivery, of exhaustion. The child is still alive and well. The other was delivered during the stage of incubation. The typhoid symptoms, rash and diarrhœa, soon developed. Abscess of both breasts occurred, and the patient died of exhaustion three weeks after delivery.

Abortion from the third to the fifth month in 6 cases, all recovered. Pregnancy in 4 cases was not disturbed by the fever, although the temperature and symptoms were of average severity. Perforation occurred 7 times, with six deaths, one recovery. A short account of this case may be of interest.

The patient was a woman, aged thirty-eight. She had been ill three weeks with a most malignant attack, had suffered three hemorrhages, the last two days before the perforation. Suddenly in the night she was seized with intense pain in the right inguinal region, which she described as more severe than any she ever experienced; this was followed by nausea and vomiting. When I saw her, a half hour later, she was almost in collapse; thready pulse, cold perspiration, semi-comatose; abdomen markedly distended and

very tender. Under free stimulation, hypodermics of morphia, and ice-bags, she finally rallied. The next day the abdomen was still greatly distended. Recovery finally occurred after twelve week' illness. This patient also had a mild type of insanity, lasting for some weeks after recovery, but which has now entirely disappeared.

Phlebitis in a mild form was seen in several cases. In one otherwise mild case there was an intense phlebitis of the internal saphenous vein, great swelling and tenderness of the leg, and entire inability to use the leg for weeks after convalescence was established. At present the leg is still one-third larger than its fellow, but no hardness can be made out over the course of the vein.

Many ambulatory cases were seen ; one of these died of sepsis the day after coming under observation. There were quite a number of abortive cases that, after a usual onset and unmistakable symptoms, in the second week would soon return to normal. The condition of the spleen was noted in so few cases that it is not worth recording. Dry and cracked tongue and sordes were rarely seen in cases that received proper care and nursing.

Of the 40 cases which came under my care at St. John's Hospital and the temporary hospital adjoining, nearly all were of a severe type. One aborted at the fifth month during the second week of the fever ; the temperature at the time was 105° F., the placenta was adherent, and the hemorrhage free. After removing the placenta by peeling off the adherent portion with the finger, the uterus was thoroughly curetted, washed out with boiled water, and packed with iodoform gauze. There was profound shock following the operation, and while the specific temperature remained there was never any symptom of uterine infection. Lochia normal and without odor throughout.

Several cases had repeated reinfection, delirium, incontinence of fæces and urine, and 15 of the 40 had hemorrhage. Heroic stimulation was used in 4 cases ; three pints of whiskey each, daily, for eight days. There were four deaths among the 40, but of these two were in collapse on admission and died in a few hours, one from perforation, one from hemorrhage. The third, a baby, twenty-two months old, died of bronchi is within twenty-four hours of admission, so that really only one patient died under treatment, 2.5 per cent. of all. One child of twelve years had twenty boils on different parts of the body.

Autopsy was performed in three cases ; one on a child of twenty-two months, who died of bronchitis, was made by Dr. Northrup and will be reported by him. Another was in the case already mentioned, who died of perforation on the thirtieth day ; both showed the characteristic lesions.

The last was upon the lamented Dr. Edwin J. Meeks, whose case presented some unusual points of interest. His was the longest undoubted period of incubation, twenty-eight days from the last drinking of the infected milk to the first onset of symptoms. He was removed to the Presbyterian Hospital, New York, for treatment, and the record there shows rapid pulse and high temperature from the start, on which tubbing had no effect. During the latter part of the second week the temperature ran lower, but reinfection occurred a few days later, with sustained temperature between 104° and 105° F., persistent rash, repeated hemorrhage, and general sepsis, followed by death twenty-eight days after admission. The autopsy showed extensive ulceration in the lower two feet of the ileum, and a few ulcers were also found in cæcum and ascending colon. The ulcers were ragged and extended to the muscular layer, in one instance only the peritoneal covering remained. In the six feet of ileum above this there was a later crop of lesions, a general swelling and sloughing of the Peyer's patches ; large blood-clots were found in this part of the intestine ; the spleen was much enlarged.

There were in all twenty-seven deaths, including that of Dr. E. J. Meeks and Misses Clark and Begg, nurses, who died in the New Haven Hospital, martyrs to their profession. This would give a mortality of 6.6 per cent. in 406 cases, which is very much below the average in severe epidemics.

The causes of death were—confinement, 2 ; perforation, 5 ; hypostatic pneumonia, 6 ; exhaustion from hemorrhage, 8 ; toxæmia early in disease, 3 ; nephritis, 3.

The general treatment employed varied greatly. One physician, who treated fourteen cases without a death, gave absolutely no drugs or treatment of any kind for any symptom or complication ; no baths, no heart stimulants, no antipyretics, no attempt to check excessive diarrhœa or hemorrhage, and very slight regulation of diet. Four of these cases had hemorrhage, and five relapses or reinfection. The plan generally followed was to give a cathartic at the commencement of the disease, usually calomel. By some this drug was used in small doses throughout. At the hospital we relied entirely on enemas of warm water for constipation after the first week.

No tub baths were used during the epidemic for the reason that the majority of cases were in very poor families where the household conveniences were so limited that even ordinary care was difficult. At the hospital and annex it was a physical impossibility to carry out this treatment with the nurses at our command, so that such results as we had were attained without this means, considered so indispensable by many. Personally I saw only 6 cases, out of 80 or 90, where it seemed to me bathing would have been desirable in relieving high temperature, delirium, bronchitis, and flagging heart.

Alcohol and ice-water, sponging and rubber-blanket baths were generally used, and certainly had a decided effect in reducing temperature, quieting delirium, and inducing sleep.

The experience with the coal-tar antipyretics was the usual one of sweating and depression ; but later on in the epidemic I found that in all except septic cases one-half grain doses of phenacetine, repeated every hour when the temperature was above 103° F., would act promptly, and without sweating or depression, in reducing it one or two degrees.

Intestinal antisepsis was attempted by most of the physicians ; the drugs most used were calomel, carbolic acid, bismuth, salicylate and subnitrate, and salol. At the hospital this treatment was early abandoned in favor of large draughts of cold water, except in those cases where the diarrhœa was very profuse, when bismuth and opium were given. For hemorrhage, free hypodermics of morphine were the main reliance. Ergotole, also by hypodermics, was used in some cases, as were the vegetable astringents hamamelis, tannic acid, and the like ; ice-bags to the abdomen and moderate alcoholic stimulation did good service. For tympanites, turpentine stupes and sometimes small turpentine enemas were used.

Digitalis was rarely used as a heart stimulant ; our main reliance was on strychnia by hypodermic or per oram in from $\frac{1}{70}$ to $\frac{1}{50}$ grain doses every four hours, for lasting effect. For quick action, nitro-glycerine, grain $\frac{1}{100}$ every hour, and alcohol.

One physician reports brilliant results from protonuclein, grains five every three hours, and further states that since he began its use, late in the epidemic, he had no complications whatever, and in many cases the progress of the disease has been checked, temperature and other symptoms subsiding early in the second week. It is to be regretted that this remedy, to fully test it, could not have been used early in the epidemic when all the cases were of more severe type.

The usual rule during convalescence was to keep the patient in bed and withhold solid food for one week after temperature was normal ; but in some cases in which

moderate temperature persisted with no apparent cause; if the tongue was clean, the eruption had disappeared, and the tympanites and diarrhœa had ceased, solid food was allowed; usually a normal temperature was soon observed. Apparently the temperature was due to post-typhoid anæmia.

The striking characteristics of the epidemic may be summarized as follows:

1. Its source traced to contaminated milk, the sale of which was cut off within one week from its first appearance. 2. The almost complete cessation of new cases within two weeks after the sale of milk was stopped, showing that incubation is usually not more than fourteen days. 3. The large proportion of patients having well-marked rash, eighty-eight per cent. 4. The large number of young children infected, sixty-nine under ten years and sixty-five under five. 5. The unusual number of hemorrhagic cases, 17.9 per cent. 6. The low death-rate, 6.6 per cent., which was attained without the use of tub baths in any case. The best results claimed for this method of treatment being seven per cent. 7. That the general history of the cases proves it to have been an epidemic of virulent type.

In conclusion, my thanks are due to each physician in Stamford for his cordial co-operation, without which it would have been impossible to have given a clinical history of the Stamford typhoid fever epidemic.

THE NEUROLOGICAL ASPECT OF ASTHENOPIA.

By H. GRADLE, M.D.,

CHICAGO, ILL.

PROFESSOR OF CLINICAL OPHTHALMOLOGY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

In the extensive literature on the influence of eye-strain upon the nervous system, but little mention is made of any other factors concerned except the refractive condition of the eyes. Some authors, indeed, write as if the various nervous symptoms observed in some patients, in consequence of an ocular defect, were the inevitable results of such a cause. Yet a critical study of any series of patients with anomalies of refraction shows that other circumstances besides the optic condition must be taken into consideration in order to account for the variability of the subjective complaints. For why is it that the same degree of optic imperfection causes only fatigue of the eyes and blurring of sight in one person, while in others it leads to headaches of various types and other nervous symptoms? and why is it that some persons can tolerate without discomfort an amount of refractive error which forces others to the use of glasses?

The case-book of any oculist can furnish numerous illustrations of different forms of headaches, of a feeling of dull pressure in the head, of spells of dizziness, and even of nausea, due to eye-strain. The ocular origin of these complaints can be easily proven in proper cases by the permanent relief afforded by spectacles correcting the optic defect. These cases are so common that illustrative instances from my own practice would be superfluous. But, alternating with these patients, every oculist sees also many people who, with the same degree of refractive anomaly, do not complain of any annoyance beyond fatigue or discomfort in the eyes on close work and blurring of sight. If we extend our observation to those patients who do not call on us on account of asthenopic symptoms, but whose eyes we examine in the course of other diseases, or whom advancing age compels to apply for glasses, we will find that nervous symptoms in consequence of optic anomalies are, after all, not as common as an exclusive office-observation might suggest. Compared with the frequency of optic anomalies as shown by all systematic examinations of schools and military recruits, patients with nervous symptoms resulting from eye-strain represent but a small minority of ametropes.[1] Moreover, if we study the refraction of people who do not complain of asthenopia, we will find a very noticeable percentage with low degrees of hypermetropia or astigmatism who are not annoyed at all by their defect.

It is thus taught by actual observation that refractive errors (outside of simple myopia) disturb the majority of ametropes only by the fatigue of the eyes and unsteadiness of sight which they cause, and that the lower degrees[2] do not, as a rule, interfere to any practical extent with the use of the eyes. There is, however, a small class of patients who are sensitive to the lowest measurable optic anomaly, and in whom eye-strain can lead to various nervous symptoms.

For the purposes of this paper it may be well to term that degree of discomfort which is the regular and inevitable consequence of a given refractive error *normal asthenopia*, and to refer to the eye distress in excess of this limit or due to unproportionately small optic anomalies, as well as to any resulting nervous symptoms, as *excessive*, *unproportionate*, or *exaggerated* asthenopia. It must be understood, of course, that there are all possible degrees of exaggerated asthenopia, and that there exists no sharp dividing line between normal and unproportionate eye-strain.

If we compare the general health of ametropes with normal asthenopia with that of patients complaining of unproportionate symptoms, we will find the former representing the more perfect physical type of mankind. If hence an anomaly which, according to its degree, is either tolerated without discomfort, or causes only local fatigue and distress in healthy persons, leads to much greater discomfort or even distant nervous disturbances in certain patients, we cannot but conclude that in the latter class other factors besides the refraction are concerned in the etiology. This view is confirmed by the history of those patients in whom the unproportionate asthenopia began abruptly after the occurrence of unfavorable environment, or followed some debilitating disease. It is also confirmed by the possibility of recovery from the exaggerated form of asthenopia while the refractive error remains the same.

Inquiries concerning the health, past history, and habits of patients with unproportionate asthenopia reveal that many of them possess the so-called "nervous" or neurotic disposition. Their nervous system reacts to impressions made upon it in a different manner from that of average healthy subjects. Many are excessively disturbed by minor annoyances of sensory or mental nature. They may complain inordinately of trifles like the pressure of the spectacles on the nose, or of any itching skin lesion present at the time. Indeed this irritability coincides with the popular notion of "nervousness." Of course, those persons who have cultivated mental discipline may not betray the annoyance produced by trifling causes, but they feel it subjectively. Emotions are very easily aroused in most of these people, and in some the emotional activity is revealed at the time by vaso-motor and cardiac disturbances. Quite often such patients have poorly developed muscles. Even if strong for momentary efforts they tire easily. But neither this one nor any of the other evidences of the neurotic disposition are present in all instances.

There is nothing characteristic about the nutrition of these patients, at least in the case of adults. Among the children of this class I have, however, found a large proportion delicate and below average weight.

In some instances more definite proof of an unstable

[1] It is well to call attention again to the fact that most eyes are hypermetropic at birth, according to numerous observers (Ely, Schleich, Horstman, and others), and that hypermetropia is the predominant state of refraction during early childhood.

[2] On the strength of my own experience I would state the average limit of tolerance to H. and Ast, without annoyance, at about two Dioptrics up to the tenth year, about 1.5 D. up to the thirtieth year, and perhaps 0.75–1 D. at the fortieth year of life. Myopic astigmatism is rarely tolerated after puberty if it exceeds 1.25 D.

nervous system is given by the history of past (or even present) nervous affections, such as chorea (or habit spasm) in childhood, or nervous prostration at some period of life. The more thorough the neurological training of the observer, the more readily will he detect in many of these patients evidences of an imperfect condition of the nervous system. Yet it must not be expected that we can demonstrate the neurotic tendency in every case of unproportionate asthenopia. In some we can only infer it through the family history. A few times I have seen the hidden neurotic tendency manifest itself later in life by the occurrence of nervous affections, although the examination made when the patient applied for glasses on account of exaggerated asthenopia did not show any anomalies of the nervous system at that time.

Just as we may find all gradations from normal to highly exaggerated asthenopia, so, too, will we find transitions from the normal stability of the nervous system through slight "nervousness" up to extreme want of nervous resistance. I have, however, observed but little connection between unproportionate asthenopia —in the sense employed in this paper—and hysteria. For I am referring now only to those cases in which all the symptoms are removed by correction of the optic error. It is true, some few of my patients belonging to this category have been hysterical subjects, but not any large proportion. On the other hand, asthenopia, often associated with muscular anomalies, is not a rare condition dependent on hysteria, but this form is not remediable by glasses.

The condition of the nervous system manifested by unproportionate asthenopia may result from a number of different influences. While I have tried to inform myself regarding the causes leading to this state in most of my patients, my preserved records are not sufficiently complete or uniform to be presented correctly in a statistic form. My statements, however, are based on the examination of about three thousand cases of hypermetropia and astigmatism, of which between one-fourth and one-third complained of exaggerated or unproportionate asthenopia. This figure does not represent the real proportion between normal and exaggerated asthenopia in a community, since a large number of ametropes without nervous symptoms are fitted with glasses by opticians and are not seen by any oculist.

Perhaps the most frequent etiological condition leading to exaggerated asthenopia is inherited instability of the nervous system. For obvious reasons it is difficult to learn much regarding the family history of adults in office examinations, but in the case of children brought by their parents, inquiry reveals very often the existence of the neurotic disposition in one of the parents. It is, of course, necessary to inquire systematically for headaches, chorea, asthma, and other morbid reflexes, nervous spells, and nervous prostration. I have met but little with organic disease of the nervous system in these family histories, probably because it is much less common than functional neuroses. Parental alcoholism has likewise played a very small rôle. My interpretation of the results of these inquiries may be questioned on the ground that a neurotic parent can be found in many families, the children of which do not suffer of exaggerated asthenopia. I know of no statistics to prove or disprove this view. But I have often noticed the coincidence that the family history was especially bad in the more pronounced cases of unproportionate or exaggerated asthenopia. I have furthermore been led to think that in children, who have not yet been exposed to the vicissitudes of adult life, heredity is a more important factor than when exaggerated asthenopia appears later in life.

Even in the absence of hereditary disposition the neurotic basis of exaggerated asthenopia may be created by various diseases. Of acute infections I have often seen measles the precursor of asthenopia, unproportionate to the age or the optic defect of the patient. This applies also to influenza, as seen in the last few years. As to typhoid fever, tuberculosis, and other debilitating diseases, I have only seen that patients were made more sensitive by them to moderate refractive errors than they had been previously, but I have not seen them followed by nervous disturbances.

Of coexisting diseases none have as often prepared the way for exaggerated asthenopia, within my experience, as anæmia and chlorosis. The importance of the impoverished blood I have often seen illustrated by recovery from exaggerated asthenopia in consequence of hygienic measures and the use of iron. I have records of numerous young people who, after their recovery from anæmia, could either lay aside their glasses entirely (in the case of weaker numbers), or were at least able to dispense with them except in reading; while previously they had found their continuous use essential for their comfort.

Not very often, but at least in a dozen instances, does my case-book show that children who had required glasses were again comfortable without them after a hypertrophy of the pharyngeal tonsil had been removed by an operation.

Functional disturbances of digestion, especially symptoms referable to the stomach, were frequently mentioned by my patients. From some it was learned that the more pronounced their dyspeptic complaints, the more conscious they became of their eye-strain. In a few instances under my observation the asthenopic symptoms diminished or ceased entirely after recovery from the digestive disturbances. The dyspepsia, as far as I was able to learn, was in very few of these patients indicative of serious gastro-intestinal disease, but generally of the type of nervous dyspepsia.

I have found, besides these patients, representatives of all the different forms of neurasthenic manifestations. But I do not claim that any large proportion of patients with unproportionate or exaggerated asthenopia present manifest neurasthenia to any pronounced extent.

Although in more than one-half of the patients with the more pronounced exaggeration of symptoms, systematic inquiry showed some other abnormal reactions on the part of the nervous system, or some deviations from the standard of perfect nervous health, still in others no further evidences of nervous disturbances could be ascertained at the time of the examination. In these persons the asthenopia out of proportion to the optic defect, or nervous symptoms induced by eye-strain, seem to me in themselves evidence of imperfect health of the nervous system.

The disposition to exaggerated asthenopia can be fostered by unhygienic habits. The histories I have collected mention but too often the baneful influence of persistent eyework, confinement indoors, and lack of muscular exercise. It is common ophthalmic experience that asthenopic complaints—normal or exaggerated—increase with the amount of eyework. An optic defect which is tolerated without symptoms by a healthy person, who does not use his eyes much, may begin to annoy him as soon as he taxes his eyes with more work. Moreover, asthenopic complaints started by the use of the eyes at short distances can persist after reading or other work has been discontinued for hours, or even for a few days. In illustration of this fact I have seen some elderly presbyopic people, with ideal emmetropic eyes, complain of more or less steady discomfort even during the period of rest of the eyes, on account of the strain while reading, and have removed such persistent annoyance by the use of proper reading-glasses. Personal observations, however, have led me to consider continuous eyework rather as a condition which makes the exaggerated asthenopia manifest than as a productive factor in its etiology. For I have repeatedly enabled patients to continue their eyework without the use, or at least without the steady

use, of glasses, after inducing them to take up more outdoor exercise. The influence of confinement indoors, and insufficient muscular exercise, is also shown by the vocations principally represented among my patients, viz., bookkeepers, typewriters, and other office-employees, female teachers, advanced pupils, and girls of comfortable circumstances leading an indolent life at home. While, besides, I have seen occasional instances among many other business pursuits, it has certainly seemed noticeable how very few of the patients with exaggerated asthenopia do manual labor. Yet I see normal asthenopia quite often among the laboring classes, and do find exaggerated forms of eye-strain among their children raised in the large city, and among their wives who are closely confined in the house.

According to some of my histories, the unproportionate eye-strain was first observed after long periods of interrupted sleep, especially in nursing mothers. Mental worry has also figured to a small extent in my records.

The observations upon which this paper is based suggest that the duty of the physician is not entirely fulfilled if he contents himself with a prescription for glasses for the relief of unproportionate or excessive asthenopia. Whatever real benefit can be obtained from spectacles the patient should certainly receive. But glasses, after all, are merely optic "crutches," which in vigorous health are not necessitated by the lower degrees of ametropia. Whenever we find the complaints of the patient out of proportion to his optic defect, we should also search for the influences which have undermined his powers of resistance, and remedy them if possible. For, by fortifying his health at the time when the first indications of nervous weakness are manifested, we can guard him against subsequent other nervous accidents which glasses cannot remedy.

Progress of Medical Science.

Syphilis and Blood Serum.—Dr. Vieviorovski has made some experiments on the treatment of primary syphilis by means of blood-serum from individuals affected with gummata or other tertiary forms of the disease. Blood was obtained from the median basilic vein and serum prepared from it. Five patients were experimented upon, all of whom were suffering from the symptoms of the early stage of syphilis. The primary symptoms disdisappeared under this treatment, but it had no effect upon the development of secondary symptoms, and the experiment may be considered a failure.

Transmission of Typhoid Fever by the Air.—Investigations on this subject have been made by Dr. Licard, of Beziers, whose plan of experimenting was to have patients suffering from this disease breathe through tubes into water that had first been sterilized. Specimens of water thus treated were frequently found to yield the bacilli under cultivation. The bacilli were not always found, but this is not a matter of surprise when it is considered that the best bacteriologists frequently fail to find them under conditions strongly suggestive of their presence. Dr. Licard's results were, however, sufficiently uniform to warrant an inference that the expired breath of typhoid patients, like that from those having typhus, may serve as a channel for fever infection. The vast majority of typhoid infections have their origin in a contaminated water-supply, but every observer has been puzzled more or less by cases of the disease which have arisen apart from any known inculpation of the drinking-water. These cases of obscure origin may originate from two causes whose bacillar contact is atmospheric—not simply by means of the breath of the sick, but also by emanations from sewers, cess-pools, and other receptacles of typhoid dejections.

Beriberi.—Three cases, that varied greatly in clinical outline, were recently reported by Dr. J. Hill Abram before the Liverpool Medical Institution. The disease is uncommon in Europeans, and women and children usually escape. Weakness, inability to stand, unsteadiness in walking, ability to go only a step or two without assistance, were the first symptoms complained of by a sea-captain, thirty-six years of age. There was marked ataxic gait; and the man could not stand with the feet together, even when the eyes were open. Slight ataxia was present in the arms. Muscular power was poor in the upper and lower extremities, especially in the extensors of the forearms and flexors of the ankle; wrist-drop and foot-drop were therefore present. The patient was unable to rise in bed without assistance; the grasp was weak. There was coldness in the limbs, and sensations of pins and needles. Pain, touch, heat, and cold, all forms of sensations, though usually distinctly recognized, were markedly delayed in the legs up to Poupart's ligament; the delay in the arms was less, and sensibility normal above the elbow. Marked tenderness in the calves existed on deep pressure, in the posterior surfaces of the thighs, and the flexor aspects of the forearms. There was absence of knee-jerk, of wrist- and elbow-jerk. Superficial and organic reflexes were present. The trouble began by a feeling of lassitude and pains all over the body, followed by œdema gradually extending up to the knee; disappearance of this after five days in bed, and gradual increase of pain and paralysis. There was marked palpitation during this time. The second case was the mate on the same vessel. The symptoms were slight ataxia, leg muscles weak, no obvious wrist-drop, sensation delayed, marked muscular tenderness in lower limbs, all reflexes present, heart enlarged, and double aortic bruit. His trouble began by pain in the back, which had been present in some degree for about twelve months. Then there was œdema in the left leg followed by general dropsy. Pains in the limbs, and unsteadiness and weakness in the legs and arms came on later. The third case, the ship's carpenter, was practically well when seen; calf muscles were tender, and the man complained of tiring easily. In all these cases of peripheral neuritis the trouble had begun in the legs, not the arms, as in alcoholic neuritis. The men were total abstainers, just home from a two months' stay on the coast of Brazil, and without evidence of malarial sporozöon in their blood, which was carefully examined. The diagnosis of beriberi was therefore plain. The treatment consisted of absolute rest in bed, good feeding, the administration of iron, strychnia, and massage. The morbid anatomy of beriberi is practically limited to the nerves, the muscles, and the heart. The nerves show the characteristic parenchymatous inflammation, and the muscles and heart varying degrees of fatty degeneration (Scheube, Baelz, Pekelharing, and Winkler). The disease prevails endemically in Japan, India, Burmah, Java, Ceylon, and the Malayan Archipelago, the west coast of Africa, and South America. Excessive proportion of rice, fish, impure water, etc., have been considered predisposing causes. The exciting cause is now looked upon as an organism, and the nerve changes as due to the absorption of a toxin, the organism not being present in the nerves themselves.

Typhoid Fever in Connecticut.—The report of the Connecticut Board of Health for October shows an unusual prevalence of typhoid fever in the State. Out of 168 towns in the State, the disease is recorded in 50, the total number of cases reported being 189.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, December 7, 1895.

ELUSIVE KIDNEY DISEASE.

THERE are circumstances in the study of disease well calculated to mislead the most careful physician. Among them are those vague symptoms of small value as isolated facts, often set down and cavalierly dismissed as neurasthenic or hysterical, and not taken into account when summing up evidence. Another class, also dangerous to the diagnostician, are symptoms that point directly to the confirmation of a preconceived idea. These obscure diagnosis and delay proper treatment. The patient who does not sleep very well, eat very well, or see very well, may no doubt be neurasthenic or hysterical. On the other hand, insomnia, disorders of vision, and digestive disturbances are associated also with organic changes that it is wise to recognize early. Added to the discomforts already mentioned, there may be headache, mental depression, rheumatic pains, or neuralgia; or more marked nervous symptoms, loss of memory, anorexia, nausea, vomiting, frequent urination, and attacks of diarrhœa. In any new case presenting these features, wholly or in part, the urine is analyzed as a matter of course, not once, but many times. Results are negative: no albumin, etc., and kidney disease is therefore eliminated. Another complains of auditory troubles, loss of strength that interferes with the business of life and with personal obligations, of drowsy, dull, stupid attacks, and some fever afternoons. Temperature may be subnormal mornings, rising to 100°, 101°, or 102° F. toward evening; or it may be one or two degrees above normal in the morning, and one or two degrees still higher in the afternoon. Again, the only variation may be a subnormal temperature mornings. These temperature variations may continue for days, weeks, or months, at intervals. Urinalysis reveals nothing. There is growing weakness, however, pallor, some loss of weight, and even night-sweats. What is really the matter? Tuberculosis? Cancer? Irregular malarial fever? Causes wide of the mark are sought for the emaciation, the constant weakness, and the change in the character. The symptoms mean so little or so much, that a correct diagnosis is made perhaps for the first time on the day of the patient's death. Just as life is ending, or perhaps later, a cause is suddenly discovered for apparently insignificant and unexplainable phenomena.

What Bartels calls a "singular nephritis" in describing it, can give rise to this varied and irregular train of symptoms. Interstitial nephritis, often the most misleading and elusive of renal disorders, develops insidiously, perhaps by jumps and starts, and in unexpected ways. It is one of the most stealthy of all diseases in its approach. Dropsy does not occur, though there is often œdema of the eyelids, and sometimes of the ankles. Disturbances of the nervous system are very marked, and appear early. The most amiable and sanguine dispositions may become morbidly depressed, peevish, suspicious, and impatient, with sometimes hyper-excitation of the nervous system almost maniacal in character, and suicidal tendencies may also develop. In no form of kidney trouble are uræmic accidents (Charcot) and hemorrhages (Millard) so common. Hemorrhages may be from the nose, the stomach, and into the cranial cavity. In 111 cases of death from apoplexy at St. George's Hospital, interstitial nephritis existed in 55. Apathy and semi-torpidity of physical and mental powers occur in the advanced stages. Coma is more likely to exist than epileptic seizures. Patients often appear to get well after acute attacks; then all the symptoms return, weakness increases, and death may take place from pure exhaustion. The duration of the disease cannot be known, since there is no necessary relation between the development of the kidney lesions and the appearance of the symptoms. Certain foreign writers seem to believe that the limit of duration lies somewhere between ten and twenty years.

The urine may be examined at frequent intervals for days, weeks, and months, without albumin being discovered. The quantity is always small, and often in fully developed cases it is temporarily absent altogether. When detected, it is usually in the evening urine. Dieulafoy regards albuminuria as a very unreliable symptom of Bright's disease. In sixty cases under treatment in his wards during recent years, albuminuria was absent in one-fourth. That nephritis really existed was often proved post mortem. Millard calls it crude to base a diagnosis upon its presence, and quotes Semmola: "We must absolutely give up the idea still current in practice, that albuminuria must always exist with nephritis." And Francis Delafield states that though albumin is a very common symptom of renal disease, it is least abundant and least constant in certain special forms of it, of which interstitial nephritis is one. But how about specific gravity? Is it unaltered? Does this also defy all preconceived opinions? Listen again to Delafield, in "Pepper's System of Medicine": "Atrophied kidneys give rise to a great variety of clinical histories. It is impossible to describe all the ways in which the disease may begin and run its course, but some of them may be enumerated." Ten such ways are then described. This is one: "For several months the patients do not feel well; the appetite is lost, there is nausea, occasional vomiting, they become pale, anæmic, do not sleep well at night, are irritable and easily worried, and are troubled with headache. The urine continues normal, or is of low specific gravity, or contains a little albumin. They suddenly become worse and the regular symptoms are developed." In pronounced cases specific gravity ranges from 1.010 to 1.016. With heart failure and consequent diminution of the volume of

urine the specific gravity rises somewhat, and may even approach again the normal standard, after having remained for years constantly reduced (Purdy). Delafield says the urine is regularly increased and of low specific gravity (others say, "usually," "generally"), except in uræmic attacks, when it is diminished; uræmic attacks may come on when the patient is passing from thirty to forty ounces of urine of a specific gravity of 1.020. The urine itself is clear, often pellucid, and sometimes soapy-looking. Tests show that it has lost much of its toxic property. Deposits are remarkably free from cellular elements. When epithelia appear, it is the exception and not to be expected (Millard). The regular and absolute amount of urea suffers diminution from the beginning. Phosphates are also diminished, almost constantly (Purdy). Uric acid is increased and calcium oxalate, both of which are often to be noted together. Occasional hyaline casts are often the only evidence, as far as the urine is concerned, of interstitial nephritis. Hypertrophy of the left auricle of the heart is a frequent complication; but Dr. Delafield has not found it in as large a proportion of cases in New York as it is described by English and German writers.

The most important symptom is constant weakness. Next in order is headache. Then comes digestive disturbances, anorexia, nausea, vomiting, flatulence, and so-called bilious attacks. Intractable rheumatic pains and persistent neuralgia are both highly suggestive of interstitial nephritis. Ralph states that this intense pain has often led him to a correct diagnosis. It is well known that disorders of vision are common, with or without discoverable lesions. Minor symptoms are: Auditory troubles, vertigo, itching of the skin, muscular twitchings, cramps in the calves, especially at night, and sensitiveness to cold, especially of the lower limbs.

What to do when this elusive kidney disease is strongly suspected or actually discovered? Remove all strain from the heart, arteries, and kidneys. Life must henceforth be quiet, yet interesting, with gentle but not excessive exercise. Cold and damp are distinctly dangerous. The ideal condition demands a residence in some warm, equable climate from November till April. Treatment is hygienic and symptomatic, combining knowledge and experience and that superior insight known as common-sense.

WOMEN HEALERS *VS.* WOMEN DOCTORS.

A CELEBRATED surgeon in Vienna, Hofrath Professor E. Albert, has recently published a monograph upon the subject of women and the study of medicine, in which he makes a very elaborate argument against the admission of women to the medical art. Professor Albert's kind of reasoning is not a particularly new one. All professional careers, he says, from the beginning of the world, have been pursued by men alone. Since the origin of mankind, woman has had only one purpose, to bring children into the world, to nurse them, and to care for them; hence, concludes the Professor, this must be the purpose for which women were born. The difference between the mental characteristics of men and of women are dwelt upon, the smallness of her head, and the expansiveness of her imagination; the fact that she has made no great mark in literature, science, or art is again thrust ungallantly into the argument. So far, he says, the making of medical women has not led to the production of any scientific results. Medical practice requires power of thought and the capacity for work. Few male students unite both gifts, and how much fewer, the Professor asserts, the female students, in whom thought is so inextricably mixed with emotion. The writer would not even admit that women should become specialists in the eye and the ear, or the throat, since he says, in order to become good specialists, they must first of all acquire the knowledge and assume the responsibilities of a general practitioner. But Professor Albert would not exclude woman entirely from medical work. He kindly recognizes the many admirable peculiarities of woman—her constant willingness, her tenderness, her deep sympathy for the suffering, her sharp observation, etc. He would have woman educated so as to be able to take the position of a kind of medical assistant, a grade a little higher than the nurse, and little lower than the doctor. A young woman should, for example, receive training in a public school, then spend some years in special training in various directions, as nurse in the hospital, as midwife, as head-nurse, as assistant in operations upon the eye, ear, throat, teeth, and so on. She might be taught how to deal with cases of urgency, such as sudden acute attacks of disease or poisoning, and she should understand the elements of medicine and surgery, midwifery and gynecology, besides some physics, chemistry, anatomy, and physiology. Professor Albert would give to this presumably most useful class the title of "Heilfrau."

We fear that Professor Albert's protest against the admission of women to the medical profession is somewhat belated. His arguments are true enough for the large majority of women, but there is always a percentage of the gentler sex who possess qualities which enable them to work successfully as physicians. This has already been proven, and needs no argument. Whether, by giving them freer opportunities, this percentage will become larger, it remains for the future to determine. But, at any rate, we see no advantage in constructing a category of "Heilfrauen," who could never be more than trained nurses. In fact, the good trained nurse is already a Heilfrau, and possesses all the qualifications which Professor Albert has indicated.

Asafœtida in Obstetrics.—Warman (*Der Frauenarzt*, August, 1895) finds that this drug is a most valuable therapeutic agent in midwifery. It is a direct sedative to the pregnant uterus, and exercises no evil influence over the general system. It is of particular value when abortion is imminent, as it controls uterine irritability. On the other hand, it is of no use as a prophylactic agent in such cases, and must not be relied upon when the abortion has proceeded so far as to require manual interference. In habitual constipation, and also in nervous conditions during pregnancy, asafœtida is highly beneficial.

AN ANTI-NOISE LEAGUE.

The city of New York should turn itself reverently toward the town of Phœnix, Ariz., a place little known to fame, but worthy of it. The citizens of that progressive municipality have organized what is called an "anti-noise league." Whether this is meant to suppress the rumbling of heavy drays over the cobbled streets, or the thunderous jars of elevated trains through the public thoroughfares, or simply to prevent the irritating effect of the noise of pistols and shotguns discharged by excited citizens, we do not know; but, whatever the specific purpose, the general object is a most praiseworthy one. There have been many attempts to suppress the noise of this metropolis, but so far without avail. Perhaps it is because the attempts have not been organized, and perhaps because it is difficult to get statistical evidence that noise is deleterious to the public health. Noise is like tobacco: it is a slow poison, and however much harm it does, it does not do it dramatically or sensationally; therefore it does not appeal to the reporter and the chiefs of the Sunday press. We can only infer from analogy that the continual impact of dissonant sounds upon the human ear must have some slight exhausting effect, even though these sounds do not always rise into consciousness.

EARLY MARRIAGES.

The recent marriage of a young woman of wealth, aged eighteen, to a young man of title, has given rise to infinite discussion on matrimonial alliances and matrimony in general. So far as we have noticed, however, none of the commentators upon the great current hymenial events have brought up the question of early marriage in its relation to health. Yet this is perhaps one of the most important of the subjects which could possibly concern those proposing to enter the new estate. It seems almost pathetic that not one of the reporters on the daily press came across the striking remark of Dr. Clouston to the effect that "the young man who marries before his beard is fairly grown, breaks a law of nature, and sins against posterity." The subject of early marriage, and the proper time, so far as age is concerned, for marriage, has often been discussed, and medical opinions upon the matter are numerous enough. Very few physicians, however, have really investigated the matter in the careful method which physiological science demands. Dr. Mathews Duncan is one of these few. A short time before he died he wrote some elaborate article bearing upon this subject, and from his studies and his experience he drew the conclusion that below twenty years of age woman is immature. If she marries before that time, she runs considerable risk of proving sterile. If she bears a child, she runs a comparatively high risk of dying in childbirth. In addition to this, he found that an early marriage had other disadvantages associated with a more frequent tendency to have uterine disorders.

The most elaborate statistical investigation of the subject, however, has been made by Josef Carosi, of Buda-Pesth. His investigation was a purely statistical one, based upon the percentages of deaths, diseases, the births, and so on, in connection with age and marriage. He concluded that immature persons have a tendency to bring forth a degenerate stock; in other words, that persons who marry before they are mature have a larger percentage of cripples, consumptives, idiots, and criminals. The age of maturity is placed at twenty for the woman, and for the man, at twenty-five.

Dr. Farr states, in his "Vital Statistics," that the mortality among wives under twenty years is much higher than that among wives in the period between twenty and thirty, and this same author found that the mortality-rate from accouchements between the ages of fifteen and twenty-five was 1 in 149, while between the ages of thirty and thirty-five it was 1 in 235. Such statistics were collected, however, before the day of antiseptics, and it is possible that they might tell a different story now.

According to a writer in *The Hospital*, the experience of breeders of all kinds bears out the view that the progeny of immature animals has a tendency to be weaker than those of mature. Against all this may be offset the fact that a great many people who marry young have healthy children and live happy lives, and the further fact that if marriage is prolonged too late, perhaps even more disastrous results might occur, to the woman, at least.

The facts regarding early marriages in India might also be cited, as showing that they do not, at least particularly, change the character of the race.

THE ARMY MEDICAL SERVICE.

We learn from our English contemporaries that the present head of the English army, Lord Wolseley, is inclined to carry out the same policy toward the army medical service which was adopted by his predecessor, namely, that of snubbing and keeping down, whenever opportunity offers, the medical officers. At a recent inspection in Dublin, Lord Wolseley objected to the medical corps carrying swords, because, he said, they were only civilians.

The army officers do not seem to keep in touch with the spirit of the times, which tends constantly to bring into greater prominence the work of civilians, and to attract into civil life the best minds of every civilized country. In particular, the standard of education and intelligence in the medical profession is everywhere steadily rising, while we judge from the various exhibitions of the intelligence of army and naval services that these branches are not any longer drawing the best class of men into them. Yet, in the apparently desperate effort to maintain the prestige of the army and navy, the officers do all they can by artificial regulation to keep down men who are, by education and natural intelligence, their equals, and perhaps their superiors. We believe that, in the end, the importance and social value of the medical services in our armies and navies will be recognized at their true worth, and, meanwhile, we hope that the contest will be kept up until justice is secured.

Peekskill has a new hospital, the Helping Hand Hospital.

News of the Week.

St. Joseph's Hospital, New York.—Dr. John Dorning has been appointed consulting physician to St. Joseph's Hospital.

The Presbyterian Hospital, New York, in Debt.—The expenses of the Presbyterian Hospital during the past year exceeded its receipts by $97,625.71, and the usual appeal for donations is in order. In this connection it may be proper to quote a remark made by Mr. J. C. Carter, at the recent anniversary of the Woman's Hospital of this city: "The whole chain of charitable institutions ought to be put under a system. If persons able to give to charity could be assured that their gifts would be made judicious use of they would give more freely." In other words, too much so-called hospital charity sometimes brings its own reward.

Association of Assistant Physicians of Hospitals for the Insane.—The second meeting of this Association was held at the Michigan Asylum for the Insane, Kalamazoo, Mich., October 24, 1895. The membership, originally composed of medical officers of the staffs of asylums of Michigan, Illinois, and Iowa, was extended to include the assistant superintendents and assistant physicians of all asylums. The next meeting will be held at the Asylum, at Independence, Ia., during May, 1896.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about one hundred and eighty dollars, will be made on July 14, 1896. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1896. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper, and within it the name and address of the author. It is a condition of competition that the successful essay, or a copy of it, shall remain in possession of the College; other essays will be returned upon application within three months after the award. The Alvarenga prize for 1895 has been awarded to Dr. Guy Hinsdale, of Philadelphia, for his essay entitled "Syringomyelia."

The Idaho Medical Society.—In a notice of the annual meeting of this Society, in a recent issue, it was stated that the President is Dr. W. D. Springer, and the Secretary, Dr. C. L. Sweet. The positions are reversed: Dr. Sweet is President, and Dr. Springer, Secretary.

Noble Doctors. — Count de Goyan, a prominent royalist of France, has taken the degree of Doctor of Medicine. So also has the Duke de Rivoli as well as Count de Sinety, and Baron Henry de Rothschild is said also to be a medical student.

New Hospital Organization.—The attending physicians and surgeons of Bellevue, and those of the other hospitals belonging to this city, have organized themselves into an association.

The Ovary.—Absent in body, but present in spirit.

Ophthalmic Consultations Free.—On the front advertising page of a leading local medical journal of a neighboring city appears the announcement of doctor, optician, and jeweller, all in one, who gives free consultations to all applicants. This may be business, but it is not ethics. We cannot serve two masters.

London Physicians' Fees.—The weekly paper, *Tit-bits*, states that not a few fashionable doctors in London make from $1,500 to $2,500 a day for weeks together; that some half-dozen of London medical men make $200,000 a year.

Muscular Strength of Woman.—Dr. J. H. Kellogg, of Battle Creek, has devised what he calls a "universal dynamometer," and he has published a very long list of tables showing the strength of the different groups of muscles of the body in men and women. He states that the relative strength of the muscles of the thighs and legs in women is greater than that in men. These statements, according to the medical press, agree with the facts shown by Quetelet and Sargent, that the thigh is not only proportionately, but actually, larger in women than in men. This increase in size of the thigh is, in fact, one of the earliest of all the sexual characteristics, of a physical nature, which appear as the girl approaches puberty, and it seems to be due to greater development of muscles as well as to the great accumulation of adipose tissue. The fact of the relatively greater strength of the thigh and leg muscles in woman might easily be seized upon by those who favor the bicycle for women, since it is the thigh muscles especially which are brought into play in that sport.

Changes in the Staff of the Philadelphia Hospital.—Dr. William B. Porter has resigned after twenty-five years, and Dr. Alfred C. Wood has been appointed as his successor; Dr. J. C. DeCosta has been appointed surgeon, and Dr. E. B. Sangree, pathologist. Dr. Copeland, who was formerly pathologist, has accepted a chair in the Vanderbilt University, at Nashville.

Medical Department of the American University.—It is announced that the Rev. Christian B. Stemen, Professor of Surgery in the Fort Wayne College of Medicine, has been authorized to develop and organize the Medical Department of the American University, at Washington, D. C.

Typhoid Fever again threatens to become epidemic in Chicago. More than one thousand five hundred cases occurred in one week.

Homœopathy.—According to Dr. J. Lester Keep, there are in the United States 6 National societies and 1 sectional society of homœopaths, 143 State societies, 112 homœopathic hospitals, 59 dispensaries, 35 homœopathic medical journals, 20 colleges, and 14,000 practitioners. In England a new homœopathic hospital has just been opened, which cost in its construction and appointments over a quarter of a million dollars. The practice of homœopathy, he says, has gained a strong foothold in Mexico, where a law has been recently adopted placing both schools of medicine on an equal footing.

Dr. J. N. Bloom succeeds the late Dr. Edward R. Palmer to the Chair of Genito-urinary Diseases in the University of Louisville.

Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An International Encyclopædia of Modern Medical Science by leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Vol. IV., Diseases of the Vascular System and Thyroid Gland. New York: William Wood & Co. 1895.

THE fourth volume of this work begins with a lucid exposition of diseases of the heart and pericardium by Professor Whittaker, of Cincinnati. The article is an exhaustive treatise on cardiac affections, occupying a little more than half of the volume. It evidences on the part of the author not only a practical knowledge, derived from long experience, of this most difficult subject, but also an unusually extensive acquaintance with the literature. Dr. Whittaker is well known as a clear and direct writer, and he has put his best work into this treatise. We can recall no monograph on cardiac affections since the appearance of Fothergill's classic which has presented the subject in a clearer light and in a more instructive manner than this. The only fault we have to find is the absence of a bibliography such as is usual in encyclopædic articles. However, the treatise itself is such a finished product that the reader hardly feels the need of references to other works.

The second article, of equal merit, though naturally not of equal length, is one on diseases of the blood-vessels, written by the leading English authority on the subject, Dr. Ernest Sansom, of London. The interesting and important topics of atheroma, arteriosclerosis, and aneurysm are here presented in a way that leaves nothing to be desired. The section on diseases of the veins is also deserving of special mention.

Dr. Bertrand Dawson, also of London, is the author of a comparatively brief article on diseases of the lymphatic vessels. We do not know this writer, whose reputation on this side of the water is not as great as that of the other contributors to the volume. His article, however, is a good one, and a perusal of it forces us to admit that the editor has made a wise selection in securing Dr. Dawson as one of the collaborators.

The closing article of the volume is one on diseases of the thyroid gland, written by Dr. George R. Murray, of Newcastle-on-Tyne. The author includes among his subjects, in addition to myxœdema, cretinism, and goitre, exophthalmic goitre, which he regards as essentially an affection of the thyroid gland. The neurologists will probably dispute this point with him, but we must confess that he advances a goodly array of arguments in defence of his position. The most interesting section, by far, of this article is, however, that on myxœdema, of which Dr. Murray has the right to speak with authority, since it is to him that we owe the successful treatment by means of thyroid extract. The article has the freshness characteristic of all writings in which original discoveries are described at first hand. The illustrations showing the results of treatment in some of Dr. Murray's early cases are striking witnesses to the efficacy of thyroid extract in this disfiguring disease.

ANALELE INSTITULUI DE PATOLOGIE SI DE BACTERIOLOGIE DIN BUCARESTI. VICTOR BABES. Profesor la Facultatea de Medicina Bucuresci. 1894.

THIS work, published in the two languages, Roumanian and French, gives the results of pathological and bacteriological work done in the Bucharest Institute. It is the fourth volume of the series of such reports. There are a number of colored plates dealing with bacteriological subjects.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES. By ROBERT W. TAYLOR, M.D., Clinical Professor of Venereal Diseases at the College of Physicians and Surgeons (Columbia College), New York; Surgeon to Bellevue Hospital, and Consulting Surgeon to City (Charity) Hospital, New York. With Two Hundred and Thirty Illustrations and Seven Colored Plates. Philadelphia: Lea Brothers & Co. 1895.

A WORK upon a subject of this kind must of necessity lose something when the responsibility for the views contained is shared by two authors.

Dr. Taylor is, therefore, to be congratulated upon being the author of his own book, and it appears that this is all his own, with the exception of a chapter upon syphilis of the eye, which was originally written by the late Dr. Loring for Bumstead's work, and the chapter on syphilis of the ear, which is credited in the preface to Dr. J. A. Andrews.

While based upon "Bumstead and Taylor" this can in nowise be regarded as a revision or reproduction, but is a new work stamped throughout with the author's individuality, though here and there, notably in the chapter upon affections of the nervous system, portions have been retained which are as true and appropriate to-day as when they were written for the older joint treatise. Many changes have occurred since their collaboration, and the advances in knowledge, whether due to modern discoveries, bacteriological investigations, improved surgical methods, or newer and better modes of treatment find an adequate reflection in these pages.

It is not a work to be taken up lightly. Indeed its weight is the first thing that strikes one who has been in the habit of reaching down his well-worn copy of Bumstead and Taylor. He finds 1,000 pages instead of 835, but not so many more words to the page, whose space is freely encroached upon by pictures; hence it must be the added weight of the words themselves.

The illustrations, while lending beauty and attractiveness, and proving the advance which has been made in this direction since 1879, may carry with them, too, a certain weight. Not only are the plates numerous, but many of them are excellent, especially some of the colored drawings, and those showing palmar lesions; while that on page 608, a reproduction from the plate illustrating the author's article in the *Cutaneous and Genito-Urinary Journal* of 1890, fails to give any clear idea of the condition present. It is impossible within our limits to discuss the author's views upon the leading unsettled questions in venereal diseases. We can only say that he has stated them clearly and unequivocally, while giving at the same time the opinions of those who differ with him.

The work is one which reflects much credit upon its author.

A PLEA FOR A SIMPLER LIFE. By GEORGE S. KEITH, M.D., F.R.C.P.E. London: Adam & Charles Black. 1895.

AFTER fifty-five years a physician, and once associated with Sir James Simpson in practice, the author now points out some of the evils which have affected medicine during the present century.

Though most readers of this little book may not agree with all of the author's views, still no one can be harmed by reading it, and if the advice is followed to give less medicine and pay more attention to diet, their patients will undoubtedly be the gainers. Americans, however, need such advice perhaps less than their English cousins.

ATLAS OF THE DISEASES OF THE SKIN. In a Series of illustrations from the Original Drawings, with Descriptive Letterpress. By H. RADCLIFFE CROCKER, M.D., F.R.C.P.; Fasciculus XII. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

THE subject of purpuric erythema is illustrated by a figure of peliosis rheumatica, and one of erythema hæmorrhagicum, both excellent, one showing the arm, the other the leg. "Eczema" has three figures: one of E. pustulosum with crusts over a man's face; one of E. urbrum of the leg, designated as scrofulosorum; and a small figure representing the early stage of Paget's disease of the nipple.

Psoriasis follicularis occupies the whole of the next plate in a striking figure, in which follicular elements scattered here and there are almost overshadowed by circinate and gyrate forms. Under "Telangiectoses" there are two interesting representations of rather rare conditions; one the telangiectic form of erythematous lupus upon the cheeks; the second figure showing small multiple telangiectoses scattered over a girl's face.

In the text, which usually contains an account of the case from which the portrait was made, it states that electrolysis is the proper treatment, but that "the patient was too young for electrolysis to be attempted," patient then being seven years of age. The writer would state that he has repeatedly operated by this method upon multiple telangiectoses in youthful subjects as well as upon various forms of nævi in infancy, and knows of no contra-indication.

Fibroma and F. pendulum have characteristic pictures calculated to cause a layman to exclaim "How terrible!" Adenoma sebaceum, a rare condition, which Rayer called *Végétations vasculaires* and Vidal designated as *Nævi vasculaires et papillaires*, is shown occupying its characteristic location, the central portion of the face. Fig. 2 shows a follicular fibroma of the back from the same patient. The present fasciculus is quite up to the standard of those previously received and mentioned in these columns.

PHYSICAL, INTELLECTUAL, AND MORAL ADVANTAGES OF CHASTITY. By M. L. HOLBROOK, M.D., Editor of *The Journal of Hygiene* and *Herald of Health*, etc. New York: M. L. Holbrook & Co. London: L. M. Fowler & Co.

THE author believes such books will eventually do for purity what works on agriculture are doing for farming interests, etc. "What I Know About Farming" once did much toward adding to the attractions of life, and made one more resigned to struggle on. What the author knows about chastity may not produce such results. What "he most desires," as he says in his preface, is to inspire "especially the young," etc. In our opinion parents had better read the book carefully before entrusting it to the son or daughter for their sexual education. There are many truths in the book, and they are often told openly and plainly.

ANATOMY OF THE HUMAN HEAD AND NECK. Graphically illustrated and Described by DR. SCHMIDT. Revised and Edited by WILLIAM S. FURNEAUX, Author of "Animal Physiology," "The Outer World," etc. New York: Thomas Whittaker.

MODEL of superimposed parts, giving to the young an excellent idea of anatomy. It might be used to advantage by the first-year medical student for reference and ready reminder.

WHITTAKER'S ANATOMICAL MODEL. A Pictorial Representation of the Human Frame and its Organs. With Descriptive Text by DR. SCHMIDT. English Edition, by WILLIAM S. FURNEAUX. New York: Thomas Whittaker.

THIS is intended for school children, to take the place of plaster models. Children old enough not to tear out the viscera might profit. There is not sufficient scientific accuracy and detail for medical students at all advanced. The descriptive text is very simple.

A HAND-BOOK OF MEDICAL DIAGNOSIS FOR STUDENTS. By JAMES B. HERRICK, A.B., M.D., Adjunct Professor of Medicine, Rush Medical College; Professor of Medicine, Northwestern University Woman's Medical School; Attending Physician to Cook County Hospital; Assistant Attending Physician to Presbyterian Hospital, Chicago. Philadelphia: Lea Brothers & Co. 1895.

THIS is a very well arranged guide to diagnosis, and one that ought to be of great assistance to the advanced student, for whom it is primarily intended, or to the young practitioner when confronted with a puzzling case. The author deals with all the aids to diagnosis—chemical, microscopical, and physical—and illustrates his work with excellent cuts. There are two colored plates of the blood in malarial and other diseases.

RAPPORT ET MÉMOIRES SUR L'ÉDUCATION DES ENFANTS NORMAUX ET ANORMAUX. Par DOCTEUR E. SÉGUIN. Préface par BOURNEVILLE, Médecin de la Section des Enfants de Bicêtre. Paris: Bureaux du Progrès Médical. 1895.

DR. SÉGUIN'S well-known book appears in French translation as the third volume of the *Bibliothèque d'Éducation speciale*, in the hope that its valuable precepts and elaborated principles, so successful in the education of idiots and deaf-mutes, may be brought to the careful consideration of directors of schools and of teachers, and thus in time become also the privilege of ordinary normal children. In the preface is the certificate of Esquirol and Guervant as to Séguin's great success in a case observed by them; and also an account of the lamented author's death in 1880, and the speeches made at his funeral by Brockett, Wilbur, Brown, and Marion Sims.

The book is divided into four parts. The first treats of the education of the child during its nursery years; the *Salles d'Asile*, or school, where poor children from the age of three to six or seven acquire ordinary knowledge; the *Jardins des Enfants*, or kindergartens; and education in the Physiological School for children. A most interesting and instructive chapter is devoted to the education of hand, eye, ear, muscles, touch, taste, etc., according to the well-known principle, "There is nothing in the mind that was not first in the senses." Toys and object-lessons are of great importance in physiological education. What normal children do spontaneously is an indication of how they may be led into knowledge. To learn through doing is their natural method of mental development. Destruction of toys, etc., has a meaning other than wilfulness; it comes from a desire for knowledge, just as the apparently senseless proceeding common to infants of touching all objects with the tongue is the first effort toward an acquaintance with the outside world. Part II. treats of the education of deaf-mutes in different parts of the world, and of the good Abbé de l'Epée, who, when sixty years old, opened a school in 1770, to teach deaf-mutes to hear with their eyes and speak out loud. In Part III., methods and schools for the instruction of idiots in different civilized countries are described and fully explained. Then, in Part IV., popular education as usually carried on is critically reviewed and the philosophic author's own principles of general education given with force and convincing logic. Two memoirs close the book: one, on the psycho-physiological training of the idiot eye; and the other on the psycho-physiological education of the idiot hand, both illustrating a system of human development that Séguin was first to put into actual practice and publish to the world. It must never be forgotten that the late Dr. Séguin passed the richest and ripest years of his life and labors in the United States, and that America shares with France the honor of appreciating him while he lived. In any language and any country, whatever he has written must, of necessity, retain its original and permanent value.

PREGNANCY, LABOR, AND THE PUERPERAL STATE. By EGBERT H. GRANDIN, M.D., Consulting Obstetric Surgeon to the New York Maternity Hospital; Consulting Gynecologist to the French Hospital, etc.; and GEORGE W. JARMAN, M.D., Obstetric Surgeon to the New York Maternity Hospital; Gynecologist to the Cancer Hospital, etc. Illustrated with Forty-one Photographic Plates. pp. 261. Philadelphia: The F. A. Davis Company. London: F. J. Rebman. 1895.

THE favorable reception accorded to the previous volume on obstetric surgery by the same authors would alone insure a similar one for its companion. When the two are published together, which we understand is the intention, the present monograph will form the first part of a work on obstetrics.

The subjects discussed, though less attractive to many readers than those treated so ably in the "Obstetric Surgery," are nevertheless set forth in a thoroughly practical as well as pleasing manner. The history of successful books in this age of competition, whether in fiction or in science, proves that it is not so much originality which wins many readers as it is the presentation of familiar facts in a fresh and attractive form. This the authors have succeeded in doing even when dealing with apparently outworn themes. The central idea of their former work—facts as opposed to themes—is kept steadily in view throughout. For example, every medical student can rattle off glibly the signs and symptoms of normal pregnancy, but only the mature accoucheur realizes how often "all signs fail." In Chapter I. attention is called to numerous minor points, which are seldom or never referred to in the text-books, and yet are of vital importance at the bedside. The anomalies of menstruation, fœtal movements as felt by the examiner, softening of the entire cervix, rather than the tip alone, and other practical hints will be noted. The short section on the care of pregnant women (pp. 27 to 31) is replete with sensible advice. Chapter II. is devoted to a comprehensive review of the pathology of pregnancy, the introductory section on the pernicious vomiting of pregnancy being especially helpful. Chapter III., on obstetric palpation, pelvimetry, etc., is richly illustrated and contains a large amount of useful information condensed within a few pages.

Part II. is devoted to labor and includes four chapters on the mechanism and clinical course of labor, the management of normal and abnormal labor, and the care of the new-born. The general practitioner will find the third chapter of great value, since it is filled with hints which represent the results of years of experience in the lying-in chamber. As an example of its judicious teaching reference may be made to the use of ergot after delivery (pp. 161, 162), and of chloroform during labor (pp. 144, 145). The details of the first examination of the parturient are presented most happily in the same chapter. The concluding chapters on the normal and pathological puerperium are most commendable. It is impossible in the brief space allowed to us to call attention to all their excellent points. The reader will note as especially good in Chapter I. the remarks on nursing (p. 211), and on artificial feeding. In Chapter II. the etiology of puerperal septicæmia is discussed at length in the light of recent bacteriological investigations. The symptoms are graphically set forth, and the remarks on diagnosis (pp. 236, 237) are clear and practical. The concluding section on mastitis is brief, but full of useful suggestions.

One of the most prominent features of the book is the number of plates, especially those illustrating the management of labor. This is a favorite method of supplementing medical teaching at the present day, and whatever criticisms may be urged against it on the ground of propriety, it cannot be denied that a single photograph showing exactly how a thing is done is worth pages of description. They certainly add to the value of the present volume, especially with the class of readers for whom it is intended. The favorable criticisms applied to the literary style, arrangement of the subject-matter, and the general make-up of the "Obstetric Surgery" can only be repeated, and we prophesy for it an equal success.

Society Reports.

MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND.

Semi-Annual Meeting, held at Belair, Md., November 19 and 20, 1895.

The meeting was called to order with Dr. C. Birnie, Vice-President, in the chair, and Dr. A. K. Bond, Secretary. The Society was welcomed by Hon. Walter Preston, of the Belair bar, and Dr. W. L. Smith, of Jarretsville, President of the Harford County Medical Association, and was responded to by Dr. C. Birnie.

The Surgical Treatment of Laryngeal Tuberculosis.—This was the subject of remarks by Dr. John N. Mackenzie, of Baltimore. He referred to the papers read before the American Laryngological and British Laryngological Societies on this subject. Krause, of Berlin, and Hering, of Warsaw, had done the best work on this subject. The surgical treatment of tuberculosis of the larynx is carried out by total and by partial curettement of the lesions, with the application of lactic acid. Usually the tissues are first curetted out with specially prepared instruments, and then the acid is rubbed in. The Germans use a fifty per cent. solution of lactic acid, while others use it pure, and some operators rub the acid in without curetting, provided ulcerations exist, for the acid will not go through the intact mucous membrane. The tissues may also be injected with a solution of the acid. The results of this treatment by curetting and lactic acid are wonderful. The ulcers may heal even when the lungs are far gone. When the infiltration is circumscribed and in the epiglottis, portions of the tissue may be excised. The subsequent treatment is to paint the surface with pyoktanin, or lactic acid may be used. Sometimes the whole diseased area is not easy to get at. These wounds generally heal very well. Sometimes there is hemorrhage, but this may be stopped by application of equal parts of lactic acid and perchloride of iron. Some operators use the scissors to cut off the diseased part when this is possible, and some use the electrolysis, putting one pole in the lesion and the other on the neck. The galvano-cautery is also used. In stenosis intubation has been suggested, and tracheotomy is a last resort in some conditions, but this is only justifiable to prevent suffocation. Thyrotomy has been practised under some circumstances, and even it has been proposed to extirpate the whole organ. As the disease is rarely primary in the larynx (only about five cases having been reported) this operation is not advisable. Such cases usually die. Most observers agree that the effect of this treatment is beneficial to the lung disease, and a few have the opposite view, but it seems rational that it must do good. It does not effect a cure, but it does prolong life. Relapses occur. In hectic fever, and when the disease is diffuse, this operation is contra-indicated.

Dr. William B. Canfield thought these facts very interesting for the specialist and general practitioner. He would like to know something of the technique of these operations. How strong was the cocaine solution used before curetting and how applied?

Dr. Mackenzie said this was very simple. The cocaine was in ten to twenty per cent. solution, and the pyoktanin used was a two per cent. solution. Special instruments had been devised by Hering, of Warsaw, and he had sent for some, but the curetting and application of the lactic acid was not difficult.

Management of Advancing Corneal Ulceration in Gonorrhœal Ophthalmia.—This was the subject of a paper by Dr. Hiram Woods, of Baltimore. The danger in this disease lies in the involvement of the cornea, and this danger is in proportion to the extent of the inflammation in the ocular membrane, and is greater the earlier the cornea is affected. Corneal trouble may come from—1, interference with the circulation; 2, direct infection; and 3, pressure on the cornea from pus or the swollen eyelids. The latter is most usually met with. The pus must be let out. To prevent infiltration use leeches, cold, and scarification. Nitrate of silver may also be used in the strength of ten grains to the ounce. This should be applied very thoroughly. The crayon-stick may be applied once in twenty four hours. Dr. Woods said further that just as most of the curable cases of blennorrhœa yielded to the two per cent. silver solution, so most of the manageable cases of corneal complications are amenable to milder methods than cauterization. At the other extreme stand cases hopeless from the beginning. A small area of infection rapidly destroys the weakened cornea. Efforts to stop its progress, successful usually in primary infection, not only fail, but seem harmful. Probably defective vascular supply is the trouble. Between the two there is a third class, to which the cases he related belong. The presence of purulent inflammation demands something more than corneal disinfection.

Tears of the Cervix Uteri; their Significance and Repair.—This was the subject of a paper by Dr. J. M. Hundley, of Baltimore. He thought surgeons were too ready to repair torn cervices when often the mere suturing of the laceration was not so much needed as strong tonics and attention to the general health. He recited cases tending to show that the cervix had been sewed up too tight, and related other cases showing that the cervix would often heal kindly after a difficult birth, even when it was badly torn, without operative interference. He thought it was meddlesome surgery to be too ready to operate on every little tear, and to attribute every kind of ill feeling a woman had to a small tear in the cervix. These tears came most usually from the use of the forceps, and were at times not to be prevented.

Dr. John Morris, of Baltimore, said this was a most sensible and practical paper. He had had a large number of labor cases in his professional life, and many times he had applied the forceps, and he endorsed Dr. Hundley's remarks thoroughly. Too often such interference is meddlesome.

Dr. A. K. Bond, of Baltimore, had delivered a woman in whom he had found a dense band of tissue across the cervix, and when he examined it he found it was the result of suturing an old tear, the stitches having been put through the canal. He cut this fibrous, cicatricial band and the labor proceeded without complication. He related a case of lacerated cervix where the tear was constantly suppurating and at the birth of a child its eyes became infected with this matter. He asked what was the connection between a lacerated cervix and defective lactation.

Dr. John Neff, of Baltimore, related several cases of difficult labor which he delivered after great trouble, and in which a laceration healed without operation and one in which pregnancy followed.

Dr. Woods said that because a new-born infant had ophthalmia, it did not follow that the mother had had

gonorrhœa. It might be a non-specific ophthalmia which usually gets well with little or no trouble. In the cases related by Dr. Bond, Dr. Woods thought that the child might have had inherited syphilis or some post-partum affection not from the mother.

Dr. Bond said he had eliminated both of these sources.

Dr. Morris said he thought Dr. Bond's ideas were heretical. He thought some other trouble must have affected the infant's eyes than the mere lacerated cervix.

An Epidemic of Typhoid Among Children.—This was the subject of a paper by Dr. A. K. Bond, of Baltimore. These cases he had seen in an institution for destitute children, and the ages were from seven to nineteen. There were twelve cases in all. The fever lasted longer in the younger children, and the temperature was also higher. There were usually headache but no delirium worth mentioning. There were some nervous symptoms noticed in some of the patients; one was slightly deaf for a few days and several had nosebleed. Rose spots were observed in all but three cases. There was no marked tympanites in any case, and only slight iliac gurgling. The bowels were neither markedly loose nor costive, and in only a few instances were the characteristic typhoid stools observed. The spleen was enlarged in one case, and in one case there was albuminuria for a few days. No casts were found. In all but two cases there was considerable catarrh of the lungs. In all these cases the tongue was coated, but the hard, dry character as seen in adults was not observed here. There was not much emaciation. In one case there was gangrene of the mouth. The treatment was begun with thorough purging with castor-oil and calomel. The sweet spirit of nitre and sponging was used, and in two cases baths and douches were tried, but they were given up later. The nourishment was looked after very carefully; a cupful of milk was given every two or three hours in the day, and through the night when necessary, and in some cases pepsin was also given. Small doses of Epsom salt, from a half drachm to a drachm, were given during the illness to keep the bowels clean. It is not easy to trace the cause of epidemics in a city. There were two buildings, both having the same water and milk-supply, and nothing could be proved on either. The following conclusions were drawn from a study of these cases: 1. That children often bear high temperatures well in typhoid fever. 2. That bathing (in full bath) should be very judiciously applied, if at all. 3. That the disease in children under five years of age may easily be mistaken for other digestive disorders or for bronchitis. 4. That albuminuria coming on during the fever does not necessarily lessen the chances of a favorable issue. 5. That gangrene of the mouth, if superficial, may sometimes be cured by permanganate of potassium lotions. 6. That careful consideration should be given to the furtherance of digestion, as by the use of pepsin and acid; and also to the prevention of the accumulation of unwholesome or hardened fæces in the intestines, as by the systematic and judicious employment of Epsom salt in the manner above indicated.

Dr. J. W. Scott, of Belair, asked why Dr. Bond preferred Epsom salt to calomel.

Dr. William Les spoke of the atypical cases occurring in children, and quoted authorities on the subject.

Dr. Charles Bagley, of Bagley, thought that Epsom salt was a very important part of the treatment. Active purgation might cause hemorrhage, and that should be considered before strong cathartics were given.

Dr. Bond said, in reply to Dr. Scott, that he gave the Epsom salt because he did not wish to salivate with calomel, and he thought the salt was a better purgative in these cases.

Dr. James A. Steuart, Secretary of the State Board of Health, said that it was difficult to trace these cases and the cause of the disease, and it is hard to find the bacillus in water, but if the water contains sewage of course it is unfit to be used.

The Radical Cure of Inguinal Hernia in a Child by the Implantation of a Section of Aseptic Sponge to Occlude the Internal Ring.—This was the subject of remarks by Dr. Walter B. Platt, of Baltimore, who also exhibited the patient. The boy came to him last August with an inguinal hernia like an old man's. He had used different kinds of trusses. He was seven years of age. Dr. Platt tried the worsted truss, but but with no results. He then decided to operate by a plan of which he had never heard, though it might not be original. He opened the inguinal canal in the usual way, reduced the hernia, and then he took a small piece of sponge, washed it thoroughly and by boiling he made it thoroughly aseptic, and put it in the conjoined ring and sewed it in here, with the idea of keeping the hernia in place and having the sponge organized. It is not possible to speak of a cure as the operation has been done only three months, but so far the boy can run about and play, and the hernia stays up, and the sponge has caused no disturbance, so it must be organized by this time. Macewen says that only about forty per cent. of the cases operated on in the usual way are cured after two and half years. If this case turns out well he shall treat all other children afflicted with the same kind of hernia in the same way. The idea is new to him, and he hopes it will be successful.

A Critical Review of Modern Operations for Hæmorrhoids.—This was the subject of a paper by Dr. S. T. Earle, of Baltimore. He briefly related the various methods of operation and then described the modification of Outerbridge's operation, which he preferred. He gave a demonstration of the clamp and manner of suturing, and said it gave less discomfort than other operations.

Dr. C. M. Ellis, of Elkton, asked if Dr. Earle did preliminary dilatation of the stricture before operation.

Dr. Earle said he rarely did this, for no matter if dilatation was practised there was always a certain amount of burning of the rectum after the operation that demanded a hypodermic injection of morphia, but if it is a bad case with many hæmorrhoids he does dilate

A Case for Diagnosis.—Dr. C. H. Hollingsworth, of Belair, then presented a case in which he needed help. The boy was seven years of age, and was taken sick about six months ago with pleurisy on the left side followed by a pneumonia of that side, and then that all cleared up and there was a pleurisy of the right side, and that cleared up, and the boy was going on well to recovery when he was suddenly taken with severe pains in the back of the neck and had a severe pain down the back, and now his head is bowed forward and he cannot straighten it; he cannot put his feet to the ground, cannot use his hands very much, and can lie in the same position but for a few moments only. His weight fell off at first, but now he has regained about three pounds, due to the tonic treatment, but he seems to be no better in other respects. There were hard nodules or lumps in the abdomen which seemed to disappear on purging. The sterno-clavicular and sterno-costal articulations are all enlarged and painful.

Dr. W. F. A. Kemp, of Baltimore, said it was not easy to express an opinion from a cursory examination, but he was inclined to think it was tuberculosis, although the swollen articulations looked a little like a gouty diathesis. He suggested an examination of the urine microscopically and also of the sputum.

The Clinical Course of Forty-seven Cases of Complete Extirpation of the Uterus for Carcinoma.—This was the subject of a paper by Dr. W. W. Russell, of the Johns Hopkins Hospital, in which he gave statistics on the results of the operation in these cases and explained the manner of operation and the danger of

secondary deposits depending on the situation of the primary lesion. It may pass from the uterus to the bladder in front, to the rectum behind, or even to the vaginal mucous membrane or to the ovaries, and he spoke of the results of early operations. In answer to Dr. Kemp, he said that only one case was living for five years after operation, but that Boldt had reported a case that lived for seventeen years after total extirpation of the uterus for carcinoma.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 18, 1895.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

Some Results of Experimentation with a New Antiseptic Fluid.—DR. HUBBARD W. MITCHELL read a paper with this title. After giving an interesting and rather full description of his extensive experience with the new antiseptic fluid, he stated that it was simply a solution of halogen salts chemically combined.

DR. VON DONHOFF asked what were the ingredients, and as Dr. Mitchell's answer did not appear to him to be sufficiently specific, he asked if it was a secret remedy, and Dr. Hinton seconded his motion that the subject be not further discussed until the question had been answered.

DR. MITCHELL replied that he did not remember just the ingredients, but that the remedy was not secret, and he would hand the formula to the President when he obtained it from the chemist. The therapeutic value of the halogen salts, he said, was known to all. Taken in nearly equal proportion and mixed by the chemist, there seemed to be a rearrangement of the atoms of the salts in the solution, and the resultant was a straw-colored fluid, acid reaction, specific gravity of about 1.023, strong odor of chlorine, slightly acid taste.

About two years ago a chemist, a friend of his, brought him the fluid, which he said was good for almost everything, and among the things which he named specially were ulcerative and suppurative processes, and gonorrhœal and syphilitic lesions. Dr. Mitchell first tried it on a large, broken, painful carbuncle of the neck, and by next morning the inflammation had about half subsided, and by the fifth day the patient was practically well. He then got permission of Dr. Taylor, of the Vanderbilt Clinic, to try it in thirty cases of gonorrhœa. It was difficult to apply the treatment in these patients satisfactorily, and the results were hardly complete, yet in many rapid benefit had followed. He then, through the courtesy of Dr. Taylor, selected about thirty-five cases of lesions of syphilis in various stages, and of chancroid. In all cases, whether of phagedenic bubo, indurated chancre, or other sore, the results were extremely satisfactory, the lesions healed without difficulty in a short time. The same was true of cases seen in the venereal wards of the City Hospital, through the courtesy of Dr. Sturgis and Dr. A. M. Phelps. The sores healed in an unusually short time whenever the treatment could be carried out. There were about twenty cases of chancroid of the vulva, some old syphilitic lesions of the leg, gonorrhœa, etc. Varicose ulcers also did well, but owing to their nature required more attention. At the suggestion of Dr. Steinach, the fluid was injected from four directions into a large but unbroken bubo, and this dispersed without going on to form an ulcer. Two or three cases of extensive epithelioma of the face, extending down to the bone, were treated, the ulcerative process was arrested, granulation took place, and by further aid of a plastic operation the raw surface was nearly or quite covered by the time the patients left the hospital. Endometritis and ulcerative tonsillitis had likewise been treated successfully, and even carcinoma of the cervix had disappeared in one case in which he had tried the fluid. In six cases of pulmonary tuberculosis, the diagnosis being based on physical lesions, presence of tubercle bacilli, and the usual symptoms, the fluid was given internally, drachm and a half at a dose, three times a day, and in all the subjective and physical symptoms disappeared.

Wherever possible, in external lesions, the parts were bathed in the fluid once or more a day, and in addition were kept wet by gauze or dressings dipped in the fluid. Its presence caused the tenaceous membranes on ulcers to dissolve, and a healthy granulating surface to spring up and to rapidly heal. In the treatment of gonorrhœa in women and cervical lesions, it was poured in through a rubber speculum, and after remaining a few minutes was allowed to run out; more was poured in, finally the parts were cleansed by cotton probe and the vagina tamponed with gauze soaked in the fluid.

DR. C. J. MACGUIRE, who had helped carry out the treatment in some of the cases in the City Hospital, said that in the case of epitheliomatous ulcers of the face the fluid had the effect in two months to reduce the ulcer from a diameter of six inches to an inch and a half. The patient then left the hospital.

Diagnosis and Treatment of Gout.—Dr. L. F. BISHOP read this paper. He said: In a previous paper we dwelt upon the theory and distribution of gout. Now we propose to study as a more practical outcome the means of its recognition and the application of a proper plan of management. The diagnosis divides itself into that of acute attacks and of the gouty habit or constitution. Acute gout arising for the first time in a young person, is comparatively uncommon in the experience of American practitioners, therefore it might easily be overlooked. The points to be considered are the time of the attack, usually in the small hours of the night, the location of the pain, usually in the metatarso-phalangeal joint of the great toe. The character of the inflammation with its intense hyperæmia, and, most characteristic of all, the fact that the inflammation is followed by desquamation. An acute attack usually lasts, with intermission during the daylight hours, for from five to eight days.

Diagnosis of Suppressed Gout.—This is a term applied to a series of symptoms not typical of gout, but which occur in a gouty person, and which from strong negative and positive evidence we believe to be gouty in origin. These attacks are worthy of close study, because they must occur sometimes in our practice and can so easily be overlooked. They may immediately follow an attack of acute gout, or replace an attack. The patient may have severe vomiting, pain, diarrhœa, and profound depression, or there may be cardiac trouble manifested by dyspnœa, irregular action of the heart, and pain referred to that organ or to the left shoulder. We should remember at all times these attacks of suppressed gout, because they may occur independently of articular gout. The difficulty of diagnosis is great, but it should be borne in mind as the possible cause of some of the obscure, severe, and often fatal cardiac attacks accompanied by extreme dyspnœa, with failure of the heart's action in force and rhythm which we sometimes encounter. These are apt to be uniformly put down to uræmia, but in the absence of albumin and of typical signs of kidney disease, the possible gouty factor should be considered.

The diagnosis of chronic gout following a series of acute attacks is a simple matter on account of the characteristic joint deformity. Hospital reports in this country show a frequent diagnosis of chronic diffuse nephritis, and rarely that of gout. It would seem that many of these cases were primarily a gouty sclerosis of the vessels, and that the nephritis was secondary. The distinction in mortality reports is not important, but if the lithæmia could be recognized early the

sclerosis might be avoided with its fatal kidney complications. This involves the early detection of the gouty diathesis, which is a condition representing many various pictures. It is perhaps best approached by a consideration of some of the more irregular manifestations. These may be nervous, gastric, cutaneous, pulmonary, or may affect the organs of special sense. These irregular manifestations are as often due to hereditary tendencies as to acquired gout; hence we see them often in very young persons. The gouty habit or lithic state may even appear in infants.

Skin affections are among the most frequent irregular manifestations. Eczema is recognized by all as such. Psoriasis is believed by Dr. L. Duncan Bulkley to be more frequently due to this cause than to any other single constitutional vice. Chronic bronchitis is frequently gouty, and is modified only by gouty management. The most serious manifestation of the gouty constitution is the gradual production of sclerosis of the vessels and of the valves of the heart. It is in the avoidance of this condition that the early recognition and management of gout is most important. Gastro-intestinal disorders of gouty origin are characterized by constipation, headache, a dirty tongue, and the usual symptoms of biliousness, but with all these symptoms exaggerated and prolonged. The nervous manifestations are very numerous, migraine perhaps most common, but there may be symptoms referred to particular nerves as due to a true neuritis or to neuralgia. A very frequent form is the tingling and formication in elderly people.

Thus the nervous manifestations may be immediately due to the deposition of sodium urate circulating in the blood and coming in contact with the nervous elements, or the symptoms may be due to a secondary effect of the gouty ravages upon the tissues in the neighborhood of nerves, or upon the blood-vessels by which the large nervous centres are nourished.

Haig's observations upon migraine have attracted wide-spread attention, but it would be a mistake to attribute every case to uric acid due to gouty ravages upon the vessels. There may be cerebral symptoms, such as a definite failure of power, lasting for a few days or weeks, attacks of dizziness, and all the symptoms that go with cerebral endoarteritis.

Gout is said to cause deafness by the deposit of urates between the layers of the drum of the ear. Gouty subjects, either on account of the constitutional vice or the debility which diminishes their power of resistance, are specially liable to catarrhal inflammations of the nose, throat, and larynx.

Treatment. — The word management, as a name given to our efforts to bring about a cure of gout, is better than the word treatment, because treatment carries with it a trace of an idea of a specific plan of medication. It has often been said before, and we say it again, that management of gout is chiefly a question of hygiene, but we must not fall into the error of supposing that the hygienic treatment is easy of accomplishment. The cure of a disease by the modification of a patient's surroundings and the habits and actions of his organs, may well tax the patience, knowledge, and ingenuity of a physician. Hygienic treatment includes not only the modification of his mode of life, food, and drink, but the skilful use of such drugs as are directed to the improvement of the physical action of the organs, for it does not seem quite philosophical to include tonics, blood-foods, and laxatives under the head of a drug treatment of the disease proper.

The question of food arises first. Dr. W. H. Draper's experience negatives the definite line drawn between carbohydrates and proteids. The safest hypothesis upon which we can work is that in gout there is an impairment of the chemical powers of the body, which in different persons affects somewhat different processes. Each case must be worked for itself, but it will be often found that the food most suitable to a particular case will contain a good proportion of proteids, or even that proteids are better borne than carbohydrates. Much depends upon the form of the disease. Sugars and sweets of all kinds are definitely bad, and fermented liquors must be interdicted. Indulgence in wine or improper food may bring on a definite attack of gout, or is more likely to bring on eructations of wind with gastric pain, or some of the nervous or irregular symptoms. Potatoes tax a weak digestion very heavily, and might perhaps be the first thing cut off. The fact is that our knowledge of chemistry is not sufficiently complete for our theory to dictate absolutely to our practice. The best working theory is that by not overtaxing the digestion with carbohydrates, its forces are more at liberty to take care of the proteids. The use we make of water is important. Nearly all chemical operations are carried on with water as a vehicle for the chemical agents and reagents. Every chemist knows that in seeking a chemical result the reaction of the fluid—that is, its degree of acidity or alkalinity—is important. Now, by supplying to the system water in abundant quantities, especially if it tends to modify favorably the reaction of the system, we are certainly benefiting the enfeebled chemistry of the gouty body. Lithia seems to be of value, but its action is probably not, as was formerly supposed, principally by increasing the solubility of sodium urate, but it seems to have a catalytic action —that is, by its presence it favors the actions and reactions of the fluids of the body to a degree out of proportion to its amount. However, it should be given in an appreciable amount, and not by means of mineral waters, in which it has been detected by a spectroscope. There is no magic in native mineral waters. Artificial waters are just as good, and have the advantage of a definite formula and safety from the possible infection of a rural spring. We would not deprive a patient on this account of the locality benefits of watering-places. But scientific truth is not modified by the popular belief in nature's magic combinations in the bowels of the earth. The verdict of the laboratory upon the absence of any such combination in native waters is positive.

Thus we see that gout is a disease which may manifest itself in a great many different ways, and the recognition and management of which must always be of great interest to physicians in every department of the profession.

Dr. Max Einhorn thought recent investigations had made it doubtful whether the theory of the uric acid diathesis as the cause of gout, which had been accepted so long, was correct. It was accepted by some authorities, however, that there was some matter present in the circulation, the nature of which we did not yet know, which caused gout. But it had been proven that uric acid was not excreted in smaller amounts by gouty people than by others, and that also there was no retention of uric acid in the blood. But it was true that uric acid was found in the joints of gouty people, and it was thought that the uric acid in the blood, present in small amounts, crystallized there. But the uric acid itself was not the origin of the disease.

For a long time it was believed that the diet should consist only of vegetable matter, or of foods which contained little of the albuminates, because these were supposed to cause so much uric acid. This theory had not been proven. Even albuminates in large quantities did not necessarily increase the amount of uric acid. It had been found that the uric acid which was excreted took its origin really from nuclein, or substances which contained nucleated elements. It was not a sign of suboxidation. Still, the empirical points of the past were true to-day. It had been found that the patient's tendency to gout was lessened by out-door life and exercise, and since gout was oftenest present in the well-to-do, it was necessary to caution them

against eating too much, and to advise the use of plenty of water to wash out the waste matters.

An Enormous Clinical Fact.—Dr. L. D. Bulkley said that however one might regard gout in the laboratory, it was at least an enormous clinical fact, and the more we recognized it the more we would benefit our patients. He had long ago ceased to look for actual joint diseases in his skin patients with a gouty tendency. He saw skin manifestations of the disease in the absence of enlarged or inflamed joints every day. He who looked upon gout as only a joint disease would never recognize its true position in medicine. The chain of factors which culminated in the joint lesion should be broken long before reaching such an extent. Clinically, we did see uric acid and urates in enormous quantities in the urine of gouty patients. Eczema occurred frequently in children of gouty parents, and in one generation there might be joint lesions, while in another the skin was affected.

Dr. Bulkley corroborated the author's statement with regard to mineral springs. He had visited many of them, and had become convinced that few of them were better than Croton water. The temperature, however, had something to do with their efficacy, for they were usually taken hot. We little realized how important it was to give water in the right quantity, at the right temperature, and at the right time. Add to this the regulation of the patient's habits relating to exercise, meals, and sleep, as carried out at mineral spring resorts. As to lithia, he did not use it much, but frequently employed acetate of potash. He found many gouty people taking soda and common salt, and the consequence was a deposit of urate of soda. Potash salts had no such tendency to become deposited in the joints. He did not think we appreciated sufficiently the harmfulness of alcohol in various forms, including even wine. Haig's work was a most interesting one, and his suggestion to cut off red meats and use white meats, had been adopted by Dr. Bulkley with beneficial results. Dr. Bishop's remark that management was better than treatment in gout, deserved to be emphasized.

Dr. F. J. Quinlan had several times seen gouty manifestations in the throat and ear which cleared up under anti-gout remedies.

Dr. Bishop made a few closing remarks, and expressed regret that there had not been time to read the whole paper, as much of the unread portion had a bearing on the subsequent discussion.

Functions of the Cerebro-spinal Fluid.—Dr. James A. Campell read a paper, the full title of which was: "Some Notes on the Functions of the Cerebro-spinal Fluid, Gathered from Lectures delivered at the Faculté de Médecine, Paris." Although the lectures were delivered as far back as 1883–84, by the late Professor Sappé, he said they had not been published, and he thought the facts expressed would be of some interest, since they showed the fallacy of some statements in more recent works on anatomy. The arachnoid, Sappé said, could be inflated, but it contained no fluid, and there was no communication between it and the ventricles. Some had claimed there was such communication, but their error was due to cutting across the vein of Gallian which the arachnoid surrounded. Briefly expressed, the function of the cerebro-spinal fluid was to regulate the capacity of the skull and spinal canal. Before closure of the fontanelles it could be noticed that with inspiration there was less blood in the skull, during expiration more, and the amount varied also with the heart-beat. After the cranial bones had become hardened, there could be no variation in the capacity with the pulsations and respiration, and now the intervertebral spaces acted as numerous fontanelles, allowing expansion of the cerebro-spinal fluid within the meninges. A function of the fluid, of considerable importance, was to refill the space in the event of nervous atrophy.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 21, 1895.

Joseph D. Bryant, M.D., President, in the Chair.

It being the forty-eighth anniversary meeting, the President explained to the audience, composed in no small part of the lay public, the purposes of the Academy and the work which it had already accomplished. The membership numbered eight hundred, and was steadily increasing. As a manifestation of their earnest effort, and that of their friends, they had established a library of fifty-five thousand volumes, which as a medical library was only second in size to the largest one in the United States, that of the Surgeon-General's office at Washington, which was under the support of the Government.

Anniversary Discourse, "Progress in Medicine."—Dr. Edward G. Janeway delivered the anniversary discourse, about an hour in length, on progress in medicine. The subject was limited to the medicine of the last thirty years. He first spoke of medical teaching and instruction, the advance relating to longer course of study and replacing teachers largely by numerous educators who instructed the students in laboratory work, in anatomy, and at the bedside of the patient. Histology, pathology, and bacteriology, which thirty years ago had scarcely received any attention in a medical course, had come to take prominent positions. In this connection it was suggested that the instructors in the more strictly scientific branches should receive salaries through endowments, as their labor, unlike that of the clinical teacher, was not of a kind which increased their income through general practice. In the monarchies of Europe these instructors and investigators were compensated by government. It was different here, where colleges had to depend upon private endowments and fees to meet expenses.

Medical examining boards had acted in some degree as safety-valves against the turning out of so many poorly educated doctors by innumerable colleges. Another advance related to training-schools for nurses, that at Bellevue being mentioned in particular.

Many systematic treatises had been brought out on diseases which thirty years ago scarcely had a name. This was especially true in the department of diseases of the nervous system. Charcot was mentioned for his distinguished work. We were indebted not a little to vivisection for advance in the location of brain areas, etc. In diseases of the heart we had advanced beyond giving attention only to murmurs, which often were of adventitious character. Formerly we spoke of perityphlitis, and knew nothing of appendicitis, which must have destroyed many lives that were saved to-day by surgical interference. In this matter the profession abroad was behind New York surgeons several years. Recovery from tubercular peritonitis as a result of laparotomy was an advance whose real explanation yet eluded us. The discovery, by Koch, of the tubercle bacillus was in itself a marked advance, and had led to other long strides forward. It had shown the necessity for the destruction of the sputa of tubercular patients, the avoidance of food containing tubercle bacilli, etc. Dr. Janeway said that notwithstanding the disappointment with tuberculin, he understood that Dr. Trudeau, in this country, and Dr. Koch himself still had hope of obtaining from it remedial properties free from objectionable features, and had not ceased their investigations in this line. The discovery of the bacterial origin of many diseases had led to the adoption of measures more or less efficient in preventing their spread and in their cure. While Lister had done a good work, a much greater stride forward was taken when the surgeon learned the value of asepsis as secured through cleanliness of instruments, dressings, and person. Indeed one was appalled to think of the

number of lives sacrificed in previous years through want of knowledge on the part of surgeons of the value of cleanliness.

Lines of investigation which promised much therapeutically related to serum, toxin, and antitoxin therapy. Dr. Janeway was of opinion that in diphtheria antitoxin had proven itself efficient as shown by collective and individual statistics, and believed time would enable us to avoid any harmful results of the serum. Reference was made to the epidemic of small-pox in the city in 1874, and the opinion was expressed that any one on studying the statistics of small-pox in New York prior to 1875, and since that period, when a corps of vaccinators was established, would be convinced that by vaccination we were able to control this disease. Dr. Janeway himself had not had success with toxins in the treatment of sarcoma, but Dr. Coley's experience had been encouraging in that direction, and also led us to hope that a cure might yet be found for carcinoma.

It had become somewhat the custom to decry the coal-tar derivatives in the treatment of fevers, but the writer did not hesitate to recommend their use in suitable cases. The control of typhoid fever by water-baths was noted, but a better thing was prevention of epidemics by Boards of Health inspecting the water-supply.

The growth of specialism had tended largely toward the advance of medicine. While he believed in specialties he would not advise young men to take them up until they had acquired a broad knowledge of general medicine. The evil of conflicting testimony in courts by medical experts was mentioned, together with the remedy which had been suggested of having the experts appointed by law to pass impartially upon the diagnosis and such medical points as were brought before them. Whatever might be done, there was not the least doubt but what a change was desirable in our medical testimony.

Dr. Janeway thought it would be well if the Academy, through donations, were enabled to establish a laboratory in which investigations could be carried on. How extensive such a laboratory should be, would be a proper subject for discussion after it had been decided to have one. If it were contended that the library should first be placed on a solider foundation, let us hasten with that good work.

THE PRESIDENT said they had listened to a classical discourse on progress in medicine from the highest authority, and before declaring the meeting adjourned he invited the audience to stay for refreshments and to inspect the library and building.

Surgical Suggestions.

Syphilis of Larynx.—An early diagnosis of syphilis of the larynx is important, as in this stage it can be satisfactorily treated, while neglected tertiary lesions are often incurable, except, perhaps, by radical surgical measures.—ANDERSON.

Examination of Virgines Intactæ.—The bimanual examination of *virgines intactæ* should always assume the form of a recto-abdominal palpation. There is no need in these cases of a vaginal examination; the finger in the rectum will teach us all we wish to know concerning uterus, tubes, and ovaries. The only difficulty to be overcome is to identify the cervix; a little practice will enable us to master this detail.—EDEBOHLS.

Intra-cranial Hemorrhage.—Intra-cranial hemorrhage is regarded as a very natural accident in Bright's disease, atheroma, and hemorrhagic pachymeningitis.

Tuberculous Iritis.—1. Tuberculous iritis must be distinguished from other varieties of iritis. 2. This form of iritis is premonitory of the appearance of tuberculous nodules elsewhere. 3. Its invasion is insidious, slow, and with but little local reaction, but is accompanied by numerous posterior synechiæ. 4. The absence of pathognomonic symptoms makes the diagnosis difficult. 5. The tendency to spontaneous healing of miliary tuberculosis of the iris depends upon the natural resistance of the iris tissue. The encapsulation of the tubercle and the rapid obliteration of its nutrient capillaries favor its isolation and the protection of the healthy tissues.—VIGNET.

Shock is a disturbance of the functions of the nervous system, induced suddenly by a violent stimulation made directly on the nerve-centres, or indirectly through the peripheral nerves, whereby the harmony of action of the great nervous centres, more especially of the sympathetic ganglia, and through them of the various organs of the body, becomes deranged. It is essentially a depression of nerve-force, and bears in effect the same relation to the nervous system as syncope to the vascular.—CONNERY.

Black Eye.—There is nothing to compare with the tincture or strong infusion of capsicum annuum mixed with an equal bulk of mucilage or gum arabic, and with the addition of a few drops of glycerine. This should be painted all over the bruised surface with a camel's-hair pencil and allowed to dry on, a second or third coating being applied as soon as the first is dry. If done as soon as the injury is inflicted, this treatment will invariably prevent blackening of the bruised tissue. The same remedy has no equal in rheumatic stiff neck.

Dislocation of Ulnar Nerve.—Dislocation of the ulnar nerve at the elbow is a comparatively rare affection, occurring independently of fractures or dislocations of the bones of the elbow, and may result from direct violence, or from muscular effort or violent flexion of the arm at the elbow, causing laceration of the fascia which holds the nerve in its groove at the back of the inner condyle of the humerus. The symptoms resulting from this injury—pain, tingling in the parts supplied by the ulnar nerve, and a certain amount of disability of the elbow—are usually more marked immediately after the injury, but the symptoms usually become less marked in a short time, in many cases very little permanent disability seems to follow, the nerve accustoming itself to its new position. Very rarely a neuritis is developed. In view of the possibility of the development of a neuritis, it seems wise to replace the dislocated nerve and fix it in its normal position as soon as possible after the injury. The most satisfactory method of securing the nerve seems to be that practised by Mr. MacCormick, who exposed the ulnar nerve, and having made a bed for the nerve by dividing the fibrous structures behind the inner condyle of the humerus, fixed it in its usual position by two kangaroo-tendon loops passed through the inner margin of the triceps tendon and somewhat loosely around the nerve; several sutures were also used to unite the divided margin of the fascial expansion of the triceps tendon superficial and the nerve. In all cases where the nerve was exposed and sutured in its normal position the result was satisfactory, and the dislocation did not recur, and in no case is it recorded that neuritis developed in the nerve as a result of operative treatment.—WHARTON.

Ozæna.—

Pure glycerine	70 grammes
Borax	20 grammes
Distilled water	30 grammes

S.—Use as a nasal spray two or three times a day.

A CASE OF CORTICAL HEMORRHAGE WITH RUPTURE INTO A LATERAL VENTRICLE.

By H. A. ROYSTER, A.B., M.D.,

RALEIGH, N. C.

THE following case, which occurred during my term in the medical service of Mercy Hospital, Pittsburgh, is deemed worthy of record. It possessed some anomalous features of interest, made clearer afterward by the autopsy.

Mrs. Louisa L—— was picked up on the streets in convulsions and admitted to the hospital, on March 22, 1895, with no history except the statement from a man, who came with her, that she was about sixty years of age, and that she had had these "spells" before. (As will be seen, this was rather misleading than helpful for the purposes of diagnosis.) Condition on admission: Deep coma; stertorous breathing; cheeks flapping evenly, and mouth not drawn; froth on lips and a little blood at corners of mouth (found subsequently to have been due to previous efforts at separating the jaws with a spoon); face pale; no especial odor of the breath; pupils equal, at first contracted, then dilated; head and eyes strongly deviated to the right; moves left leg but not the right, and the right arm seems a trifle rigid; pulse very irregular and weak, becoming fuller afterward—"hard arteries;" second pulmonic sound accentuated, but no murmur; temperature in right axilla, 96.2° F., in left axilla, 97.4° F. Analysis of a small quantity of urine showed some phosphates, no albumin, no sugar. A diagnosis was made of cerebral hemorrhage on the left side of the brain in the motor region of cortex for arm and leg. Death occurred forty-five minutes after admission.

The autopsy, by Dr. J. W. Boyce, revealed an extensive cortical hemorrhage on the left side, involving the leg and arm centres, with rupture downward into the left lateral ventricle. The ventricle itself was filled with clots, and there were points of minute hemorrhages in its walls.

The diagnosis of this case was based upon three important observations, to which particular attention will be called. Two of these symptoms, at least, were somewhat at variance with authoritative statements on the subject.

First, there was a difference of temperature between the two axillæ, the temperature of the paralyzed side being 1.2° lower. To insure accuracy, three different thermometers were used, allowed to remain seven minutes in each axilla, and the mean temperature taken. These observations were made within an hour after the attack. No explanation could be offered for the anomaly. Usually, when any difference is noted, the paralyzed side, owing probably to vaso-motor paralysis, is distinctly warmer just after the attack, becoming after some days or weeks of the same temperature as the opposite side, or colder, as atrophy takes place.[1] This difference of temperature between the two sides in apoplexy seems to be rarely looked for, and even then not always found. References to it in medical literature are extremely rare. Most of the text-books have ignored it completely, their authors possibly regarding it as either of little value as a diagnostic sign, or unworthy of any notice at all. Edes[2] mentions a case of crossed hemiplegia reported by Johnson, where the temperature was a degree higher on the paralyzed side of the body, and, also, one (exact location of lesion not stated) reported by Allbutt with a difference of 1.6°. With these two exceptions, no cases in which this phenomenon had been noted, were found in an extensive search among the writings of many authorities.

[1] Edes: Pepper's System of Medicine, vol. v., p. 937.
[2] Loc. cit.

The second point considered in the diagnosis was the conjugate deviation of the head and eyes, an observation commonly made and certainly one of great importance. There seems to be no perfectly constant relation between the lateral inclination and the half of the brain affected, though, in most instances, the eyes are turned toward the injured side, *i.e.*, they look toward the lesion and away from the affected side of the body.[1] In the case under consideration the condition was just the opposite, the head and eyes being directed toward the right (the paralyzed) side. Ferguson[2] has reported a case in which the patient presented conjugate deviation toward the paralyzed side, and which he accounted for by the fact, found at the autopsy, that the fibres for the head and eyes in the internal capsule were not involved. The exact clinical significance of conjugate deviation has apparently not been determined. Landouzy considers it to be chiefly connected with a lesion of the lower temporal lobe; Osler associates it with cortical lesions; while Musser regards it as one of the diagnostic symptoms of hemorrhage into the ventricles.

A third observation of interest was the rigidity of the arm on the paralyzed side. The true meaning of this condition did not suggest itself during the investigation of the case, and it was not until afterward, while studying the subject, that my attention was called to it. Strümpell[3] says: "In contrast to the usual laxness of the arms and legs during the apoplectic coma is the tonic rigidity sometimes seen in the extremities, particularly on the side opposite to the hemorrhage. This symptom seems to be especially, although not exclusively, connected with a bursting of the escaping blood into a lateral ventricle."

In regard to the source of the blood when hemorrhage takes place into a ventricle, Osler states that it rarely comes from the vessels of the plexuses or from the walls of the ventricles. Almost all the cases of ventricular hemorrhage he has seen in adults were caused by a rupture of blood in the neighborhood of the caudate nucleus. According to Hughlings Jackson, ventricular hemorrhage is only occasionally found. When it does occur, the blood, he says, breaks through, in the vast majority of cases, from the corpus striatum or the optic thalamus, and there is usually a convulsion followed by profound coma, coming on after the hemiplegic seizure. In such cases a grave prognosis is always to be given.

323 WEST MORGAN STREET.

A CASE OF TRAUMATIC NEURASTHENIA.[4]

By CHARLES E. NAMMACK, M.D.,

SURGEON OF POLICE, NEW YORK CITY.

PATROLMAN G——, thirty-one years old, United States, an athlete, who, previous to his appointment to the police force, had been a gymnasium instructor, was assigned to duty October 12, 1892, at Union Square, during the passage of the Centennial parade. A fire engine weighing several tons, and drawn by three horses abreast, formed part of the pageant. The horses took fright at the dense crowd of spectators, and the driver lost control of them. They dashed toward the people, and Patrolman G——, realizing the great danger, sprang for the bridles, and succeeded, by an almost superhuman effort, in stopping the terrified animals within a few feet from the closely massed on-lookers. He was the hero of the hour with the press and the public, and was next day promoted to the grade of roundsman in recognition of his bravery. He sustained no immediate physical injury, but received a profound

[1] Strümpell: Text-book of Medicine, p. 729.
[2] Alienist and Neurologist. [3] Loc. cit.
[4] Patient presented before the New York Neurological Society, November 5, 1895

psychical shock, the symptoms of which were at first swallowed up in his naturally great joy at the success of his brave effort. One week later, he was obliged to consult his family physician on account of a severe pain in the chest. He was treated for two months without relief, and then went to Dr. Loomis, whose diagnosis was strain and shock, and who ordered him absolute rest. In the spring of 1894, he consulted Dr. C. L. Dana, who advised him to go to Germany for hydropathic treatment. He accordingly obtained leave of absence, went to Europe, and saw Dr. Leyden, of Berlin, who sent him to Thalheim. He remained abroad from June, 1894, to October 12, 1895.

Patient states that he was perfectly well up to the date of the incident first referred to. He is not aware of any hereditary nervous taint, nor of any family tuberculosis. He has never been rheumatic, syphilitic, or alcoholic. He has enjoyed rest and freedom from anxiety since his nervous shock to a degree unknown to other similar sufferers who have a prospective claim for damages against somebody, because the commissioners of police have kindly allowed him ample time to recover, with full pay therefor. He remained on duty, despite the initial traumatic strain, for some time after the occurrence, and until the development of other symptoms. Of the latter, the first noticed was a diminished power of persistent mental and physical application. Then developed a nervous irritability, and although his promotion had relieved him of the monotony of continually patrolling the same post, he found it impossible to take up his new duties with any vim. Mental exaltation became marked, and the re-iteration of the story of his heroism worked him up to a pitch of excitement foreign to his temperament. Insomnia became most distressing. Pain, except that in the chest, was not severe. Hyperæsthesia and paræsthesia were not noticed. He did not observe any diminution of vision, hearing, smell, or taste. His principal subjective symptoms were (1) pain over the heart on exertion, with (2) dyspnœa; (3) weakness in the legs; (4) profuse sweating; and (5) insomnia.

Examination, October 23, 1895, Three Years after Accident.—Pain and temperature sense normal. Tactile sensibility slightly impaired. He cannot distinguish pencil-point from end of finger. Pain conduction is not delayed. Hyperæsthesia is wanting. Examination of the visual fields, by Dr. Leroy Pope Walker, shows decided contraction of each, with the existence of the shifting type (Verschiebungstypus) of contraction, due to the fact that the peripheral portions of the field speedily become fatigued. Color perception is fairly good. There is no motor weakness, and there are no abnormal pupillary reactions. Hearing is not diminished, but hyperacusis is shown by patient's inability to listen to band concerts, which he formerly enjoyed. Smell and taste are not affected. Pharyngeal reflex is normal. Station and gait are both good; no Romberg symptom; some tremor of hands, but none of the face, tongue, or eyelids. Dynamometer: Right hand, 75; left hand, 70, but grows weaker with each successive test, showing that the muscles are easily fatigued. Knee-jerks are slightly exaggerated. The skin does not perspire freely at this examination, nor is it unduly dry. Pulse, 96 sitting, 104 walking, and 114 after walking two thousand four hundred feet in twenty minutes, which is as fast as he is able to go. Pulse on the two sides was synchronous, and the neuralgic cardiac reaction of Dana could not be demonstrated. Respirations, 24. Temperature under the tongue, 99° F. Heart action weak; no enlargement; no valvular disease. Patient complains of cold extremities, and of flashes of heat followed by local flushings. Slight irritation of skin leads to persistent redness, but no actual dermographia. Appetite, stomach, and bowels are normal, but his weight has fallen from two hundred and twenty to one hundred and seventy-five pounds. Micturition is not vigorously performed, the stream escaping without any force, and needing a straining effort at the end to evacuate the bladder. Urine is free from albumin, sugar, casts, or excess of phosphates. Sexual desire is weak, but power is preserved, although satisfaction in the act is lacking, being replaced by an augmentation of the nervous irritability.

The diagnosis in this case lies between traumatic neurasthenia, traumatic hysteria, and simulation. The last was excluded by the absence of motive therefor, absence of striking symptoms, and absence of efforts to exaggerate existing slight symptoms. Hysteria was excluded by the absence of anæsthesia, or other stigmata of hysteria, such as paralysis, contracture or spasm, and absence of paroxysmal phenomena. Although the case has now continued over three years, improvement has been slowly progressive, and the patient has had the benefit of skilful treatment at home and abroad. He has had none of the vexations and excitement incident to medico-legal cases of this character. His own observation of his case has given him the opinion that hydrotherapy has been of more benefit than any other therapeutical procedure.

CASE OF DIPHTHERIA TREATED WITH ANTITOXIN.

By W. V. GAGE, M.D.,

McCOOK NEB.

GLENN H——, male, aged eleven. The case was first seen October 26, 1895. The child then had a pulse of 120; temperature, 104° F. The throat was congested and red; tonsils swollen; faint bluish film on both tonsils. No diagnosis made at the time.

October 27th.—Pulse, 112; temperature, 102° F.; patches distinctly formed, yellowish-gray in color. No diagnosis was made, but in view of the possibility of it being found to be diphtheria I wired to Omaha for antitoxin serum.

October 28th.—There is a patch on each tonsil well formed, thick, dense, and adherent; pulse, 110; temperature, 102° F. At 10.15 A.M. a diagnosis of diphtheria was now made, and an injection of antitoxin was given, one-half of the contents of the vial, in anterior surface of each thigh. 11.30 A.M.: Pulse, 88; temperature, 99.6°. 12 M.: Pulse, 88; temperature, 99.3°. 2 P.M.: Pulse, 88; temperature, 100°. 4 P.M.: Pulse, 104; temperature, 100°. 7 P.M.: Pulse, 90; temperature, 96.5°.

October 29th, 8 A.M.—Pulse, 84; temperature, 97.8°. 2 P.M.: Pulse, 88; temperature, 99.7°. 8 P.M.: Pulse, 84; temperature, 99°.

October 30th, 9 A.M.—Pulse, 80; temperature, 98.5°. 2 P.M.: Pulse, 80; temperature, 97.8°. 6 P.M.: Pulse, 76; temperature, 96.8°.

October 31st, 10 A.M.—Pulse, 78; temperature, 97.8°. 5 P.M.: Pulse, 84; temperature, 98.1°.

November 1st, 10 A.M.—Pulse, 84; temperature, 98.5°.

The child recovered without complications, except a subnormal temperature on the first, third, and fourth days, when strychnine and brandy were exhibited.

Two cases of diphtheria in this town terminated fatally a few days prior to the occurrence of first symptoms in this case.

An Immortal Item.—About once a year an item, regarding a report to the British Medical Association on the relative longevity of drinkers and abstainers, goes the round of the medical press. The fallacy of the figures giving a longer life to habitual drinkers than to total abstainers has been repeatedly exposed, but the item lives on, to the consolation and encouragement of all indulgers.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRADSHAW LECTURE AT THE COLLEGE OF PHYSICIANS—NEW VASO-DILATORS—CLINICAL SOCIETY — SUPRA-PUBIC OPERATIONS — INTUSSUSCEPTION THROUGH MECKEL'S DIVERTICULUM—FRAGILITAS OSSIUM—DRUGS FOR CEREBRAL TUMORS—MEDICAL SOCIETY—EXHIBITION OF CASES—"A DOCTORS' WAR" —"RETURN CASES" FROM FEVER HOSPITALS—EPIDEMIOLOGICAL SOCIETY—MEDICO-CHIRURGICAL DEBATES—POSTURE DURING ANÆSTHESIA—ABERDEEN UNIVERSITY—CARLYLE'S DYSPEPSIA.

LONDON, November 15, 1895.

THE Bradshaw lecture at the Royal College of Physicians was delivered on Tuesday (12th) by the Downing Professor of Cambridge, Dr. Bradbury, who devoted it to introducing to the profession some new vaso-dilators which he has been investigating. The effects of nitro-glycerine and some other nitro-compounds are powerful and too transient, and a search has been made for other medicines to replace them, but hitherto with little success. Dr. Bradbury, therefore, determined on renewed research in this direction, and gave an account of his work. The alcohol nitrates were the most promising, but he also examined those of the sugars, starch, cellulose, etc. The bodies which seem most likely to prove of practical use are erythrol tetranitrate and manitol hexa-nitrate, and both act similarly to nitro-glycerine, but are weaker, and their effect is more prolonged. The action does not begin so soon as that of the other nitrates, but lasts longer. Obviously such a medicament may be of considerable service, and it is possible that "high tension," to which some attach so much importance, might be controlled for a certain period by a drug having such influence. But whether, as was hinted, tension could be thus kept permanently reduced without ill-effect is a point that demands full consideration before thoughtful practitioners will care to resort to such a method of treatment. At present no ill-effects have followed the administration of these nitrates, but caution is evidently needed, and it is to be hoped that they will not be resorted to by routine, especially as Dr. Bradbury will continue his researches. We may safely wait until the pharmacological and therapeutical properties of these nitrates are more perfectly determined, and the limits within which they may be properly given indicated. The erythrol nitrate Dr. Bradbury employs in a solution of 1 in 60. The manitol nitrate, one per cent. The dose of the former is one drachm in one ounce of water, of the latter 1½ to 2 drachms in water. The solutions are stable and unirritating. I would suggest that both solutions should be of the same strength, and one per cent. is at present the favorite for solutions, to which it is conveniently applied. The relative potency of drugs is more easily remembered and more important to prescribers than the strength of pharmaceutical preparations.

At the Clinical Society the first subject was supra-pubic prostatectomy, *à propos* of two cases by Mr. Moullin. In one a calculus, about the size of a penny, filled the pouch; in the other there were eighteen small calculi worn by attrition. In each case there was a good deal of upgrowth of the prostate, which was removed and the route made as level as possible. There was no constitutional disturbance in either case, and union was aided by an instrument, similar to a double truss, to keep the deep surfaces together. Mr. Buckstone Browne considered that removal of the prostate greatly increased the risk, but Mr. Moullin held that ablation of the middle lobe, if the urine remained acid, did not add much to the risk, and he was supported by Mr. Golding Bird.

A case of intussusception through Meckel's diverticulum was then related. After this came a curious case of fragilitas ossium, with a record of several spontaneous fractures, in all of which, except one, firm union had occurred. In that one (the femur), after unnecessary violence at the hands of a bone-setter, no union took place. Later, two of the united fractures became again disunited, and one of them became the seat of sarcoma. Some more or less similar cases were mentioned, but none in which disunion had taken place after years of union.

That drug treatment could cure a cerebral glioma would seem to be an untenable proposition, but Dr. Althaus related a case in which he believed this had occurred, and was a clear reply to the therapeutic nihilists who did not know how to use remedies. He admitted it was the only case he had heard of. The diagnosis of tumor seemed clear, but the question whether it was syphilitic was naturally raised. Both Dr. Althaus and the usual attendant disbelieved this, and could find no trace of such infection. Still we know how accidental infection may sometimes occur and leave hardly any trace, while we have no evidence that drugs can influence other cerebral growths. The treatment was by mercury and iodide, and the response was rapid, but several relapses occurred and eventually complete recovery. Of course it cannot be said to be impossible for drugs to influence non-syphilitic growths. Mercury and iodide would perhaps be the most likely to do so, but there is such a lack of evidence that doubts are only natural. Dr. Wilson related a remarkable case in which it was thought a cerebral tumor or deposit, probably tubercular, was present in a boy of twelve. He was treated with perchloride of mercury and iodide, but steadily got worse and was sent to the seaside, on the assumption that it must be tubercular. After four or five months he began to improve, and ultimately got quite well. In some doubtful cases of disease of the tongue or œsophagus we now and again see great improvement follow mercurial treatment, though later on there is renewed activity and malignancy is established. Still, perhaps we have been too hopeless and must, at any rate, give our patients the benefit of any doubt.

The first clinical evening for the session at the Medical Society was on Monday, when some interesting cases were on view. There was a man of twenty-five who had been treated with supra-renal extract for Addison's disease. He recovered strength enough to go to the seaside, but relapsed. The treatment is to be resumed, and will show whether the improvement was due to the extract or to one of those remissions which so often occur in this disease. Another case was mentioned in which improvement for a time occurred, but ultimately the usual course was resumed until death.

A man of forty-nine was shown who had been operated on for naso-pharyngeal growth, the upper jaw having been detached and tilted out of the way to make room and replaced after removal of the tumor. The right carotid had also been exposed so as to be prepared for severe hemorrhage, but this proved to be unnecessary. Mr. Moullin had performed a similar operation, but instead of exposing the carotid, did a preliminary tracheotomy. Mr. Walsham preferred obtaining access by dividing the soft palate and removing part of the hard palate, and Mr. Wallis advocated this less serious operation. The last-named surgeon showed a man for whom he had wired a fractured patella with an excellent result, and he also exhibited a wired patella met with in the dissecting-room which showed how capital union may follow this operation.

Mr. Swinford Edwards had present a patient who had fallen from a third-story window on to some railings. A terrible wound in the lumbar region, laceration of the kidney, and severe hemorrhage, to say noth-

ing of broken ribs, resulted. The injured kidney was removed and the man recovered.

Other exhibits were congenital imbecility with deficiency of chest-wall and heart disease, periostitis of tibia, spina bifida occulta, postero lateral sclerosis, etc.: altogether an interesting series.

London, November 22, 1895.

It seems we are in for another expedition to Ashantee, which, like the last, will be essentially "a doctors' war." A day or two ago it was hoped an arrangement would be made, but some troops and stores have already been embarked and more will quickly follow. *The Lancet* has engaged a special correspondent to go out who has experience of the climate, so we may expect reliable information in due course. But what a slur on our boasted civilization, it seems, that its resources must be directed to the massacre of the uncivilized. And "a doctors' war" is likely to incur sad losses among the white troops.

We have had much talk of late about "return cases" from our infectious hospitals, and the subject has been appropriately brought before the Epidemiological Society. These are cases that occur in a family soon after the return of a member who has been in such hospital. The medical officers of health and the superintendents of the hospitals who were present did not dispute that such cases occur. The important question would seem to be how soon a patient ceases to be infective, and differences have been noticed. Some think a properly disinfected convalescent may safely return earlier than others suppose. Scarlet fever seems to linger longer than some other diseases of the class, but the differences of desquamation deserve consideration.

A recent report of a sub-committee of the Asylums Board shows 106 "return" cases in the two years 1893 and 1894. During those two years 30,227 patients, who had had scarlet fever or diphtheria in those hospitals were discharged. This gives one "return" for every 285. The conclusion of the committee is that no appreciable number of infections have taken place from the discharged patients. But this conclusion may be dissented from on several grounds. The figures are compiled from the statistics of only half the number of officers of health, and 93 cases seem to have come from only five districts. It seems to me, too, that other important points should be investigated, and that this is a case in which an eminent statistician might extract important lessons from the figures, to be confirmed, perhaps, by examination of more extensive numbers. The Epidemiological Society was an excellent one to which to submit the question, and Dr. T. W. Thompson, who read the paper, is an inspector of the Local Government Board, which office should give him experience in such matters. He admitted that a certain proportion of "return cases" may at times be due to carelessness in discharging patients or to some other fault of administration, whether on the part of the hospital officials, or of those responsible for the disinfection of the patients' homes and effects. At the same time he thinks some more obscure factors are probably at work which are bound up with the natural history of scarlet fever. Clearly there is room for the investigation of the epidemiologists.

The Royal Medical and Chirurgical Society will have four special debates this session, induced, doubtless, by the success of the plan when tried last year. The first of these will be on possibilities as to latency of parasitic germs in animal tissues in hydrophobia, erysipelas, syphilis, leprosy, ringworm, tuberculosis, and other diseases. If that should not be a wide enough field for discussion, I hardly know what would. Mr. Jonathan Hutchinson is president this year, and will, I hear, in opening the debate, endeavor to define its aim and scope. I hope he may be able to restrict the other speakers to the limits he may lay down, or they may wander over wide, unfertile fields.

At this same society the adjourned discussion on posture during anæsthesia, which I have already mentioned, came off last week. Though not without interest, the debate seemed hardly of sufficient importance to have called for an adjournment. The paper read at the previous meeting was by Dr. Hewitt and Mr. Shield. The authors laid down a number of propositions as to the effect of posture, most of which were familiar and few of which were controverted. The paper was a long one, and dealt fully with the subject. There was really no time left for discussion: hence the adjournment. An obvious result of adjourning is that the speeches take too much the character of prepared articles, and have therefore less life and naturalness than when made on the spur of the moment. Drs. Hewitt and Shield had dealt with: 1, The posture of the head in relation to the trunk; 2, the influence of gravity on the circulation and respiration; 3, the several surgical postures; 4, the posture after the operation; as to which it was recommended, in the absence of contra-indication, to at once turn the patient on the side. Mr. Gill thought some of the dangers named by the authors were really very slight, *e.g.*, that in the supine posture, with the head extended, it was very rare for blood to find entrance into the larynx.

At the adjourned meeting Dr. Spicer advocated operating in the throat in the erect posture, to facilitate illumination. In these cases Mr. Spencer Watson thought local anæsthesia should be trusted, and Sir W. Dalby talked of its being "common knowledge" that he had long removed adenoids in the sitting posture. The "common knowledge" is scarcely bounded by his practice, though perhaps it may to some extent embrace it.

Dr. Sansom, in a somewhat tedious speech, evidently got up for the occasion, referred to his own work on the subject, and said he knew no condition of cardiac disease which by itself forbade anæsthetics, and it appeared to him that strong hearts were more likely to succumb than weak ones. He urged that both circulation and respiration should be watched; he regarded the recommendations of the Hyderabad commission as dangerous.

Mr. Woodhouse Braine was in favor of anæsthetizing the patient in bed and then removing him to the operating theatre, in opposition to the authors, who had advised anæsthetizing on the table.

Dr. Leonard Hill, speaking as a physiologist, attributed chloroform shock primarily to dilatation of the heart, *i.e.*, cardiac failure, after which respiration may continue, and this he called "post-mortem respiration." The only resource was rhythmical compression of the heart to force the blood out. This did not occur in ether narcosis. Failure of respiration was not dangerous so long as the heart acted well. He described another state due to changes in the splanchnic vaso-motor system. Great dilatation here leads to collapse by the withdrawal of the blood from the heart. In this condition pressure on the abdomen or inversion might be useful, but could only make matters worse in the former state. The tone of the vaso-motor system he found varied in animals just as it does in man.

Dr. Bowles referred to experiments he had made forty years ago, said pulling the tip of the tongue did not affect the back of it, urged the necessity of accurate dosage, and declared that so-called sthenic apoplexy is only incipient suffocation, and that its stertor and other symptoms all disappeared on turning the patient on his side. This last statement is important if true. The anæsthetists had much to say, but showed considerable differences of opinion. These specialists seem only second in acute differences to the dermatologists, who at present are the most remarkably "happy family" in the profession.

Scotland has shown that it can take on considerable enthusiasm. The quarter-centenary of Aberdeen Uni-

versity gave occasion to a celebration rather unusual so far north. For enlargement of the buildings the late Dr. Charles Mitchell, of Newcastle, had contributed munificent sums, amounting in all to some £30,000. The Government added as much, and the Town Council some £10,000. Day after day teachers, students, friends, and donors joined in various plans of celebrating the quarter-centenary and the opening of the new buildings. Of course a number of honorary degrees—D.D.'s and LL.D.'s—were conferred. More interesting to observe was the closing fancy-dress, torchlight procession in which some seven hundred students took part. This seems a triumph for Scottish learning and enthusiasm.

Carlyle was not exactly an amiable man. Most of his disagreeable ways have been put down to dyspepsia, which no doubt troubled him. No one need wonder that it did after reading a revelation lately made by Sir R. Quain, who at one time attended him and who says, "The only remedy which I could get him to take was gray powder. Gray powder was his favorite drug when he had that wretched dyspepsia to which he was subject, and which was fully accounted for by the fact that he was particularly fond of very nasty gingerbread. Many times I have seen him sitting in the chimney corner, smoking a clay pipe and eating his gingerbread." I question whether this revelation, unimportant as it is, may not set others parading the habits of distinguished patients, and I hope Sir Richard is not growing garrulous.

THE POLICY OF REDUCED FEES FOR INSURANCE EXAMINATIONS.

To the Editor of the Medical Record.

Sir: In the news column of the Medical Record, November 16, 1895, occurs an announcement that one of the leading life insurance companies of your city has proposed a new schedule of fees for examinations for insurance, and that the country doctor is protesting vigorously against the reduction. The first part of the statement is true, for we are in receipt of a letter informing us of the change. The second part is equally so, for at least one county medical society of which I have knowledge has entered its protest. Your article adds that such matters are pure business. That is the plain fact of the matter, for if the leading insurance companies, or some of them, are satisfied with three-dollar examinations, why should the doctors object? Some assessment companies and fraternal associations have always been satisfied with two-dollar examinations. If the leading companies, or any one of them, expect to get five dollars' worth of time, care, and information for $3, as a matter of pure business, will they get it? In country practice, and even in towns of considerable size, the bulk of the examinations are for policies of $3,000 or less. Policies for $5,000 are less common. Examinations for $10,000 are not numerous; and examinations for $25,000 are exceptional.

Such being the case, one of the leading companies of New York City has reduced a considerable number of its medical examiners to three-dollar men. My experience is that when a company's agent gets into a new field, he not infrequently calls on his company's appointed medical examiner to get what information he can, and he frequently obtains valuable information from this source. In a matter of pure business, when an agent of a three-dollar company calls on a three-dollar examiner, who also examines for a company which pays him $5, what will be the value of the information the agent gets?

Again, the examinations for the smaller amounts are made for policies on the lives of mechanics, artisans, clerks, etc., who have not studied the subject of insurance and will not sign an application for insurance until they consult some one of their friends. The family doctor is most frequently the one consulted. He is especially asked what company is the most desirable. A doctor who is sufficiently appreciated by one of several companies for which he examines to receive a fair fee for his services, is also governed by the business of the transaction, for with him, too, "business is business;" so that in the end the reduction of fees may not be as good a business policy as it at first appears.

Bangor, Pa.

New Instruments.

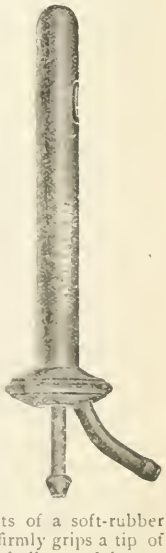
A DOUBLE-CURRENT RECTAL IRRIGATOR; REPORT OF CASES.

By Robert Coleman Kemp, M.D.,

New York City.

Surgeon to the Church Infirmary and Dispensary.

I should preface this article by stating that this irrigator is made either of soft or of hard rubber. I shall first describe the latter. This instrument consists of a hard-rubber tube, with conical end, shape of a rectal bougie, and about five inches long. It is closed throughout except at two points. On the upper surface of the tube, just posterior to the tip, is an opening for the entering current to pass into the bowel. On the lower surface, about half an inch posterior to this, is a somewhat larger opening for the passage of the return current. The outer end of the tube is closed by a rubber cap which screws in place. This is perforated by a longitudinal tube, the outer end of which is furnished with a tip for the attachment of the tube of a fountain syringe. The inner end of this longitudinal tube screws into the tip of the main tube (within), and is arranged to conduct the entering current into the bowel through the upper opening. The return current passes through the lower opening, through the lower part of the main tube, and down into the bedpan through a short curved tube which is screwed into the lower part of the cap. This curved tube has an attachment for a soft-rubber tube to carry off the outflow. The instrument is so made that the calibre of the return current is greater than that of the entering. The irrigator can be readily taken apart, cleaned, and disinfected. The hard-rubber instrument is made in four sizes, by the Ford Instrument Company. No. 1, external diameter of the tube, ½ inch; No. 2, ⅝ inch; No. 3, ¾ inch; No. 4, ⅞ inch.



For general use No. 2 is the most practical. The larger sizes are only applicable for some special case, as washing out fecal accumulations, etc.

I should state that the first instrument that was made was ordered by Dr. William H. Thomson, for a special case, at the Ford Instrument Co., about seven months ago, after a suggestion and model made by me for him. This was of hard rubber and size No. 2.

The soft-rubber irrigator consists of a soft-rubber tube five inches long and which firmly grips a tip of hard rubber. This tip is partially hollow and has an opening above, which lies closely against the upper opening of the soft tube. A small longitudinal hard-rubber tube passes through the centre of the soft tube

and screws into the hollow tip, and through this central tube the entering current passes into the tip and up into the bowel. There is an opening for the return current below, as in the other instrument; but the return current passes out on all sides of the central tube, so even if the sphincter contracts on the soft tube the escape will not be prevented. The outer cap is of hard rubber perforated for the longitudinal tube, and with the curved collecting-tube as in the other instrument. This cap fits firmly against the soft tube. The external diameter of the soft tube is 5/8 of an inch, or No. 2. It can be ordered in other sizes if desired. The soft tube can be replaced at a trifling expense, when worn out. The hard tube is unquestionably more durable, but in some cases somewhat more painful to use. The soft tube can also be readily taken apart and disinfected.

For use in the lower part of rectum, the semi-oblique (sitting) posture, with the openings just inside the sphincter. For higher up, the dorsal position, or hips slightly elevated. The height of the current can also be regulated by douche-bag, and by checking the return current. It will be found, at times, that at the commencement of the irrigation the mucous membrane of the bowel will stop the openings, until there is a small amount of fluid in the bowel. Slightly turning the instrument, or pushing it in slightly and then withdrawing it, will free it from this obstruction. In introducing the irrigator it should be well lubricated and inserted gently. In high irrigation I generally insert it the full length (five inches) up to the cap. I shall briefly report a few cases:

Case I.—W. M——, male, aged twenty-eight; chronic cystitis, strictures, nocturnal irritability of bladder, one of the worst symptoms. Under cocaine, meatotomy, internal urethrotomy of strictures at 2½ and 3½ inches up to 32. Stricture at 6 inches, advised operation and bladder drainage. Patient refused. Gradual dilatation to 32. Later No. 30 as regular size. Persistent irrigation of bladder, alkalies, suppositories, etc. Nocturnal irritability continued in spite of all treatment. I suggested to patient a trial of the continuous hot current just before retiring, using about a gallon, as hot as could be borne. He reported almost immediate relief, only urinating thereafter once or twice during the night, when previously he had done so every two hours.

Case II.—W. B.——, male, aged thirty-one; chronic colitis; enlarged spleen (malarial). History dated back for three years. The patient had had no medical treatment for splenic enlargement, and had been taking salol, bismuth-subgallate, and high injections of boric for the colitis on his own responsibility. About every two weeks there was an acute exacerbation of the colitis with considerable mucus and a little blood. The margin of the spleen extended one and a half inch to the right of the umbilicus and one and a quarter inch below. The enema with the soft tube always exhausted the patient, and did not seem satisfactorily to remove the mucus, etc.

Treatment.—Warburg tincture without aloes, alternating with quinine and ginger; boric injections with the double-current irrigator. The spleen in five weeks contracted one and a half inch horizontally and vertically, and the colitis improved radically, and there was no exhaustion following use of the instrument.

Case III.—G. B——, male, aged thirty-one. Acute uræmia. Fecal accumulation in the sigmoid. I was called in by the family physician to see this case. Patient was in collapse; nearly complete suppression of urine; a large accumulation of fæces in the sigmoid. Calomel, compound jalap, salts, etc., had been given. Enemata with the long, soft tube had been given a number of times with no effect, as none could be retained. With hot normal salt solution the fæces were washed out without difficulty, the irrigation being continued for some time after. Stimulants were occasionally added to the irrigating fluid. The patient reacted nicely and the kidneys also acted. The case, however, died several days later, of nephritis. I cite this case as several conditions may be of interest.

Case IV.—B——, aged sixty-four, male. Retention of urine. I made a number of vain attempts to pass several soft catheters, there being severe spasm at the neck of the bladder. I happened to have no other instruments at the dispensary. After using the hot irrigation for a few minutes, the first instrument tried slipped in without difficulty.

Case V.—Through the courtesy of Dr. Francis Delafield, the irrigator has recently been used at Roosevelt Hospital in a case of colitis following typhoid fever. Dr. Sumner, the house physician, has kindly furnished me with notes on the case:

A. W——, female, aged nineteen. Admitted September 28, 1895. Typhoid, mild type. Usual treatment as at Roosevelt. First hemorrhage October 12th. Drugs used, nitrate of silver, bismuth et pepsin, emulsion turpentine, strychnine, whiskey, etc.

October 17th.—Involuntary evacuations, etc. Salol and castor-oil added, also tincture opii deodorized.

October 22d.—Last hemorrhage. Involuntary defecation continued from this time on. There were ten to twelve movements a day, watery, with mucus. Temperature kept 102°–103° F.

November 5th.—Bichloride irrigation, 1 to 10,000 ordered by irrigator. Salol, castor-oil, and opium stopped.

November 6th.—Bichloride irrigation 1 to 10,000. Portions of false membrane came away with the injection. No more irrigation. From this time the diarrhœa decreased; temperature gradually fell to normal.

On November 11th there were only two voluntary stools, and on November 17th the patient sat up for the first time.

Case VI.—Dr. S——, aged thirty-eight. Patient of Dr. Charles T. Parker. Two months ago Allingham's operation on both sides for severe hæmorrhoids. Mucous membrane sloughed on both sides of rectum, there being on each side a foul ulcer two inches in diameter; bowel dark in color, highly congested; severe pain on movements; patient confined to bed. Three weeks ago irrigation with cold boric injections morning and night.

November 25th.—Examination by speculum, one ulcer entirely healed, the other half its original size, and healthy. No pain on defecation; congestion nearly disappeared. Patient attends to his profession.

Case VII.—J. H——, male, aged thirty-two. Patient of Dr. Charles T. Parker. Prostate enlarged and acutely tender. Pressure causes desire to urinate. Irritability at neck of bladder. Frequent urinations during the day, and especially troublesome at night.

Treatment.—Cold water injections, continuous current for fifteen or twenty minutes, morning and night; no other treatment. The patient writes to the doctor that at present he sleeps nearly all night, and urinates about every five hours during the day. The irrigation has been used for three weeks.

The use of the irrigator has also been suggested in rectal ulcers, pelvic inflammation (post-uterine), etc., as an adjunct to other methods of treatment.

449 Park Avenue.

Anticancrin.—The promoters of a German erysipelas serum for cancer treatment have adopted the proprietary name "anticancrin" for their product. Drs. Emmerich and Scholl could have saved themselves this trouble; clinical reports, including the records of their own tests, show that their serum possesses no special value—and, anyway, we will not need their serum in this country, as we have long had it available from domestic laboratories.—*Southern Medical Record.*

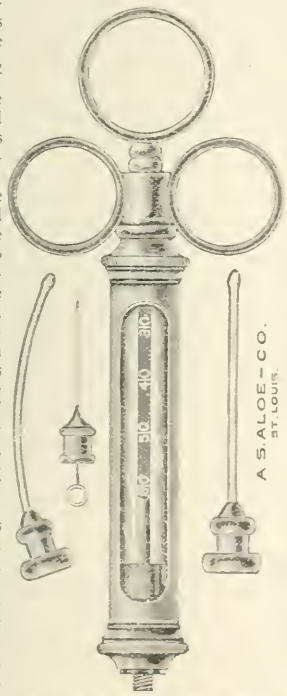
AN IMPROVED SYRINGE FOR INFILTRATION ANÆSTHESIA.

By BRANSFORD LEWIS, M.D.,

ST. LOUIS, MO.

During the past year I have been making large use of Schleich's method of producing local anæsthesia by infiltrating tissues with innocuous solutions of salt, morphine, cocaine, etc., the anæsthetic effect resulting from the method of applying the fluid rather than from the drug or drugs employed in it. It has been a source of great satisfaction to both me and the patients on whom it was used. The minuteness of strength of drug employed[1] removes every element of danger from that source, even though a large quantity of the solution be injected: and the completeness and promptness of the effect are advantages readily evident.

But I have met with one objection that has restricted the use of the method in a marked degree. It is the fact that, no matter how easily and satisfactorily it may be employed in the superficial structures, where there are no large vessels in danger of being punctured with the hypodermic needle, when one is injecting in the depths of a wound in the neighborhood of large arteries or veins, as in enucleating bubo-glands immediately above the femoral vessels, etc., the likelihood of running the needle into one of them and producing disastrous results is not a fancied one.



The Transfor[illegible] Syringe.

By means of the needles represented in the cut I have been enabled to do away with this difficulty. They are blunt-pointed, and made of German silver, so that, though of sufficient stiffness to be thrust into the connective tissues of a wound after the skin has been severed, they would not injure a blood-vessel if pushed against one.

The anæsthesia is begun, therefore, with the sharp steel needle, and continued with either of the two silver ones. The choice between the latter depends on whether a curved or straight needle is more conveniently used.

The advantages offered by this improvement have shown themselves to be eminently practical and serviceable, and, in my estimation, will advance the scope and usefulness of the method to a great degree. This instrument was made for me by "A. S. Aloe Co.," of St. Louis, Mo.

1006 Olive Street.

The Sixth International Congress of Otology will be held in London, in 1899.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 30, 1895.

	Cases	Deaths
Tuberculosis	192	59
Typhoid fever	21	8
Scarlet fever	50	1
Cerebro-spinal meningitis	0	1
Measles	167	14
Diphtheria	172	22
Leprosy	1	0

The History of a Patient Cured by Tuberculin.—In 1890, a patient suffering from phthisis, with cough, night-sweats, hæmoptysis, and progressive emaciation, came under the care of Professor Robert Koch. After fifty-two weeks of repeated tuberculin inoculations he was discharged, apparently cured. Five years later all the old symptoms returned, and in a short time he died of hæmoptysis. At the autopsy, which is reported by Dr. Adami, in the *Montreal Medical Journal*, the lungs were examined, and found to be practically healed, so far as the original lesion was concerned; that is to say, the apices of both lungs showed well-marked fibroid changes, and contained encapsuled caseous nodules. Throughout the rest of the lungs, however, a fresh process had started up, which was the cause of the patient's death.

The Publication of Patients' Pictures.—A St. Louis surgeon has been sued for $15,000 damages for the publication of the portrait of one of his patients in connection with the report of the case. The surgeon was granted the privilege of taking a photograph of the child, but the mother claims it was for his personal use, and there was no permission asked for or given that it should be published.

A Proposed Memorial to Sir Andrew Clark.—The proposal to invite medical men to subscribe for a memorial to the late Sir Andrew Clark, is meeting with some opposition from a portion of the London profession, headed by the *Medical Press and Circular*. It is objected to the plan of a general subscription that Sir Andrew Clark was a wealthy man who owed his reputation as much to the patronage of the great as he did to his medical ability, and that it "would be absurd to ask the general practitioner, who finds a good deal of difficulty in making both ends meet, to subscribe to a memorial to a man who was making £15,000 a year, and who, although immensely rich, left nothing to the London Hospital, to which he owed so much of his success." Despite the opposition, however, a sum of $15,000 has already been raised. But the project of appealing individually to each member of the profession will probably be abandoned.

Sudden Death from Cardiac Syphilis.—At a recent meeting of the Clinical Society of London, Sir Dyce Duckworth reported the case of a strongly built man, thirty-five years of age, who was walking in the street, carrying his little boy, when he suddenly fell down and expired. The body was carried to St. Bartholomew's Hospital, and was examined two days later. A very meagre antecedent history was obtained, which threw no light on the nature of the case. There was evidence of old syphilitic disease on the tongue and on the glans penis. A small gumma was found in the left lung. The heart weighed twenty-two ounces, and had firm adhesions to the pericardium, both at the apex and at the base. The right ventricle was hypertrophied and dilated. The valves were natural. The left ventricle was hypertrophied and dilated. There

was a round depression in its wall above the apex, the diameter of a shilling, covered by long adhesions. This was due to a thinning of the wall, with much endocardial thickening. A large aneurismal pouch was found behind the posterior cusp of the mitral valve. This appeared from without as a tumor growing from the base of the heart, completely covering the left auricle. Its walls were one-half inch thick, and the pericardium was closely adherent over it. On section, the muscle was found to be replaced by tough fibrous tissue, with foci of gelatinous matter. The endocardium was greatly thickened and fibrous. Microscopic examination proved it to be gummatous in nature, with patches of caseation. The smaller arteries showed signs of endarteritis. These appearances indicated plainly a recent gummatous growth at the base of the left ventricle, and a similar, but older, one near the apex of that cavity. The fact of sudden death as a frequent occurrence in cases of this nature was alluded to, and it was pointed out that these clinical features were but little known and necessarily but seldom recognized. The morbid anatomy was well understood. The speaker had collected particulars of fourteen similar cases, some of them reported in this country, but none communicated to this Society. Death occurred almost, if not quite, suddenly in eight of these cases. The disease was rare in women, only one of the fourteen having occurred in that sex. The mean age of all the patients was thirty-two years. Many of the cases appeared to have been previously devoid of urgent symptoms. In some there had been pericardial pain. It was pointed out that graver symptoms were to be expected when fibrotic changes followed on the evolution of the gummatous growths, and when they led to aneurisms of the ventricular walls. The valves were usually not involved, and hence murmurs were not to be met with as in the case of rheumatic endocarditis. The ventricles and their septum were the common sites of these growths. Tendency to fatal and sudden syncope was probably explicable by the fact that endarteritis affected the coronary arteries in part, and possibly by the occurrence of embolisms from the softening contents of aneurisms into coronary arterial branches, the ventricular walls degenerating in consequence and becoming gradually intolerant of strain. The great object was to make an early diagnosis when possible, and to seek for syphilitic concomitants in cases where there were obvious cardiac symptoms, such as palpitation, or infrequency of pulse, hypertrophy, dilatation, etc., and no signs of involvement of the valves. The treatment was to employ iodide of potassium in full doses.

The Substitution of Vaccinia Serum for Vaccine Lymph.—Drs. Hlava and Houl have investigated the immunizing and curative properties of vaccinia serum, in order to see whether, by the use of it, vaccination could not be done away with, and inoculation be made to take its place. The experiments were made by taking serum from the vesicles of calves suffering from vaccinia, and also by taking the serum from the blood of these animals. It was found that a mixture of serum, plasma, and blood, when injected into children, prevented the subsequent development in these children of vaccinia. No experiments have been made with small-pox, but it is hoped that a method may be provided by which inoculation can be made to take the place of vaccination, and thus do away with all the accidents that occur in the application of this method.

Biborate of Sodium in Epilepsy.—Since Dr. Gowers first introduced this drug as a remedy in certain cases of epilepsy, various observers have from time to time published observations on its effects. Among these are Stewart Lockie, Risien Russell, James Taylor, and Alexander in this country, Folsom and Jones in the United States, and Mairet, Féré, and others in France. The last-mentioned observer has recently published in the *Revue de Médecine* an account of an extensive series of observations of the effects of borax in epilepsy, the result of which is to show that, while in certain cases benefit is conferred by the use of the drug, in most cases the disadvantages are such as to more than counterbalance the slight benefits. Altogether 122 cases were treated, and of these 87 derived practically no benefit; but in some cases benefit was experienced. In 6 of these cases the benefit was doubtful on account of the short duration of the trial; in 7 patients amelioration was followed by relapse; and in 11 cases improvement resulted from the use of borax, but not so marked as the improvement following the use of bromides. The third chief group consisted of 11 cases in which undoubted, and in some cases remarkable, benefit resulted from the use of borax, all the more noteworthy because of the absence of benefit from bromide in large doses in some of those same cases. Full details of the treatment and its effect in these cases are given, and the tolerance of large doses of the drug in certain cases is striking. Dr. Féré next considers the various drawbacks to the treatment under the name of "borism." Intestinal troubles he found to be most troublesome—nausea, vomiting, and anorexia; but in certain cases the administration of borax in glycerine instead of in water obviated this drawback. Dryness of the skin, and redness and inflammation of the mucous membranes were also produced. Dryness of the hair also followed, and in some cases loss of hair resulted, but only temporarily. The most frequent form of skin eruption was a kind of eczema answering to the description in most particulars of seborrhœic eczema; in other cases the eruption consisted of reddish patches which desquamated; while in still another class the eruption was papular and accompanied by prurigo of varying intensity. This also was sometimes followed by desquamation. In some cases a condition of great weakness succeeded prolonged treatment, this being the result, apparently, partly of the toxic effect of the drug and partly of the anorexia which followed its use. These different effects, it may be mentioned, have for the most part been mentioned by other observers, but another much more serious result is alluded to in this paper as following the use of borax in certain cases. This is an effect upon the kidneys, giving rise to the presence of albumin in the urine, and as a rule accompanied by œdema of the face and extremities, so that in all cases in which borax is given in anything like full doses it is essential that a careful watch should be kept upon the state of the urine. In one of the cases under Dr. Féré's observation uræmia and hyperpyrexia developed and the patient died. The kidneys were found to be inflamed. The general facts in the paper indicate that, while borax is not as a rule to be compared to the bromides in regard to its efficacy in the treatment of epilepsy, still there are cases which, while intractable by the bromides, are very remarkably benefited by borax, but that the drug whenever it is given in large doses has certain disadvantages, and even dangers, which should be carefully guarded against.—*The Lancet.*

Pasteur's Will was a very simple document. It read as follows: "This is my testament. I leave to my wife all that the law allows me. May my children never forsake the path of duty, and always cherish for their mother the tenderness she so richly merits. L. PASTEUR."

The Skeleton of Paracelsus.—The bones of Paracelsus have been several times exhumed from several different places. The last and most authentic exhumation took place in 1887, and the results of an examination of the bones have been described by Dr. Aberle, of Salzburg. According to this author, Paracelsus was a dwarf, being barely five feet in height, with a skull much below the average size, deformed and thickened by the effects of rickets.

ANALYSIS OF ONE HUNDRED AND FIFTY-SIX ADMISSIONS TO THE ST. LAWRENCE STATE HOSPITAL, WITH ESPECIAL REFERENCE TO ACUTE INSANITY.

BY J. M. MOSHER, M.D.,

FIRST ASSISTANT PHYSICIAN, ST. LAWRENCE STATE HOSPITAL, OGDENSBURG, N. Y.

THE great population of chronic cases in a large public hospital for the insane misleads the superficial observer as to its possible curative functions, and overshadows the results of treatment prevailing in the few wards organized and disciplined for the application of remedial measures to patients who present prospect of recovery. The custom of including in the same figures an overwhelming number of chronic with a few acute cases, and the adoption of tables of classification which ignore the vital distinction between these two classes, vitiate statistics and result in injustice to the institution, and misapprehension as to the merits and successes of its administration.

To overcome in some measure this difficulty, the present contribution treats the admissions to the women's department of the St. Lawrence State Hospital during the last fiscal year apart from the permanent population, and seeks to establish some basis upon which to justify the methods for the relief of patients whose history and condition, when received in the hospital, lead to the hope of cure.

In order to differentiate plainly functional from organic conditions, the following supplemental table of classification has been adopted, in which this distinction is made the prominent feature :

CLASSIFICATION OF INSANITY.

a. PSYCHOSES :
- 1. Mental disorders with pronounced physical debility.
  - *a*. Acute delirium.
  - *b*. Acute stupor.
- 2. Mental disorders without pronounced physical debility. (Confusional insanity.)
  - *a*. Acute melancholia.
  - *b*. Acute mania.
  - *c*. Subacute melancholia.
  - *d*. Subacute mania.

b. PSYCHIC DEGENERATIONS :
- 1. Mental degenerations of diathetic origin.
  - *a*. Primary delusional insanity.
  - *b*. Periodic and circular insanity.
  - *c*. Recurrent insanity.
- 2. Mental degenerations with organic disease of the brain.
  - *a*. General paralysis.
  - *b*. Chronic endarteritis without senility.
  - *c*. Senile insanity.
  - *d*. Epileptic insanity.
  - *e*. Terminal dementia.

During the fiscal year from October 1, 1894, to September 30, 1895, inclusive, there were 156 admissions of women. Of these, 1 patient was a victim of the opium habit and was classified as not insane, 7 patients were classified as idiots or imbeciles, and 2 patients were admitted twice during the year. Of the 146 cases remaining, 59 were classified among the psychoses, or curable forms, and 87 among the degenerations, or incurable forms.

In the second class, that of the degenerative forms, have been included the chronic delusional manias and melancholias, the periodic forms, and the insanities depending upon organic disease. The term recurrent insanity has been used to indicate cases characterized by three or more attacks of insanity in which the fact of periodicity is in doubt. Recoveries from the recurrent attacks have not been regarded in the table of results. In the class of mental disorders depending upon organic disease, it has been found necessary to give due consideration to the various forms of chronic inflammation or degeneration of the blood-vessels. Chronic endarteritis, or arterio-capillary fibrosis, may be regarded as one of the degenerations of old age, but it has also been found as a distinct disease at a period of life in which senility could not be claimed. Several patients of this class, under sixty years of age, have presented various mental manifestations, usually with indications of dementia, and also with few or many of the physical deteriorations usually accepted as the natural conditions of old age. In a few instances these patients have so far improved as to be discharged from the hospital ; in other cases, chronicity has been positively established ; and in others death has resulted from apoplexies, or apoplectiform, or uræmic conditions. In the early differentiation of these cases, attention has been given on the physical side to organic lesions of the heart, to prominence and tortuosity of the radial pulse, prominent blood-vessels at exposed surfaces, wrinkled and attenuated cutaneous structures, arcus senilis, and changes in the bones. Although improvement has occasionally resulted to such degree that it has been possible to discharge the patient from the hospital, its temporary nature has been considered and the cases have not been included in the table of results.

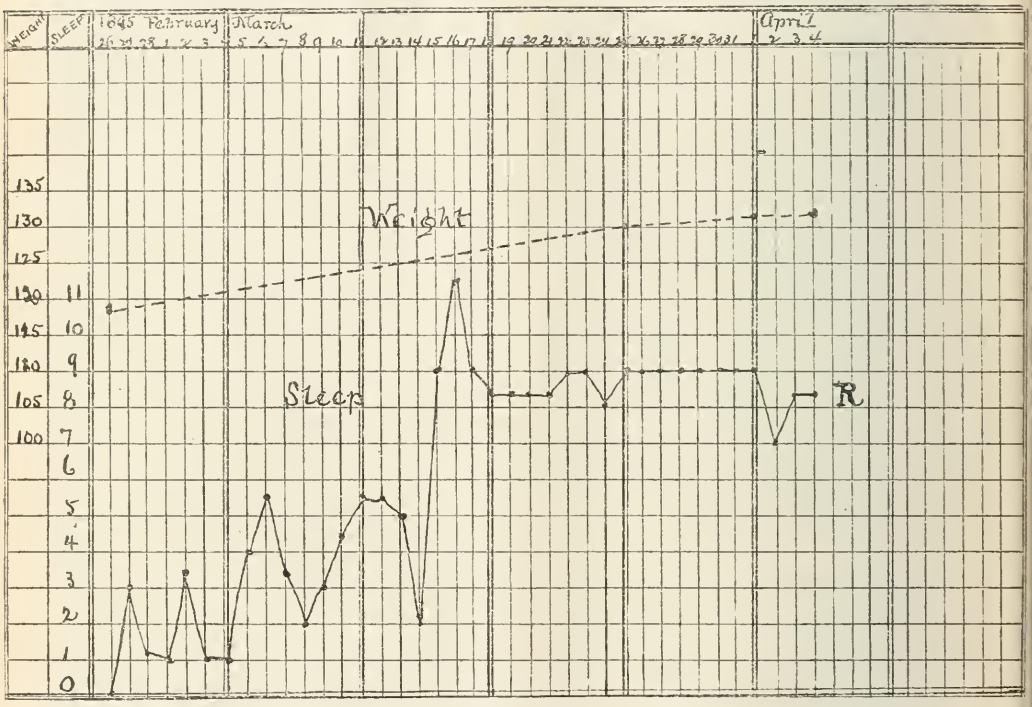
Within the limits of the present contribution consideration of the curable cases only is feasible. Of the 59 cases so classified, 37 have attained such period of development as to render the result of the disease certain ; 12 patients still under treatment are regarded as in the acute or developing stage of the disease, in whom, during the presence of the element of probability, it has been thought best not to anticipate the result. Of the 37 determined cases, 25 have recovered, 6 have died, 2 have, in all probability, become chronic, and 4 have been discharged improved. The percentage of actual recoveries is thus 67½, and the percentage of deaths, upon the whole number of recoverable cases admitted, has been slightly over ten per cent. ; upon the whole number of admissions three per cent.

Acute Delirium—Nine Cases.—The term acute delirium has been applied to cases hitherto generally described as acute delirious mania, sometimes acute delirious melancholia, but recently in several instances acute delirium. The great motor or mental excitement, whose emotional manifestations may be either depressing or exhilarating, is not considered to justify a distinction between the terms mania and melancholia in the presence of the great physical prostration of

which the delirium appears as a symptom. The differentiation of this form of mental disorder has been variously made upon 1, a pathological basis;[1] 2, a symptomatological basis;[2] 3, a diathesis;[3] 4, the generally fatal result.[4]

Dr. H. C. Wood (*loc. cit.*) draws attention to the various forms of disease comprehended by different writers under the term of acute delirium, and seeks to differentiate cases involving organic cerebral disease from those whose recovery demonstrates their functional character. He deplores the necessity of invoking the result to the aid of the diagnosis, but finds no symptoms for their differentiation, and shows especially the failure of a characteristic temperature curve, to which Regis (*loc. cit.*) attaches great importance. Between the recoverable cases defined as the "culmination of active nervous exhaustion with a psychical explosion,"[5] and the fatal cases resulting from acute periencephalitis, there were found no distinguishing signs.

and hard. The temperature attained only a moderate degree, and in no case was there marked pyrexia or hyperpyrexia unless from complication. Active hallucinations of the senses, with entire incoherence and great restlessness, were prominent in all cases, frequently showed periodicity, with intervals of calm of shorter or longer duration, during which there occasionally appeared an entire remission with approximation to a normal mental state. The short duration of the active stage and the speedy convalescence of the recoverable cases were features of the disease. To contrast with these cases the hospital can refer to the record of only one case of acute periencephalitis.[1] In this case the temperature was not elevated above that of the cases of acute delirium now under consideration, and the only symptomatological difference was the report of a longer duration of the disease before admission (one month), a fact of uncertain and indefinite value.



Case 1937.—Acute Delirium.

In the nine cases observed during the past year at the St. Lawrence Hospital there have been many points of similarity. The disease began suddenly in patients whose previous condition gave no intimation to the ordinary observer of departure from health. In the eight cases of which definite information was received, the longest duration preceding admission was two weeks and the shortest was two days. There was extreme and rapidly increasing physical prostration, generally attaining the typical typhoid state. The pulse was accelerated and weak, the tongue and mouth were parched and dirty, the bowels constipated, the abdomen collapsed and without resilience, and the skin dry

The principles of treatment of these cases were seclusion, rest, abundance of nutritious food, stimulants, and tonics. Contrary to the methods of treatment usually advocated, hypnotics were not used.[2]

The patients were placed in bed in a retired and moderately darkened room. Nurses were detailed for day and night service, and instructions were given at the outset for the administration of liquid diet, preferably milk, whenever the patient could be induced to accept it. Advantage was taken of the quiet intervals, and coercive measures were entirely prohibited, or in some instances reduced to a minimum. In one case

Blandford, Insanity and its Treatment, p. 251: "By chloral or the combination of it with bromide of potassium, sleep may be procured in the majority of cases, and in my experience, deaths from exhaustion have been greatly diminished."
Bucknill and Tuke, Manual of Psychological Medicine, 4th ed., p. 736: "Beware of Hypnotics."

only was forcible feeding with the nasal tube attempted, and the result was not thought to have justified this proceeding. The administration of laxatives was an initial procedure, enteroclysis was occasionally found of value, and stimulants and tonics were given at the earliest possible opportunity. Under favorable conditions prolonged warm baths were found to promote sleep. Convalescence was managed by properly regulated exercise and the occasional administration of electricity and massage.

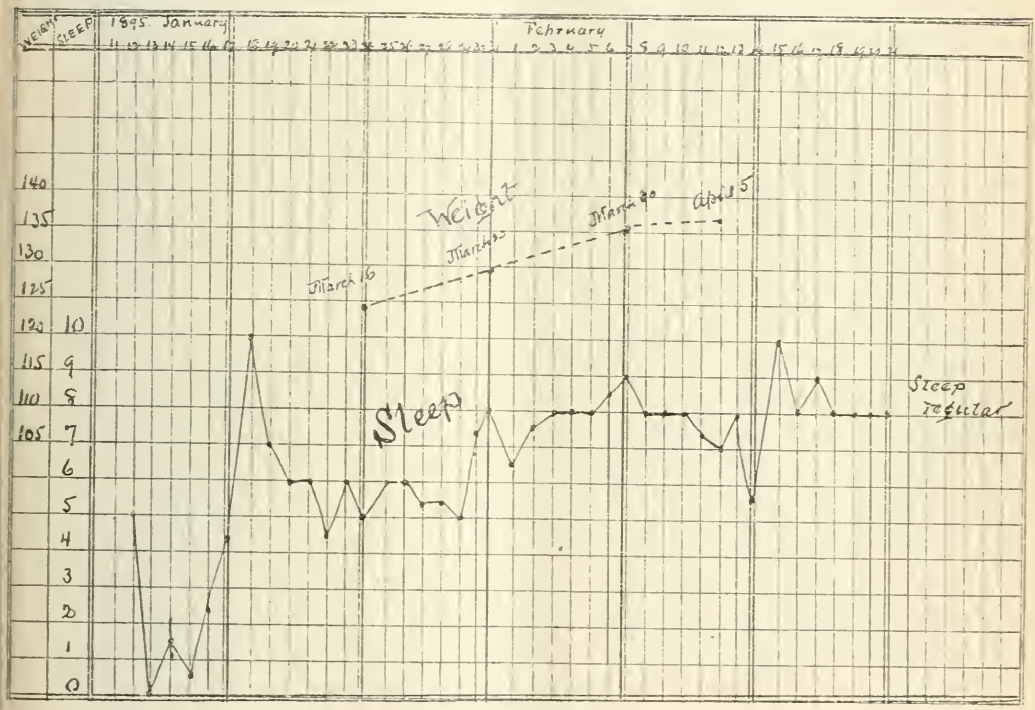
Case 1937. *Acute Delirium with Complicating Pulmonary Emphysema.*—Woman, aged fifty-three, widow; nativity, Canada; occupation, housewife, midwife; cause, overwork.

Family history: two sisters insane; one son has asthma. Personal history: patient has been strong except for asthma. Two and one-half years before admission she had pneumonia, and her health since that time has not been good. During a period directly preceding admission to the hospital, patient attended as nurse three cases of confinement in succession, and in each case, besides caring for baby and mother, attended to the household duties, often working at the wash-tub until late at night. The present attack began suddenly while she was thus employed, a few days before admission.

The features of the case were persistent refusal of food and medicine, and complicating asthma. Patient was admitted to the hospital February 25, 1895, and accepted only a small amount of nourishment from that time until the evening of March 3d, when she began to drink milk. In the succeeding week the excitement subsided, and with an intervening period of loquacity without delusions, she passed from delirium to a rational and intelligent mental condition. Convalescence was rapid and she was discharged recovered April 4, 1895.

Case 1900. *Acute Delirium with Accidental Scald during Plunge Bath, followed by Marked Reaction and Improvement, and resulting in Recovery.*—Woman, aged fifty-one; widowed; nativity, New York; occupation, housewife. Causes: predisposing, nervous temperament and climacteric; exciting, death of husband and financial losses.

Family history good. Personal history: Patient has been of nervous temperament and easily startled, but always strong and capable. Her husband died about ten years before her admission to the hospital, and money losses were sustained in the disposition of her estate. During the six months preceding admission she appeared in her usual health, except that on one or two occasions she seemed distracted. One week before admission active mental symptoms were noted, and five days later she became suddenly excited and delirious.



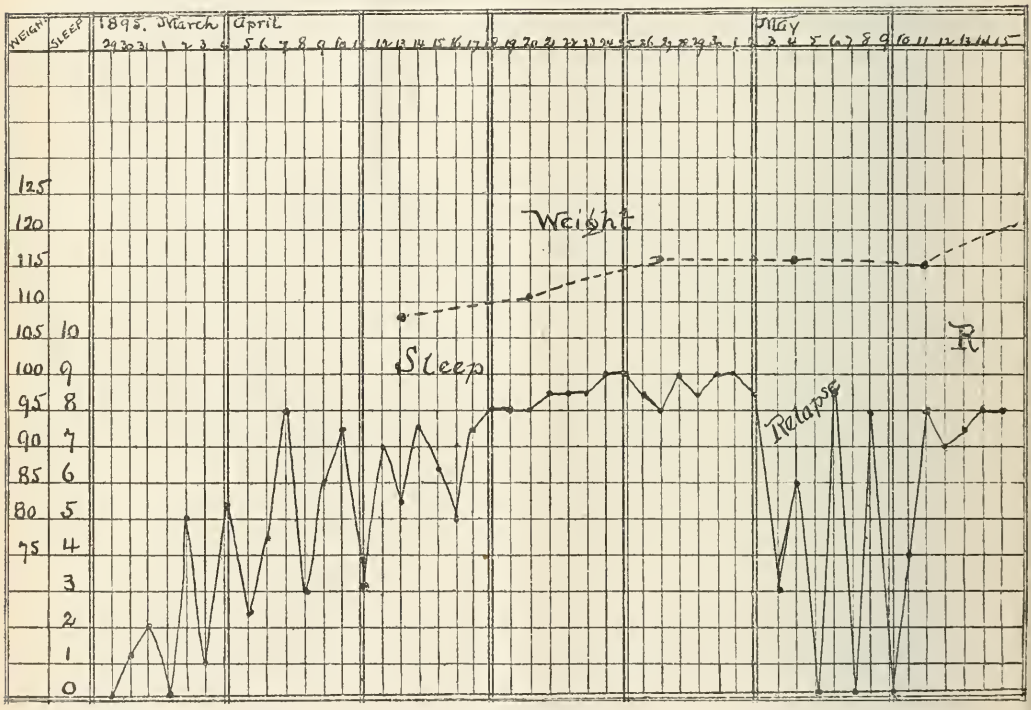
Case 1900.—Acute Delirium.

The features of the case devolved upon an accidental scald, sustained during the administration of a bath on the evening of January 18th, seven days after admission. Febrile reaction followed and the patient was physically prostrated, but there was no active delirium after the day following the accident. The mental symptoms disappeared promptly, but convalescence was somewhat prolonged during the healing of the superficial wounds. Patient was discharged recovered April 5, 1895, three months after admission.

Case 1960. *Acute Delirium Complicated by Excessive Drugging.*—Woman, aged nineteen, single; nativity, New York; occupation, student; cause, overstudy.

Family and personal history good. The invasion was sudden and occurred two weeks before admission. The patient had been industrious at study, and, as the first manifestation, she became loquacious and confused. In five days she had developed an actively delirious state. During the two weeks preceding admis-

sion, hypnotics had been administered in large doses, including bromide, morphine, sulphonal, and hyoscyamin; on the night before admission ether was administered. Patient had had quiet intervals, but they had become less frequent. She had accepted all food, but had rapidly emaciated. At the time of admission she was restless, active, incoherent, almost constantly in motion, and presented the usual physical manifestations of acute delirium. The pupils were so widely dilated that the red retinal reflex could be seen with the naked eye. Whiskey was freely administered, and on April 3d, five days after admission, the frenzy had changed to a state of exhilaration with rambling talk and laughter. After discontinuance of the stimulants this gradually ceased and the patient soon became intelligent and steady. Recovery was delayed by a period of relapse lasting about one week. Patient was discharged from the hospital June 7, 1895, ten weeks after admission.



Case 1960.—Acute Delirium.

Case 1856. *Acute Delirium of Puerperal Origin. Relapse during Attack of Epidemic Influenza, followed by Recovery.*—Woman, aged thirty-three, married; nativity, United States; occupation, housewife.

No history. Said to have been insane one week before admission. Patient was of large frame, of great strength, and weighed about two hundred and fifty pounds. At time of admission the breasts were distended with milk. On account of her unusual strength, difficulty was experienced in caring for her, and the observation of symptoms was incomplete. She was admitted to the hospital November 10, 1894, and the excitement continued for about two months. There then developed acute parotitis of the left side, and there was marked physical debility. During the period of excitement chloral was used. Upon the disappearance of the parotid swelling she became quieter, but passed through a prolonged period of irritability and mental confusion, with melancholy and a tendency to catalepsy. March 14th she was prostrated by epidemic influenza, and reduced to a condition of critical debility, with sleeplessness and refusal of food. Improvement began in the second week, and convalescence followed. Patient was discharged recovered June 8, 1895.

Case 2212. *Acute Delirium.*—Woman, aged thirty-nine, single; nativity, New York; occupation, domestic; alleged cause, continued excitement over religion.

Family history good. Personal history: Patient reported to have been eccentric upon the subject of religion. Present attack followed a visit with "two ladies who called themselves faith curists," and the night before the attack, which began suddenly one week before her admission, she was said to have attended one of their meetings devoted to prayer and song, "and the excitement was sufficient to bring about the present state of affairs." She then became excited and threatened violence, and presented marked physical symptoms—"tenderness of spine, irritable stomach, constipation of bowels, coated tongue, and headache."

Patient was admitted to the hospital July 23, 1895, and the excitement continued for one week. She then obtained a fair amount of sleep, and became quiet, dull, and confused. In September she was convalescent, and at the time of this writing (October 1, 1895) arrangements have been made for her discharge, ten weeks after admission.

Case 2168. *Acute Delirium.*—Woman, aged forty-two; married; nativity, New York; occupation, housewife; causes: predisposing, heredity, apprehension of insanity; exciting, overwork, and caring for sick husband.

Family history very bad: One brother and one sister now in St. Lawrence State Hospital; another brother has been insane; parricide has been committed by one member of the family; mother is a defective and in the county almshouse.

Personal history: Patient is said to have had several previous attacks, and to have been constantly apprehensive of insanity. At the time of admission, June 18, 1895, she had been insane for two weeks, and had shown marked homicidal and suicidal tendencies, with rapidly developing incoherence and confusion, sleeplessness, and loss of strength and weight. Under the usual treatment she responded slowly, and at the time of this writing (October 1, 1895) she is stronger and able to be up and about every day, but is dull, confused, and excitable, rarely speaking, and often attempting to injure herself.

Case 1886. *Acute Delirium with Chronic Nephritis and Partial Hemiplegia.*—Woman, aged thirty-five; married; nativity, Canada; occupation, housewife. Alleged causes: Frequent child-bearing, hemiplegia.

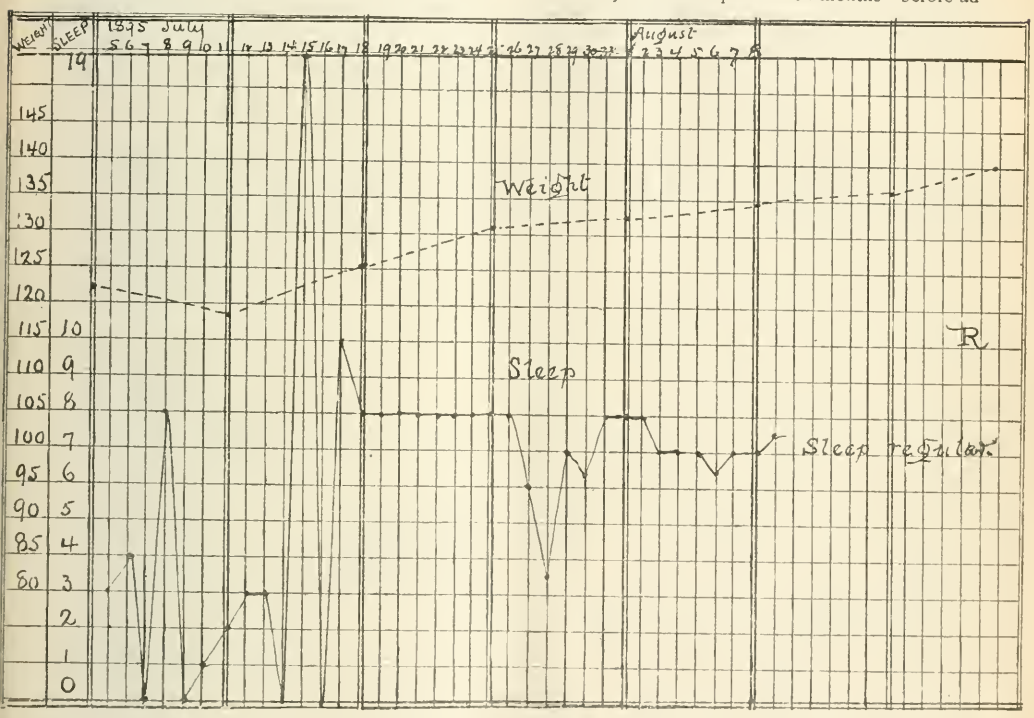
History: Patient was reported to have been in poor health for years, and to have been prostrated by an attack of hemiplegia in January, 1894. She had been submitted to worry over business matters. Two weeks before admission (December 21, 1894) excitement developed suddenly, with paroxysms, usually in the afternoon, of great severity, and separated by intervals of stupidity. Albuminuria and casts were determined. Excitement subsided in two weeks, and patient passed into a condition of uræmic stupor which continued for several months. Diuretic and laxative treatment with hydrotherapy were persistently applied, and at the time of writing patient is able to be up and about, answers simple questions, reads, but appears incapable of great mental effort, and is dull and inactive.

Case 2230. *Acute Delirium.*—Woman, aged thirty-nine; married; nativity, New York; occupation, housekeeper. Alleged causes: Domestic troubles and desertion by husband.

Family history: Mother died, aged seventy-five, with senile dementia. History of patient's illness indefinite. Her disease was said to have begun ten days before admission to the hospital, and had been characterized by great excitability and motor restlessness, religious delusions, incoherence of thought and speech, and suicidal desire. There was marked physical prostration. The delirious condition lasted one week; patient then became dull and groaned a great deal. She has since become stronger and brighter, is up and about every day, answers simple questions with intelligence, smiles when talking, but still shows the post-insane hebetude. She was admitted to the hospital August 16, 1895, and at the time of this writing has been under observation six weeks.

Case 2254. *Acute Delirium.*—Woman, aged forty-seven; single; nativity, Ireland; occupation, housekeeper. Alleged cause: Menopause.

No history accompanied this patient, except the indefinite statement that she had been maniacal, and that the insanity had developed "a few months" before admission. She was admitted to the hospital September 11, 1895, in delirious condition, and became quiet in two weeks. On September 28th she was dressed and about the ward, but she continues insomnious and depressed. She answers questions intelligently, and her general condition is favorable.



Case 2195.—Acute Stupor.

Acute Stupor—Five Cases.—Although there are too few cases of stupor to justify inviolate conclusions, their features appear to distinguish a separate class. In recent origin and in pronounced physical manifestations they approximate the conditions of acute delirium. From the latter they were distinguished by some slower development, by more profound mental "reductions,"[1] by absence of remissions, and by less favorable results. The element of combined physical and mental prostration separates them from other diseases of which stupor is an occasional accompaniment. From so-called stuporous melancholia they differ in genesis, in period of incubation, in duration, and in

[1] Bevan-Lewis. Text-book of Mental Disease.

their course. The presence of engrossing delusions to which all other mental operations are subordinate was not determined. The occasional occurrence of temporary restlessness and agitation suggest more properly affinity with a general mental perturbation of acute delirium, which, in some cases, appeared during the initial stage.

Sustaining and stimulating methods of treatment were adopted. The difference in mental manifestations between the delirious and the stuporous states are regarded, and location upon an open ward rather than seclusion was thought to be desirable, for its possible benefit in stimulation of object-consciousness.

Case 1839. *Acute Stupor with Albuminuria.*—Woman, aged thirty-seven; married; nativity, New York; occupation, housewife.

No definite history accompanied this patient. Her mother and sister were said to have been insane, and the present attack to have existed for two months. At the time of admission she was stolid and stuporous, and in poor physical condition. The pulse was feeble, rapid, and its tension elevated. The tongue was parched and coated, and the bowels were loaded. She continued in this debilitated state for three months; she then changed suddenly, became bright and active, entered upon convalescence, gained in weight and strength, and on April 2, 1895, six months after admission, was discharged recovered. The albumin detected at first in the urine disappeared. The treatment included rest, quiet, tonic stimulants, and electricity.

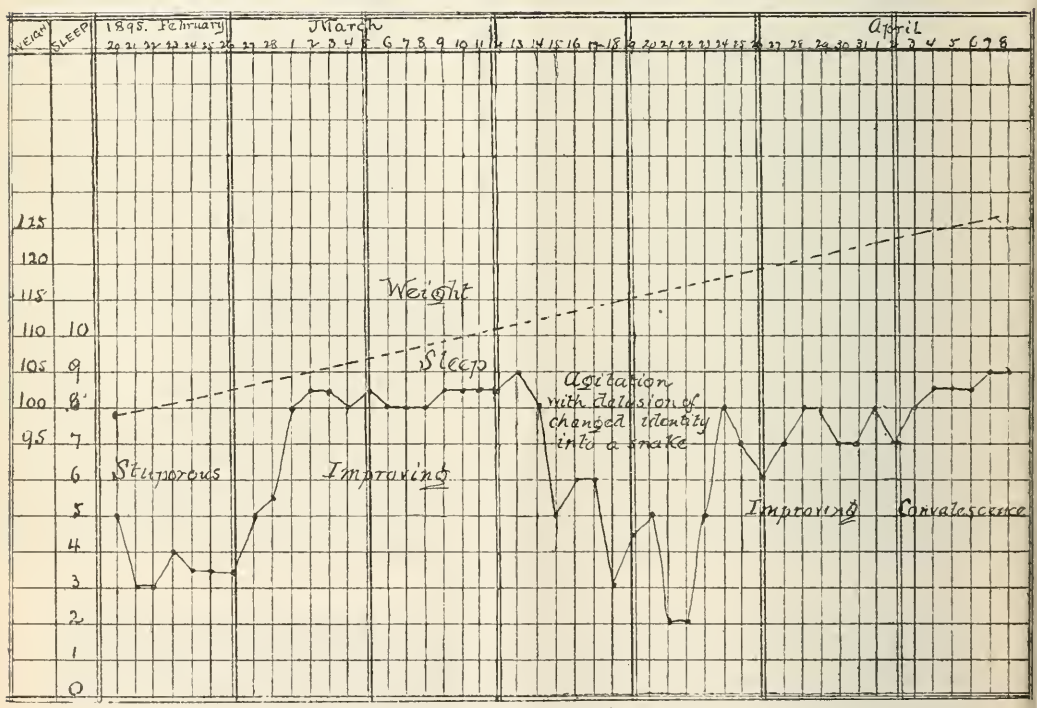
Case 1957. *Acute Stupor with Hystero-epilepsy and (probably) Excessive Drugging.*—Woman, aged twenty-eight; married; nativity, Canada; occupation, housewife.

No history accompanied the patient, except that attack of insanity began one month before admission. At the time of admission she was stuporous; the temperature was normal; pulse 88, feeble, and with elevated tension; pupils contracted and with limited reaction; skin anæmic; tongue moist, stained, and coated; there was a thick secretion in the mouth, and the breath was offensive. She was admitted to the hospital March 22, 1895, and on the evening of April 2d had two fits of hysterical character. She then improved rapidly, and was discharged recovered April 20, 1895, one month after admission. Tonic and laxative treatment, including strychnine, iron, and arsenic, was adopted.

Case 2195. *Acute Stupor.*—Woman, aged thirty-five; married; nativity, Canada; occupation, housewife. Causes: Care of insane husband and (probably) specific disease.

Patient was admitted to the hospital July 4, 1895, with a record of insanity of three months' duration. She had had the care of her husband, who was suffering from general paralysis and had been committed to an institution for the insane shortly before her admission. At the time of admission she was drowsy and dull, barely able to speak, and in poor physical condition. The temperature was subnormal; the pulse rapid, irregular, and of low tension; the pupils dilated and unequal; and the tongue irritable, swollen, furrowed, clean, moist, and steady. Functional derangement of the heart was determined. The abdomen was solid and its percussion-note flat. Acting upon the suggestion offered by the husband's disease, a course of antisyphilitic treatment was experimentally adopted. Gastric irritability followed and was controlled by the exhibition of belladonna. On the morning of July 8th, discoloration by blood was noticed from the angle of the mouth along the chin and on the bedding. The night nurse had not seen a convulsion.

Physical Examination.—Motion impaired. Legs: Extension and flexion, with forced resistance, accomplished, showing fair strength on first attempt,



Case 1933.—Acute Melancholia.

with ensuing rapid exhaustion and great weakness. Gait: Shuffling and staggering; Romberg's symptom present. Sensation, apparently normal as to quality and location. Reflexes: Knee-jerk present but not invariable—not elicited after two or three responses; ankle clonus absent; plantar reflex weak. General condition of quick exhaustion with preservation of function.

Patient now began to improve and, after preliminary loss in weight, gained in strength and nutrition. She was discharged September 21st, ten weeks after admission.

Case 2155. *Acute Stupor.*—Woman, aged thirty-six; married; nativity, Pennsylvania; occupation, housewife. Cause: Irregular menstruation and climacteric (early menopause a family trait).

Family history good. The first sickness was noticed May 16, 1895, and the first symptoms of insanity May 25th. Patient thought she had done some great wrong and must kill herself to make it right. She attempted to drown herself, to cut her throat, and to hang herself. She was in a stuporous state at the time of admission, but by an effort was able to answer a few questions. The temperature was normal, the pulse rapid and feeble, the tongue coated, the eyelids were drooping, and the eyes heavy and expressionless. The bowels were loaded. Patient failed rapidly, and on July 10th was fed with the tube. The milk and whiskey thus given were rejected. Lavage was then undertaken and an abundance of sour-smelling, slimy mucus, and two hardened and undigested milk-curds were washed from the stomach. Predigested milk with whiskey was then given through the tube and retained. This procedure was repeated at regular intervals, but patient failed steadily, and on the morning of July 13th died, five weeks after admission. Autopsy was not permitted.

Case 1855. *Acute Stupor with Chronic Nasal Catarrh and Hypertrophy.*—Woman, aged forty-six; married; nativity, New York; occupation, housewife. Alleged cause, injury.

Family history, one paternal aunt insane. The first symptom followed a fall from a ladder. Patient's back was injured, and she lay helpless for some time. She complained of pain in the back and head, and had been subject to periods of confusion in which she lost herself and was bewildered. She then became melancholy and attempted suicide. Stupor developed and continued with alternating periods of lucidity. The mental symptoms date from four months before admission. When admitted she was stupid and debilitated. The tongue was clean and moist, the pulse feeble, circulation sluggish, temperature normal, and body emaciated. The abdomen was tense, and the bowels were loaded. Albumin, casts, blood, epithelium, and leucocytes were found in the urine. Patient was given liquid diet, stimulants, iron, and strychnine, and absolute rest in bed was enforced. She showed no tendency to improvement, failed steadily, and died one month after admission. Autopsy was not permitted.

Acute and Subacute Insanities—Forty-five cases. The distinctions of the subacute and acute from the hyperacute forms have already been indicated. Of the former, a few cases of special interest are appended, the tables and charts showing the general results of treatment in these more common forms of recent insanity. It has been found advisable to surround these patients with quiet and cheerful conditions, and to avoid classification upon the basis of turbulence or peacefulness. Sedatives were used in moderation where indicated, but most frequently sulphonal and trional were relied upon to promote sleep, together with hydrotherapeutic measures, muscular exercise, and massage.

Case 1951. *Acute Melancholia.*—Woman, aged thirty-five; married; nativity, New York; occupation, housewife. Alleged causes: religious matters and uterine troubles.

Patient was first admitted to the hospital November 3, 1893, after an illness of three months' duration. She presented active changeable personal delusions with aural hallucinations, which gradually disappeared, and she was discharged June 5, 1894. She was readmitted March 15, 1895, with a repetition of the previous history and an impulse to drown herself and her child. She was in poor physical condition, and appeared anæmic. Repeated examinations of the blood showed an average of three and one half millions of red corpuscles, eight thousand leucocytes, and forty-five per cent. of hæmoglobin. Stained specimens by both Reider's and Ehrlich's methods showed crenation and poikilocytosis of the red disks, with occasional irregularities and disintegration of the neutrophilic white cells. Tonic treatment with arsenic and iron appeared of temporary benefit, but the general course of the disease was unfavorable, and during the last week in August the patient manifested the characteristic contractures and spasms of tetany. She failed rapidly and died September 5, 1895, after the development of hyperpyrexia. Autopsy was not permitted.

Cases 1932 and 1993. *Acute Melancholia with Autointoxication.*—Woman, aged twenty-nine; married; nativity, Canada; occupation, housewife.

Patient was first admitted to the hospital February 19, 1895, with history of insanity of three and one-half months' duration. She was debilitated and stupid, and writhed and groaned as if in great pain. The abdomen was very sensitive, and she stated that there had been no evacuation from the bowels for a long time. She did not enter freely into conversation, and delusions were not ascertained. Attention was directed to the enteric condition, and scybalous masses were at once removed. Improvement began promptly, but patient showed some mental weakness and soon expressed the idea that she was a source of contamination to others, and that she should be removed from the hospital. Later her conversation continually turned to the subject of snakes; at first she said she was full of snakes, that her fingers and toes were snakes, and finally that she, herself, was a snake. These delusions were partially controlled, and against the advice of her physicians she was prematurely removed from the hospital by her husband. Upon her return home she acted upon her delusions, left the house, and crept and rolled about on the ground in verification of her idea. She was recommitted to the hospital in four days. After an initial period of debility and confusion she again improved, her delusions disappeared, and on August 29, 1895, six months after the first admission, she was discharged recovered. During treatment in the hospital she gained in weight twenty pounds.

Case 2158. *Acute Melancholia.* — Woman, aged thirty; married; nativity, unascertained; occupation, housewife. Alleged cause, ill-health following childbirth.

Patient was said to have been insane for three months before admission to the hospital. At the time of admission she was depressed and debilitated, but intelligent. Her condition was then complicated by a functional intention tremor, which disappeared in a few days.[1] The treatment adopted included tonics, stimulants, massage, electricity, and quiet. Patient improved steadily, and was discharged recovered after ten weeks, having gained in weight ten pounds. Her improvement in physical health continued after her discharge from the hospital.

Case 1955. *Acute Mania.*—Woman, aged forty-eight; widowed; nativity, Ireland; occupation, housekeeper. Exciting cause: syphilis.

At the time of admission she was in fair physical condition and in a state of active mania. Under specific treatment she improved rapidly, gained in weight twenty pounds, and was discharged recovered in five months.

[1] Dr. James Hendrie Lloyd: Hysterical Tremor and Hysterical Anorexia, American Journal of the Medical Sciences, July, 1893.

Case 1976. *Acute Mania.*—Woman, aged thirty-four; married; nativity, Vermont; occupation, prostitute.

Patient was admitted in a state of active mania with slight physical deterioration. She was said to have been insane for one week, and showed marked delusions of exaltation. She was placed upon a course of specific treatment and improved rapidly, gaining in weight, in five months, twenty pounds.

Case 1863. *Acute Mania.*—Woman, aged forty-one; married; nativity, Ireland; occupation, housewife. Alleged cause: family troubles, death of son.

No history accompanied the patient. She was actively excited at the time of admission, and afterward was subject to sudden outbreaks of mental and motor disturbance, with resistance to care and the appearance of controlling delusions, which were not expressed. She did not improve. She was admitted to the hospital November 14, 1895. In May, after a prolonged period of excitement, she became depressed and remained in bed. During the last week in May she suffered from severe and intractable diarrhœa. On the morning of May 30th, her right leg became suddenly cold, pale, and paralyzed, with some cyanotic discoloration. No heart murmur was detected. The pulse was weak, and the temperature varied from 99° to 101° F. during the day. Urinalysis revealed urates and albumin.

On the following morning, at half-past seven o'clock, she collapsed, the heart-beat could not be determined, the pupils were widely dilated, the skin became sallow and livid, there were a few gasps, and without convulsion or coma she died in an hour.

The autopsy showed general sclerosis of the brain, thrombosis of the great longitudinal sinus, gangrenous enteritis, and thrombosis of the right popliteal artery. Search for a plug in the abdominal vessels was unavailing, although the existence of such was strongly indicated.

The following tables have been made upon the basis of completed cases, with the purpose of avoiding the element of probability. The results are not in variance with those previously published,[1] but verify them by greater detail. Of necessity they included cases admitted to the hospital during the last months of the fiscal year, as well as during the earlier period. They reveal the impossibility of securing definite data in the space of a year, relating to diseases whose natural course covers a greater time. This uncertainty is especially shown in Cases 1841 and 1857, admitted at the beginning of the year and not yet determined.

These patients have both passed through attacks of acute mania of prolonged duration, and have attained the state of post-maniacal hebetude, in which the forecast for chronicity or cure is involved in obscurity. Further study of these cases during the succeeding year will remove many elements of doubt and render insignificant the number of uncompleted cases.

Gynecological complications have not been discussed, because there have been no cases whose gynecological aspects appeared directly related to the course of the disease. The minor ailments of women have had proper attention and treatment, and their correction has been a factor in the restoration of health.

It has been sought by this paper to remove the uncertainties of statistics by the consideration of individual cases, and to emphasize the curative and hospital functions of an institution for the insane. In some measure is revealed the great demand made by the recoverable class of patients; the need of close physical diagnosis, of the arrangement of wards for isolation and separation of disquieting elements, refinement of diet, and skilful attention of qualified trained nurses. The success has been encouraging, and the results justify the still greater development of the medical work of the institution. The hope may be indulged that the attention of the practising physician will be attracted, and that public hospitals for the insane shall receive, as is their due, the emphatic and steady support of the general profession.

THE PALLIATIVE TREATMENT OF GONORRHŒIC TUBAL DISEASE.[1]

By W. R. PRYOR, M.D.,

PROFESSOR OF GYNECOLOGY, NEW YORK POLYCLINIC; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY.

I THINK it may be accepted as indisputable that radical cure of inflamed tissues, in which the process has gone so far as to produce pus, can be surely effected by their removal only. This is especially true where suppuration takes place in pre-formed sacs. The practice among surgeons is to remove all tubes and ovaries of gonorrhœal infection, and some of us, myself among the number, always remove the uterus also where both adnexa are destroyed, as the hysterectomy not only gives a more permanent cure and smoother convalescence, but the mortality is lower.

So much, then, for the best plan of treatment of cases of gonorrhœal endometritis with bilateral suppurative tubal complications. But nowhere in the whole sphere of surgical procedures do extraneous conditions so modify the indicated treatment as in destructive diseases of the adnexa uteri. The endometrium being a lymphoid organ, is, in function, intimately associated with other organs of similar kind, and marked tissue changes throughout the body follow hysterectomy. In young girls a distressing neurasthenia, marked by melancholia, is often seen; the external genitals and vagina shrink, and copulation becomes painful; the woman no longer menstruates, and the increased monthly intra-vascular tension normal to menstruation finds no relief, but produces headaches and hysteria. Such are the very common results of removal of the uterus and adnexa.

So then, single women wish to be as other women, menstruating; and wives as other wives. And we are often forced into doing incomplete palliative work in order to preserve to the woman certain physiological states and to avoid premature menopause.

So far as the palliative surgical treatment of the pelvic complications of gonorrhœal infection is involved, three conditions may be described: Acute salpingitis with acute pelvic peritonitis, old chronic tubal disease with recurrent attacks of acute inflammation, and cases in which hydrosalpinx, or pyosalpinx, has resulted.

Acute Salpingitis.—Seventeen cases with first attacks have been seen. In all there was enlargement of one or both tubes, great tenderness, acute pain, temperature, often tympanites and vomiting. In all curettage of the acutely inflamed uterus was made, acting upon the belief that here started the infection, and here should it be first attacked; just as the adenitis associated with a chancroid disappears when the specific virus is destroyed early. These acutely inflamed tubes are deeply injected, appear almost necrotic, but upon section the inflammatory process seems to be almost wholly in the walls of the tube, the lumen but slightly, or not at all, distended by purulent accumulation. I believe in the resistant power of these highly vitalized organs, and have no hesitancy in stating that if the proper sort of curettage be done early a radical cure of the tubal inflammation often results. Of the 17 cases so treated but 3 required removal of the affected tubes. And it is significant that all of these 3 were seen after the infection had lasted over a week. The remaining 14, so far as I could discover, entirely recovered. All pain and tenderness disappeared, and upon examination no sensitive spot, no tubal enlargement remained. They all menstruated painlessly and normally after the operation. So, then, I invariably curette these acute cases, but in a manner a little different from that commonly employed. For the technique of the operation I must refer you to the "Transactions of the New York Obstetrical Society," November 5, 1895.

[1] Read before the Genito-Urinary Section, Academy of Medicine, November 12, 1895.

There are certain of these acute cases which have been of longer duration, but which yet present acute symptoms. The lesions are still those of an interstitial infection, with much enlarged tubes, recent lymph about the adnexa, as well as slight accumulation of muco-purulent fluid in the tubes. The fimbriated ends are occluded, but the uterine openings still open. Such cases occupy the mid-state between the most acute and those presenting true pyosalpinx. In such cases we get the greatest relief from the curettage, supplemented by opening the posterior cul-de-sac. After curetting the cul-de-sac is opened in the median line by a crescentic incision. The adhesions are broken up, and the coils of intestine, tubes, ovaries, omentum, and uterus are separated. The pelvis is then filled by iodoform gauze, in very much the same way as a Mikulicz dressing is made from above. The procedure seeks the isolation of the infected area, as well as removal of the original and continuous source of infection from the endometrium. The results are very beautiful indeed. I have applied this procedure in but seven cases, and not one, so far as I know, has relapsed. There remains for some time more or less thickening about the affected tubes, and so long as this can be detected the use of vaginal tampons of ichthyol, ten per cent., in boroglyceride, ninety per cent., is indicated.

Recurrent Chronic Salpingitis.—These cases are exceedingly common. Apparently the gonococcus has little pyogenic power in certain women, and produces catarrhal inflammations only. If we examine tubes thus affected we find them during an attack much congested, and with the matted fimbriæ and adhesions which indicate old infections. There is not often recent lymph, and they do not commonly contain pus. The walls of the tubes are thickened, but dense and hard. There is a process of fibrosis going on. For these women we can do the least. Although they have a tissue resistance which does not conduce to pus-formation, or a limited pyogenic invasion has taken place, the very character of the changes insures a maintenance of the infection. Their uteri also are dense and firm, and the curettage which we here do, although thoroughly cleansing the inside of the uterus, has little or no effect upon the tubal disease. Still it is indicated as a means to remove one focus of infection. I have latterly, within the year, opened the cul-de-sac of these women, broken up adhesions, replaced a possibly adherent retroposed uterus, and drained by gauze the lowest part of the cul-de-sac. A temporary benefit is always obtained, and much relief of local symptoms. But, as I said, the repair power of these fibroid tissues is much damaged, and I shall always expect women thus affected to have permanent symptoms of tenderness and pain. I have never seen a pus-tube form in such tissue. We see these uteri and tubes in old prostitutes, and very often there are multiple broad ligament cysts associated with the other changes. The menstruation is scanty, the uterus being commonly atrophic.

Hydrosalpinx and Pyosalpinx.—These are certainly cysts of retention only—the one simple, the other purulent. Although believing firmly that radical cure of suppuration in a pre-formed sac can be with certainty accomplished by extirpation of the sac only, yet I must confess I am wonderfully pleased with the treatment I shall describe.

Here, also, the uterus is curetted and packed. The cul-de-sac is opened, and as little disturbance of existing adhesions made as is possible. The wall of matted viscera above these tubes should be left alone. A wide opening is made in the cul-de-sac, with perhaps a crucial cut down the vagina—an abundance of room must be secured. Seeing the distended tubes we puncture them with scissors. As the pus escapes we introduce the fingers and widely tear open the tubes. The pelvis is not washed out, but the tubes are wiped dry with iodoform gauze, and the entire field of operation cleaned in a similar way. We now pack the tubal

cavities full of gauze. It is a pelvic Mikulicz we make, and every exposed tissue has gauze against it. Two to four yards of gauze are often used, securing not only absorption of fluids, but pressure as well. Rapidly and progressively these tubes atrophy. No longer are acute auto-infections possible—you have prevented that by your curettage. And even though a faulty and incomplete technique shall have left an unopened pocket somewhere, yet is there abundant provision for drainage in case it breaks.

Now, gentlemen, these women are gonorrhœic, and when symptomatically cured are prone to seek the causes of their trouble. This we must, if possible, prevent; and if coition can be stopped, no return of trouble is seen.

In all these cases in which the tubes are affected, and in which the cul-de-sac is opened, the function of the tubes, so far as gestation is involved, is gone, and fortunately so; for were it possible for the ovum to enter the tubes extra-uterine pregnancy might result.

What I am striving to do is to give the surgeon, as well as the general physician, who cannot obtain the aid of a specialist, certain procedures which will in most cases effect a cure; to furnish them with methods of treatment better than the poultice and opium of the timidly incompetent, and yet not so severe and mutilating as the salpingo oöphorectomy or ablation. There is a middle ground upon which we can stand, and the best of us must sometimes occupy it.

Although the ablation of uterus and adnexa gives but three per cent. mortality, there are some things dearer to some women than life. And it is to furnish that measure of relief with that hope of recovery to just such women that I have worked along this line of conservative treatment of the pelvic complications of gonorrhœa. And I make it a rule in all such cases to lay before my patient a general statement of the limitations of such procedure. Rarely will one be found who does not grasp at the possibility of relief without danger and without mutilation. Were it possible to prevent reinfection in these women, could one seal them against coition, I firmly believe that the vast proportion of them (and I estimate the percentage at eighty) would never have a recurrence of acute trouble. But one great advantage these palliative measures give the surgeon when applied in acute cases, and in cases presenting pyosalpinx: they enable him to temporize and to do a radical operation when he, not the disease, elects.

Certainly our results will be still better when we can tide over that stage in disease during which the emunctories are taxed to the utmost to eliminate toxins, when the heart is embarrassed, and extensive visceral lesions exist.

Assuredly I offer you procedures which are better than the old let-alone policy; for the latter sought physical ease by means of narcotics and allowed a destructive infection to run riot in the woman's most important organs. The pelvic complications of gonorrhœa in women are surgical diseases, and should be met by surgical, not medicinal, measures. We can now do this with safety and success.

Quackery in Connecticut.—The New Haven County Medical Association has passed a set of resolutions declaring that other States are rejecting by their examining boards incompetents who are admitted to practice in Connecticut without examination; that, in consequence, the State is becoming a dumping-ground for undesirable practitioners. The Association suggests that the State Committee on Legislation be instructed to advocate an amendment of the law, so that all candidates for registration as doctors under the medical practice act be required to pass an examination, as is now the case in most of the States in the Union.

THE REMISSIONS OF GENERAL PARALYSIS.

By WHITMORE STEELE, M.D.,

FORMERLY ASSISTANT PHYSICIAN, UTICA STATE HOSPITAL FOR THE INSANE; PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, OUT-PATIENT DEPARTMENT; MEMBER OF THE NEW YORK NEUROLOGICAL SOCIETY, ETC.

WHETHER we look upon general paralysis as a disease which is inflammatory in origin, or with Schüle consider it primarily a vaso-motor disturbance, or with still other observers, look toward the nerve elements as the initiatory seat of the disease, the phenomenon of a remission, or sometimes several of them, seen during its course, presents an interesting, and at times puzzling, clinical picture. When we consider that we find post-mortem, in this disease, a destruction of neurons, extensive and irreparable, together with a wide-spread and permanent alteration in blood-vessels and stroma, this phenomenon of apparent recovery, although often only partial, becomes one worthy of study in regard to its causes, their nature, and significance. A point worthy of note is that remissions rarely occur in any but recent cases of general paralysis, which fact leads us to infer that the primary changes that occur in this disease are more in the nature of so-called functional disorder, affecting nutrition and the like. Opportunity for post-mortem examination in the first stages of general paralysis is not very frequent. Berkeley[1] has recently reported the lesions found in a patient who died only nine months after the beginning of his disease. The changes found in this case were undoubtedly more extensive than those which would be found in a general paralytic whose disease was running its regular, somewhat chronic course, but who had died of some intercurrent complaint. The case reported was probably one of the variety spoken of by Mickle as galloping paresis, rapid in onset and destructive from the beginning. Berkeley found, on examination, marked vascular changes, degeneration of the vessel-walls, and a general disturbance of the lymph-current. He assumed from this condition that there had been a degeneration of the neurons, consequent upon a deficient supply of nutriment; in short, a disturbed cellular metabolism. The extreme shortness of the course of the disease in this patient did not permit any of the phenomena of a remission to be present. And the interest of the case consists in the early and rapid tissue destruction which was found.

A brief *résumé* of the latest pathological findings in general paralysis is desirable at this point, in order to consider in a satisfactory manner the nature of the remission.

Mickle[2] divides the lesions, according to their location, into cortical, vascular, and changes in the neuroglia. The vascular changes are distention of vessels with blood, an increase of nuclei in the walls of the vessels, together with a colloid degeneration. The blood-vessels are dilated and tortuous, the lymph-spaces are filled with lymph-corpuscles, and there is sometimes a formation of new blood-vessels. In the neuroglia there is hyperplasia and hypertrophy; an increase of nuclei, and a formation of spider-cells, colloid degeneration and atrophy. In the neurons there are granular, fatty, and pigmentary degeneration; sclerotic and atrophic alterations in nuclei; vacuolation and calcification of cells, with atrophy of the nerve-fibres. According to Kronthal, these lesions are wide-spread, but more marked in the anterior part of the parietal lobes, and in the frontal lobes.

We see then, from this cursory and hasty survey of the pathological findings in general paralysis, that we have to deal with a disease which, fairly early in its course, involves the vital elements of the brain in a destructive process. The tissues attacked are, after a time, injured in an irreparable manner.

Assuming the view that in the beginning there is a

[1] American Journal of Insanity, January, 1895.
[2] Dictionary of Psychological Medicine.

nutritional disturbance, varying in duration and causing a functional disorder of the neurons, with a consequent inhibition of their normal activity, we then have produced the early psychic changes which are usually seen, such as amnesia, partial or complete, diminution in attention and volition, lessened muscular power, insomnia, blunting of the ethical and moral sense, and a general disturbance of the relations of the ego with its environment.

This stage of general paralysis is that in which the remissions are more frequent and last for a longer time, in some cases going on to apparent recovery.

However, the remissions of this period of the disease are less noticed, because of the physician not being consulted so early in regard to treatment, and thus not coming under his observation, except, possibly, as cases of neurasthenia, or other milder disorder. May we not look on the remissions occurring in this stage as due to restoration of vascular and nutritional activity, with a consequent return to normal function of the neuron, which as yet has undergone no organic change?

Hodge has shown that this functional disturbance so-called, this fatigue of the neuron, if carried to an extreme degree, will be followed by vacuolation and disintegration within the cell protoplasm, from which condition, it is probable, recuperation never takes place. It is fair to presume that some cases of general paralysis could be checked were the patients to be treated at this early stage of their disease and the remission be made the threshold to permanent recovery.

What, however, can be said of the cases we meet, further advanced in their course, but yet in which well-marked remissions occur? How shall we explain the return to activity of a brain, part of the structure of which at least has been permanently injured? It must be assumed in these cases that, although we have a change in all the elements of the brain, the most extensive changes are those present in the vascular system and the neuroglia; and that, although the neurons are affected to some extent, many possibly destroyed, there is yet a possibility of the absorption of the exudate, a renewed activity of lymph-currents, and a consequent improved nutrition of nerve-cells, with at least a partial restoration of the individual to mental activity. Clinically, it will be found the remissions are not as complete, and the renewed cerebral activity as marked, in those cases where the remission occurs later in the course of the disease. So we must suspect a certain amount of injury has been done the neurons which is irreparable, and which causes permanent changes in the higher faculties, the residuum of feeble-mindedness being commensurate with the destruction accomplished by the disease. What is called by Batty Tuke "the limit of functional activity changes" has been reached, and even transcended, in a certain proportion of the cerebral cells.

Thus far the remissions of general paralysis have been considered, only in those cases where the disease was supposed to have begun in the vascular system, with nutritional defects occurring as a consequence. The hypothesis of the lesion being primarily cellular, must now be considered in connection with the subject. Very decided deleterious effects are produced by extreme exhaustion of the neurons, with insufficient excretion of the substances evolved during the season of hyper-activity. Bouchard has written extensively of this in his book on Auto-intoxication, so also has Rogers.[1] The possibility of a toxæmia, with organic disease of the kidney as its starting-point, has been carefully studied by Bristowe,[2] quite recently. In eighty-eight per cent. of the general paralytics examined post-mortem, he found granular kidneys, while in only fifty-five per cent. of other forms of insanity was there found any trouble with the kidneys. These toxic substances, in addition to their destructive action, undoubtedly inhibit the function of the lymphatics and blood-vessels, with an aggravation of deleterious effects already existing.

In the Morrison lectures for 1894, Batty Tuke has elaborated this idea, and presents there in detail the forms of insanity induced by these causes. Remissions which occur in the course of a general paralysis which is supposed to be dependent primarily on cellular disorder, may be looked upon as a cessation, temporary as a rule, of the pernicious over-activity of the neuronic elements, together with an increased excretion of toxic material through the vascular and lymphatic systems, inducing a general improvement in tissue metabolism.

In considering the remissions of general paralysis, and in noting their frequency, we must bear in mind how frequently alcoholic or pseudo-paralysis is mistaken for the genuine disease. The recovery from seemingly hopeless conditions in these pseudo-cases is more complete.

The somatic condition is often more marked in its disorder than is the mental. The delusions are apt to be less expansive; the prodromic period is shorter, and the remission goes on, as a rule, to recovery, where abstinence from alcohol is practised. This class of cases are hard of diagnosis at times, and may often be passed upon as general paralysis. When they recover, as they usually do, they are tabulated often as cured paresis. Mickle has found, that in cases of chronic general paralysis with a strong hereditary history, the duration of the disorder is longest, the remissions are more frequent and complete. In two of the cases I append, this observation will be found to be borne out. The following cases, some of which were observed during a service at the Utica State Hospital, are interesting in connection with the present subject, showing as they do periods of remission varying in length from months to years. They also show different degrees of mental improvement, from a feeble-minded, non-delusional state, to one of a nearly complete restoration to vigor of mind.

Case I.—H. C. L——, male, thirty years of age, married, no children. No alcoholic history, indefinite specific history, hereditary tendency rather strong. At the time of his admission was incoherent, excitable, and very tremulous. Four months previous to admission to the hospital the disease had first manifested itself actively. Disease apparently began with an attack of unconsciousness, followed by aphasia and left side hemiplegia. He gradually recovered from paralysis, and for a period of four months was feeble minded and incoherent in speech. At this time his mental symptoms gradually cleared up, somatic condition improved, and with the exception of a slight feeble-minded state, he seemed in normal health. He remained in good condition for nearly two months, then had another apoplectiform attack, from which he slowly recovered.

Case II.—F. T——, male, aged fifty-six, married, no children. For twenty nine years had used alcohol excessively. He had been treated at a "Keeley cure" institute previous to coming under observation. From this place he had graduated "cured," but with all the symptoms of general paralysis. He had the delusion that he was a detective in the employ of the post-office, and that he could drink half a barrel of whiskey a day. After a month of treatment his delusions disappeared, his bodily condition improved, and for over a year he remained in a normal mental state.

Case III.—W. H. W——, male, aged forty-eight, single, clerk. Six weeks previous to coming under treatment was noticed to be dull and stupid in his actions. For two or three years previous to this he had gradually changed in his disposition. He arose in a revival meeting at one time, and announced he had converted thirty people; this aroused considerable enthusiasm, until he said that the conversions were accomplished

[1] Archives de Physiologie, 1893.
[2] Journal of Mental Science, April, 1895.

by means of pork and beans from his boarding-house. Shortly after this mental and physical symptoms of paresis appeared, and he was confined in the hospital. After admission he had several paretic seizures, after which he improved slowly. For three years he was in a state of fairly good mental health, with the exception of a slight feeble-mindedness. He then was again taken with paretic convulsions, and after two weeks of absolute dementia he died. The length of the remission is rather remarkable in this case.

Case IV.—J. C. M——, male, thirty-seven years of age, married, one child. History of syphilis present. On coming under observation he presented all the symptoms, mental and physical, of general paralysis. After three months improved very much, and for one year was, with the exception of a little feeble-mindedness, in a normal condition. At the end of this time he became incoherent and confused, had several paretic seizures, which were followed by slight improvement, less in degree than at first.

Case V.—H. K——, female, thirty-eight years of age, married, dissolute in habits, alcoholic, and probably syphilitic; when first seen was maniacal and violent. This condition continued for two weeks, when she improved, became quiet and rational. The remission lasted three months, when she again became maniacal. She again improved and went home from the hospital, contrary to advice. She remained at home for two years in an apparently normal mental state, but dissolute habits being renewed her disease returned, and shortly after her readmission to treatment she died in a paretic seizure.

Case VI.—Male, aged thirty-eight, painter by occupation, married. Alcoholic history. One year and a half before coming under observation had shown signs of insanity. He developed grandiose ideas and at times was violent. After six months in this state, he improved and recovered his normal faculties, according to his family. For one year this state of improvement continued, and then all the former symptoms came on, together with a rapidly increasing dementia.

Case VII.—G. L——, aged thirty-six, married, no children; alcoholic history and probably syphilitic. Four years before coming under observation was melancholic, threatened suicide, and at times was violent. This condition gradually grew worse, and all the physical and mental signs of paresis developed.

In this state he remained for a year, then improved and his mind apparently assumed its normal condition. For over a year he followed his occupation of clerk and appeared entirely recovered. Then business reverses assailed him, and gradually he failed again. At present is delusional, grandiose in conversation, and typically paretic.

Quietude and Longevity.—That quietude conduces to longevity seems to be demonstrated by the record of longevity in Philadelphia, a matter on which the city prides itself considerably. During the first half of this year the obituary columns of the *Ledger* contained death notices of two hundred and thirty-four women and one hundred and eighty men who had lived to or beyond eighty years of age. The greater part of the deaths were of residents of Philadelphia. Thirty women and twenty-six men lived to or beyond ninety years of age. The extreme ages reached were ninety-nine years by one woman and ninety-six years by three men.

A Wise Precaution.—An ordinance for the regulation of bicycle riding which is under consideration by the San Francisco City Council, prohibits bicyclists from carrying on their machines any child under the age of six years. This is the outcome of the recent crusade by the Society for the Prevention of Cruelty to Children.

TUBERCULOSIS OF THE KNEE JOINT.[1]

By RICHARD C. NEWTON, M.D.,

MONTCLAIR, N. J.

The study of the etiology of this affection presents many interesting points, and raises many questions which are as yet difficult or impossible of solution.

That the knee-joint, which is probably injured more often than any other articulation in the body, should so seldom be the seat of tubercular disease as compared to the hips—the proportion being, Dr. Park[2] tells us, one to five—seems at first sight quite peculiar. The explanation may be offered that the blood-supply to the knee is greater than to the hip, and that owing to the greater extent of synovial membrane in the former joint, there is a greater number of lymphatics present, so that not only are the articular structures better nourished, but elimination and removal of morbific matters are more readily and more thoroughly accomplished. Be this as it may, the fact remains that, with all the injuries, abrasions, contusions, and strains to which the joint is subjected, it is comparatively rarely the seat of tuberculous disease, whereas the hip, a much more deeply placed and better protected articulation, and one that is in consequence less frequently injured by blows, falls, contusions, and strains, is comparatively often afflicted with tuberculosis.

Again, what is the rationale of the development of tubercular disease in any joint? It seems to be generally admitted by surgeons that the bacillus of Koch is present and is the causative factor in every case of tuberculous arthritis.

The question naturally arises, how does this bacillus find its way into the joints? Is it present at birth, or is it subsequently introduced? Those pathologists who deny the hereditability of tuberculosis are driven to say that the bacilli have found their way into the body through the lungs, by inhalation, or into the alimentary canal, with the food or drink, and have been taken up by the blood-vessels or by the lymphatics, and carried about in the body until at last they find lodgement in or near a joint; in which sooner or later they take on an active rôle and tubercular disease is set up in that locality.

What has determined this disposition of the specific organisms? Why were they not arrested in the lungs, pleura, stomach, the bronchial or mesenteric glands, to set up their destructive processes there? Again we cannot answer; we can only say that in a very large number of cases they probably are so arrested. In the early years of life tabes mesenterica is comparatively common, and must be many times more frequent than tuberculous arthritis, and this fact is naturally brought forward in proof of the communicability of tuberculosis by food, particularly milk.

The weight of opinion seems to be, however, in favor of the hypothesis that the bacillus is handed down from parent to offspring, and that in infancy it exists in the body, where it may lie dormant for an indefinite time. Accidental causes, such as trauma, malnutrition, or the advent of other pathogenic microbes, as *e.g.*, those of scarlatina, pneumonia, or la grippe, starting it into action.

It is even claimed by some[3] that the bacillus may remain latent in the body through an entire lifetime, and be transmitted to the succeeding generation, in which it may develop some form of tuberculosis. Dr. Solly said, in an admirable paper read before the last meeting of the American Climatological Association, and published in the *American Journal of the Medical Sciences* for August, 1895: "That the bacilli can be transmitted not only from the parents, but also occasionally from the grandparents, is very probable. The

[1] A Part of the Annual Report of the Committee on Surgery of the Orange Mountain Medical Society, read before that body November 1, 1895.

[2] Medical News, Philadelphia, September 28, 1895, page 363.

[3] American Journal of the Medical Sciences, August, 1895, page 36.

revelations of autopsies which show tuberculosis of glands, etc., in persons who were believed to have no evident tuberculosis, and who died from other causes, and the probability of many of the surgical tuberculoses of children being due to latent bacilli, which gave rise to no symptoms until a traumatism furnished the inflammatory products for the bacilli to feed upon, to retire again into innocuous desuetude with the rest given by splints, etc., to the inflamed parts, renders it almost if not quite certain that bacillary infection may be transmitted through a silent generation."

As tending further to demonstrate that the bacilli are frequently born in human beings and not acquired by inhalation or otherwise, Dr. Solly quotes the remarks of Dr. Currier in a discussion before the New York Academy of Medicine, in 1892, in which it is asserted that fœtal tuberculosis does occur, and that the bacillus is found in the ova and in the testicles of tubercular subjects, albeit these organs themselves may be structurally healthy. Add to this the latent tuberculosis demonstrated by Bollinger and others in twelve per cent. of their autopsies upon children, and the powerful weight of Baumgarten's authority ; and it seems more reasonable at least to assert that the bacillus is present in persona propria in the bodies of a certain proportion of its human victims at birth. The presence of the germ in the fœtus is to my mind an unanswerable argument in favor of this belief.

If we admit all that is asserted above, we are still quite in the dark as to why tubercular adenitis, arthritis, and meningitis develop so much more frequently, relatively in children and pulmonary tuberculosis in adults. However, such is the fact. Perhaps we might assert that the hereditary tuberculoses are prone to show themselves in the more distant structures of the economy, whereas the acquired forms will more probably find lodgement and accomplish their destructive work in the air-passages, into which they have been drawn with the inspired air.

This view would seem to receive confirmation from a statement made by Dr. Janeway,[1] in the discussion just spoken of, to wit : that in the year 1890, there were five thousand four hundred and ninety-two deaths from phthisis (which means presumably only pulmonary phthisis) in New York City, of which only two hundred and forty-three, or less than four and one-half per cent., were children under ten years of age. Whereas we are told [2] that the mortality from tuberculosis (general) is greatest in the human subject during the first year of life.

It will not be proper to consume more time in this discussion on the question of the etiology of tubercular arthritis ; let me sum up by saying that the weight of testimony is overwhelmingly in favor of the statement that the child is born with tubercular bacilli already in his body, probably in his glandular system ; that an injury to one of the large joints sets up inflammatory action there ; that the bacillus is present at the seat of this morbid process, either having been there since uterine life, or perhaps, which is more probable, is brought there in the circulation or by the lymph-canals and finds lodgement and pabulum. That the germ comes to the knee as often, probably oftener, than to the hip, but owing to the superior innervation and circulation of this joint, only sets up a morbid process one-fifth as often in the former joint as in the latter.

If the rationale of the causation of tuberculosis of the knee is difficult of explanation, the early diagnosis is equally difficult. The ideal time to treat tubercular arthritis has passed when the lesions are sufficiently pronounced to make the diagnosis sure. Valuable time is so generally lost before the true nature of an arthritis is recognized, that a certain means of early diagnosis would be well-nigh invaluable, not only as regards the ultimately curative treatment of the lesion, but also the prevention of much suffering, a probable long confinement of the sufferer to his bed, and in many cases at least the risk of his life.

I am not without hopes that the suggestion made by Professor Klebs,[1] that tuberculin should be used for diagnostic purposes on the human subject in a manner similar to its present employment by the veterinarians upon cattle suspected of tubercular infection, may in time be rendered feasible. At the present moment it would hardly seem practicable, because the injection of tuberculin into cattle already infected sets up a febrile action, which would perhaps lead to great activity on the part of the tubercle bacilli if already present in the organism. In other words, if it acted in a similar way in children, it might accelerate or even develop tubercular inflammation, and is therefore, in the present stage of our knowledge, an unwarrantable liberty to take with the well-being of the child.

Good authorities, including Professor Koch himself, have condemned the use of tuberculin upon the human subject for diagnostic purposes. Also I might add that a further study of the ultimate results of the injections of tuberculin into cattle, for diagnostic purposes, is needed.

Up to this time it would appear that those cattle which develop reaction after the tuberculin injection are slaughtered, instead of being kept under observation and the ultimate good or bad effect of the procedure noted. So far as I am aware, the precise nature of the febrile movement set up by the inoculation has not been determined. The inference, however, is, that it is, or may be, a phase of tubercular disease. The suggestion of Professor Klebs, however, may bear valuable fruit in some other direction.

The ordinary rules of diagnosis for knee-joint diseases are so familiar to you all that I will not take up time in recapitulating them.

As to the treatment, it seems to be, mainly, rest to the joint, and nourishment to the patient. Operation will seldom be necessary if the cases are properly treated early enough, and the nourishment of the patient is maintained at its highest standard. Tubercular disease of the joints is a self-limited one as a rule. According to Dr. Gibney's [2] figures its duration is three and one-half to four years.

I cannot take any more time with the details of treatment, medical and surgical, the proper consideration of which would call forth a very full and elaborate paper. I will close by calling your attention to the fact that the moderate and localized action of tubercular infection in the joints and glands, as compared to the more dangerous and fatal course of the same disease when it attacks the lungs or intestines, has led to the enunciation of some important hypotheses.

Mr. Keetley [3] has said "Time will kill local tuberculosis unassisted by the surgeon."

Mr. Watson Cheyne [4] pointed out in his lecture, delivered at the Royal College of Surgeons in June, 1892, "that in the human body the tubercle bacillus has often a hard struggle for existence, and often very little is required to turn the scale in favor of recovery."

König, of Göttingen,[5] affirms that with our improved methods of treatment at least one-half of the cases of bone tuberculosis recover without operation.

Osler, after commenting upon the comparatively benign course of what he calls scrofulo-tubercular manifestations, *i.e.*, tuberculosis of skin, bones, or glands, says that it has been suggested that these lesions depend upon the action of an attenuated virus, and adds "an attempt has been made by writers, particularly Morfan, to show that the scrofulo-tubercular lesions, when recovered from, confer a sort of immunity to pul-

monary tuberculosis, but the evidence is not yet very strong."

Adhering to the hypothesis which has been advanced in the early part of this paper, it might be said that the so-called scrofulo-tuberculosis lesions are the outbreaks of inherited tuberculosis, and owe the comparative mildness of their course, when contrasted with pulmonary or intestinal phthisis, to the fact that the causative bacilli have been a long time in the system, which has acquired a partial, in some cases probably a complete, immunity against them. Whereas in the acquired form of phthisis the bacilli attack an organism quite unprepared (whose cells have had no opportunity to elaborate the saving antitoxin) and quickly overwhelm the entire system.

This view is also supported by the fact that the number of bacilli in and about a tubercular joint is often so small; showing that, in spite of the months or years in which they have had an opportunity to multiply in the economy, they have actually increased very slowly, if at all, and that in their contest with the phagocytes they have lost much of their virility and probably numbers of them have perished.

The natural history of syphilis affords numerous similar examples. The acquired form of the disease is prompt, ostentatious, and violent in its action; the inherited form, on the other hand, is gradual, uncertain, and stealthy in its advent and duration. It may develop, and it may not, in the offspring of luetic parents. If it does develop its site is apt to be in the bones or deeper structures, and recovery may be spontaneous.

As the good surgeon Gross[1] was wont to assert that all scrofula was inherited tuberculosis, even so now the leading minds in medicine affirm the same thing, we endeavor to explain what this great observer noted and commented upon so accurately and clearly.

A CASE OF TEMPORARY AMBLYOPIA FROM CHOCOLATE.

By CASEY A. WOOD, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL, CHICAGO, ILL.

Visual defects, both temporary and permanent, are not uncommon as the result of alcoholism, nicotinism, and indulgence in "high" game and other forms of food impregnated with the products of decomposition; but, strange to say, one rarely or never meets with an amblyopia or an amaurosis the result of excessive tea-, coffee-, chocolate-, or cocoa-drinking—not even in those who are otherwise easily affected by these beverages. The following history furnishes an exception to this rule:

Dr. S——, aged fifty-four, has a family history of gout, from which he himself also suffers upon occasions, but apart from that he is, and for years past has been, in fairly good health. Owing to this gouty habit he has always exercised great care in his diet, particularly since sad experience has taught him that the slightest indulgence in alcohol or indigestible food is likely to be followed by inflamed toe-joints and other indications of activity upon the part of his hereditary enemy. He cannot, for example, drink more than a single glass of Rhine wine without bringing on an attack of acute gout. He exhibited, however, one symptom-complex the cause and nature of which remained, until about a year ago, an impenetrable mystery. At irregular periods, sometimes every week, sometimes at much longer intervals, he suffered from severe headaches closely resembling migraine. Their course and character were about as follows: The trouble began with a wheel-like, confused, whitish (not colored) mass rotating in front of both eyes. This body gradually increased in size and density until the whole field of vision was covered and he became practically blind. For ten minutes not even the largest objects could be perceived; there was merely perception of shadows or ability to count fingers at a few inches. After a short time outlines of the neighboring houses, of carriages and wagons, and finally of human beings on the street, began to loom up. In half an hour smaller objects were visible through the gloom. In from three-quarters of an hour to an hour the large scotoma seemed to entirely dissolve and the patient could see as well as ever. This attack was always accompanied by vertigo, intense nausea, severe pain in, and a sense of pressure upon, the head. Altogether the patient has had over a hundred such attacks, some of them very severe, from the effects of which he did not recover until the next day, while others might be regarded as partial or incomplete seizures, from which he recovered in a few hours. In every instance the illness resembled the description just given.

During the twenty years that cover the period of these attacks he has been treated for all sorts of ailments, with all kinds of remedies, by men in all parts of America and Europe, and with very little success. The attacks have been attributed to the influence of gout, wine-drinking, indulgence in various forms of indigestible food, to dyspepsia, to tobacco, to eye-strain, and to "derangement of the liver," for all of which evils he has been at various times, *secundum artem*, vigorously treated. The late Dr. W. F. Smith and the writer of this labored long and faithfully to render his visual acts as comfortable as possible, but the migraine persisted and the amblyopia visited him as regularly as before. As far back as 1882, he had suspected the agent that "upsets his stomach" to be candy, because as long as he refrained from eating sweetmeats of any sort he seemed to be almost free from the attacks. One day, about two years ago, he purchased some vanilla chocolate for his children, and as he is very fond of that comestible in any form, he ate a small piece. He was riding on a cable car at the time; when he reached the corner where he was to alight a partial attack came on, and he was obliged to sit on the edge of the pavement and wait until the blindness passed off before he was able to make his way home. This incident aroused his suspicions of the evil effects of chocolate. Subsequent observation, extending over the next year, proved to him that it was the chocolate *per se* that induced the attacks.

Vanilla, unless associated with chocolate, does not affect him. He often drinks it in his coffee and eats it with cake and puddings without the slightest ill effect. Nor does cocoa bring on his headache. Nor do any of the spices, like cinnamon, present in some chocolates, alone affect him. Candy of any kind, as long as it is not mixed or flavored with chocolate, he can eat with impunity. Chocolate in blocks, or as creams, or in cakes, or in suspension as a drink, or in ice-cream invariably precipitates an attack, whose severity is in proportion to the amount of the chocolate ingested He has been able to associate every seizure he has had for the past few years with the previous eating or drinking of chocolate in some form, and he has had no attack not preceded by indulgence in chocolate. He seemed very positive that a moderate indulgence in cocoa does not affect him.

I tried to induce him to make some further experiments with himself, having in mind the possibility of isolating the particular agent or agents in the chocolate which had produced the amblyopia; but although he is a man devoted to science, he did not feel inclined to suffer from such blindness, nausea, and headaches for the purpose of settling this question. It is now over a year since he has had a seizure, and this freedom from attacks dates from the time when he foreswore indulgence in any form of chocolate.

It is highly probable that the patient exhibits an idiosyncrasy against theobromine when that alkaloid is taken by him in sufficiently large doses. The insuffi-

[1] System of Surgery, vol. i., p. 287.

ciency of the dose and its lack of concentration is the reason he was not affected by the ordinary cocoa of commerce, which contains much less theobromine than chocolate, and is often adulterated with ground rice, sugar, barley, etc.

Whether the amblyopia be regarded as directly the result of the chocolate-poisoning, or whether it be considered as part of the so-called scotoma scintillans, matters very little. It establishes beyond a reasonable doubt the claim of Hocken[1] that chocolate occasionally affects the visual centres. Yet with this exception I have been unable to find elsewhere more than vague references to the toxic effects of cocoa or chocolate, so far as the eyes are concerned.

Hutchinson,[2] however, reports a case of caffein amblyopia, the symptoms of which resemble those of the amblyopia of quinine intoxication, and caffein is said to be chemically identical with theobromine.

Progress of Medical Science.

Non specific Lesions in Syphilities.—A common error is that many ills occurring in a syphilitic subject are treated as though they were of syphilitic origin. The fact that a patient has syphilis does not exempt him from non-specific disorders, yet the physician is very apt to jump to the conclusion that such disorders are the result of the syphilis, and to treat them accordingly. In many cases lesions on the tongue and oral mucous membrane in syphilitics remain unaffected by specific treatment, and the fact should be borne in mind that similar lesions may occur in persons who have not had syphilis, as the result of digestive disturbance. Even if they are syphilitic, such lesions may persist in spite of specific remedies, unless the digestive errors are corrected.

Leguminous Alimentation in Diseases of Digestion and Nutrition.—Dr. Bovet refers to the apparent connection between richness in albumin, or the nitrogeneous elements of plants, and organic phosphorus, these two seeming to run parallel. In the leguminosæ they are found in greatest proportion. One consequence of the association of phosphates with albumin (vegetable), and the "diffusibility" of phosphoric acid, is that food of this character (leguminous) is very readily dissolved and digested in the alimentary canal, even in the absence of the usual ferments. The presence of a relatively large amount of potash salts in this food is also noted. In the laboratory of Professor Hayem a dog was fed for thirteen days on an exclusive diet of "legumine," a soup free from salt. The result was first a marked decrease in its weight, amounting to one-tenth. An analysis of the gastric juice at the beginning and end of the experiment showed a marked increase in two most important values, namely, hydrochloric acid and chlorine. This may be interpreted as increased digestive power. A similar experiment on a patient, aged forty-two, suffering from chronic gastritis, slight dilatation, and loss of motor power of the stomach, weakness and emaciation, showed results altogether comparable to the above. At the beginning the gastric juice, although highly acid, was free from hydrochloric acid. At the end of two months the total acidity was not increased, while hydrochloric acid was present in almost normal amount. Digestion (previously slow and painful) no longer inconvenienced the patient. Neurasthenia was lessened, and she slept eight hours daily without awaking, something she had not done for a long time previously. In this case a certain addition of leguminous aliment was made to the otherwise unaltered ordinary diet. The author therefore considers leguminous food suitable and valuable as aliment in similar cases, and also in diabetes and obesity.—*The British Medical Journal.*

Hypertrophied Prostate and Resection of the Vas Deferens.—At the French Surgical Congress recently held in Paris, M. Guyon read a paper on the above subject. He said that the solidarity existing between the testicles and the prostate gland was purely functional, for the circulation and enervation of both of these glands were independent, and different in their origin. It was consequently natural to suppose that the physiological isolation of these organs by the suppression of the vas deferens would be sufficient to obtain effects analogous to those realized from ablation of the testicles He practised, last June, bilateral resection of the vas deferens on two patients, the first of whom had suffered for ten years from incomplete retention, and when, last summer, he consulted the speaker, micturition became so imperious that the catheter had to be constantly used, and which more than once wounded the canal in effecting a passage through the prostatic portion of the urethra. Rectal examination revealed considerable hypertrophy of the prostate. A few days after the operation the frequency of micturition diminished notably, and the catheter could be passed with more ease. At the end of a month the gland had decreased in volume. The second patient came to him in about the same condition, and the operation gave a certain relief, but the prostate had not changed much in volume. In both patients the testicles remained normal. His colleague, M. Leguen, performed the same operation on a patient a month later, who had suffered from complete retention for a month previously. The results of the operation were quickly manifest; the man was able to dispense with the use of the catheter for ten days at a time, a month after the resection. In concluding, M. Guyon said that the above operation, although it could not pretend to the radical cure of hypertrophy of the prostate as that of total castration, yet it might take rank among those measures addressed to certain complications of prostatism.

Simple Manner of Overcoming the Catarrh Consequent on the Administration of Potassium Iodide.—Dr. Cohen (*The Lancet*) has often observed that patients taking iodide of potassium suffered in a marked degree from "iodism," the chief symptoms being coryza with a sometimes profuse discharge, sneezing, pains over the frontal sinuses, swelling of any part of the mucous membrane of the mouth, and a sense of heat in the chest. The foregoing phenomena are identical with those attendant upon the inhalation of free iodine (Mitchell Bruce), and it has been observed that one is more likely to be attacked with catarrh if the iodide of potassium contains free iodine as an impurity. This seems to justify the belief that the catarrh of iodism is due either to iodine being secreted by the salivary glands, or to the circumstance that iodide of potassium is broken up in the mouth after its secretion and free iodine liberated. The latter view is supported by Schmiedeberg, who has proved that iodide of potassium in the presence of carbonic acid is decomposed, the latter being abundant in the expired air in the region of the salivary glands. While taking charge of Dr. Herschell's out-patients at the National Hospital for Diseases of the Heart, the writer has been able to stop the catarrh in three well-marked cases by adding to the mixture (being in each case ten grains of iodide of potassium and half an ounce of water) five minims per dose of tincture of belladonna, his object being to reduce the salivary secretion, and in each case the result was satisfactory. Any antisialagogue would doubtless have a similar effect, but belladonna is, in his opinion, the most useful, as it can easily be given in the form of a mixture with the iodide, and in the small dose that is used in such cases, it counterbalances the so-called "depressant" action of the potassium.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, December 14, 1895.

REFORM IN THE DEPARTMENT OF PUBLIC CHARITIES.

In the early days of the present reform administration of our city government, we took occasion to suggest, from a medical standpoint, the qualifications which the Commissioners should have for the proper performance of their duties. We stated that the affairs of this department were threefold in character, viz.: 1, Medical supervision of hospitals; 2, supervision of the penitentiary and its inmates; and 3, the general business of both branches of the service. A thoroughly qualified commission would therefore consist of a physician, an expert in the care and management of criminals, and a business man. The appointments which soon followed were made on the old lines, and the outcome is what was anticipated. Not only no reforms in the management of the institutions of the Department have been made, but a most deplorable muddle of the medical service has been created which has aroused the opposition of the entire profession.

The separation of the Department, under the law of last winter, into two Departments, one of Charities, and the other of Corrections, and the necessity of the appointment of three Commissioners of Charities, raises again the question of the qualifications of the new Commissioners. The events of the last few weeks in the management of the medical service of the hospitals of the Department emphasize our previous arguments in favor of having in the Commission at least one competent physician.

We are only too familiar with the objections which laymen will raise, viz., that medical men never agree, and hence a Medical Commissioner will prove to be a disturbing element in hospital management. We might reply that it would be quite impossible for a medical member of the Commission to create in our profession a greater and more general dissatisfaction with the management of the hospitals than has the present Commission of laymen. But we shall not quibble over matters of so little importance. Our contention is based on the undisputed principle which should govern all appointments in the Civil Service, viz., the individual qualification of the person appointed to perform the duties of his office in a manner best adapted to secure from that office the largest amount of public good. It follows that the man who is best qualified for any position in the Civil Service is one who to honesty, education, mental capacity, and industry, adds the greatest familiarity with all the duties of the office to which he is appointed. This formula is the very corner-stone of all our Civil Service regulations.

Let us apply the above principle to the selection of a Commissioner for a Department composed chiefly of hospitals. It must certainly be admitted that a medical man has far more special knowledge of the affairs of an hospital than a layman of even the highest intelligence, who has not devoted himself to hospital management. If, in addition, the physician has had a large personal experience in the internal service of hospitals, and has a high rank in his profession, can there be any doubt that the public interests would demand his selection?

But, it will be asked, can a physician be found who has had the necessary hospital experience, and has the confidence of the medical profession, and who would serve if appointed? We answer yes; there are at all times available physicians in this city, of age, experience, and reputable standing, who would serve, and whose appointment would be received with profound satisfaction by the medical profession and the public. And we may add that such physicians would, by their large knowledge of the medical profession, and the requirements of hospitals, harmonize all interests, and avoid the disgraceful dilemma with which the present Commission is wrestling.

We do not hesitate to affirm that the present evils which afflict the Department of Charities are due to the absence from the councils of the Commission of a competent medical member. Nor will those great fundamental reforms on which the future renovation and elevation of the Charities service depends be effected until the head of the Department is itself renovated and elevated by the appointment of at least one thoroughly qualified medical Commissioner.

MIRACULOUS CURES.

THE annual pilgrimage to Lourdes in August last was larger and attracted more attention than any that has taken place for many years. This was possibly in a measure the result of the advertisement, so to say, of the Grotto in Zola's latest work, or perhaps it was a protest of believers against the almost contemptuous scepticism therein avowed. As was to be anticipated from the greater concourse of people and the greater exaltation of the expectant multitude of sick, the number of cures obtained through the agency of the miraculous waters was larger than usual. That in very many cases these cures are genuine and permanent, there can be, in the face of a mass of competent testimony, no question whatever. How these cures are effected we cannot say. The statement that the healing takes place through the influence of the mind upon the body, that it is a result of expectant attention, is satisfactory as far as sound goes, but it explains nothing. The argument-closing contention that the miracles of Lourdes are an evidence of divine favor and that the cures are from the hand of God, is too inclusive. Phenomena of the same order, the genuineness of which are attested by competent medical witnesses, have been observed in faith-cure conventicles and Christian-science

homes, and if the recoveries at Lourdes are supernatural, so must be faith-healing and the cures wrought by Francis Schlatter. Furthermore, miraculous cures took place in the temples of Æsculapius ages ago, in apparently the same manner as now at Lourdes, and votive tablets on the walls of the temples bore witness to the miraculous restoration of sight to the blind and to cures wrought by the hands of the gods.

Dr. Edward Berdoe, of London, writes of these miracles of healing in the October number of the *Nineteenth Century*, and discusses the explanation of them as far as they can be explained. He quotes Charcot, who regarded faith-cure as an ideal method, often succeeding where other means have failed, but says that, while of a scientific order, its domain is limited; for, "to produce its effects, it must be applied to those cases which demand for their cure no intervention beyond the power which the mind has over the body. Purely dynamic diseases are cured by this means, but not organic maladies. Ulcers and tumors may be caused to disappear if such lesions be of the same nature as paralysis and other disorders of motion and sensation." The writer refers to an analysis made by Littré of seven miracles which took place at the tomb of St. Louis in the thirteenth century. In this analysis he says Littré states the simple facts as given in the chronicles of the period, and endeavors to give a pathological interpretation of them. He notices, in the first place, that at the moment of cure the patient felt a sharp pain; the part affected seemed to be stretched, and sometimes a sort of cracking sensation in the bone was experienced; then movements became impossible, although the lengthening of the limb and the possibility of moving it freely were not experienced immediately. The cracking of the bone is just what the surgeon finds when he moves a joint which has become fixed by disuse; without breaking down these adhesions he can do nothing to restore the articulation. In cases of rheumatic paralysis a similar state of things is observed. Of course, in the accounts of the healing at the tomb of St. Louis we expect to find errors and exaggerations due to the preoccupation and ignorance of those who wrote the reports, but we at once recognize the cracking and the pain as genuine pathological details; we should not expect a natural cure without these symptoms. M. Littré explains that we have here a muscular action of the affected part; the muscle contracts energetically; it breaks down the pathological adhesions if they exist; it restores the bones violently to their place. What the surgeon has to do with his hand is here done by an influence exerted on the muscles themselves, and in a far more beneficent manner than surgery can effect. The exciting cause of these energetic contractions is that which we find in all miracles of this sort—a strong persuasion, a complete confidence. "It is the brain and feeling generated by the mind which give strength to the person who thinks strongly. A gouty man, who has long hobbled about on his crutch, finds his legs and power to run with them if pursued by a wild bull. The feeblest invalid, under the influence of delirium or other strong excitement, will astonish her nurse by the sudden accession of strength she may exhibit."

THE USE OF SHORT-HAND IN MEDICINE.

What seems at first glance to be a curious little sidepath in the history of medicine and of medical associations, is the establishment in England a year ago of the Society of Medical Phonographers. What in the world, one is tempted to exclaim, does a physician want with short-hand! Hasn't he enough to do without burdening his mind with a new art, and one that can have no relation whatever to the science or art of medicine? But the arguments of the founder and supporters of this new society, which now numbers nearly two hundred in its membership, cannot be thus dismissed off-hand. The mere fact of the existence of such an association is an evidence that those who use short-hand find it so helpful to them that they are willing to be at some pains to extend its benefits to others. In his inaugural address before the Society, the President, Dr. Gowers, presented the claims which the science of phonography has to the attention of medical men, old practitioners as well as first-year students; and possibly it may help along the work, which we cannot but regard as a good one, if we review briefly the speaker's arguments for the benefit of those who may never have heard of the Society of Medical Phonographers.

The need for writing, for a written record, is absolute in medicine as in every science that rests on observation, for memory cannot be trusted, and immediate record can alone make observation effective. But with the aid of short-hand twice the amount of record that is possible with long hand can be made, and yet there will remain a longer time in which to observe. Furthermore, many fleeting events which might escape record in long hand can be noted and preserved in memory forever by the winged characters of phonography. As was well said by the Bishop of Hereford, in a letter read at this same meeting: "Short-hand puts a new instrument into the hand of the observer, an instrument which must be specially valuable when you have to deal with subtle and quickly changing phenomena."

Thus the observer, having the means at hand for recording the evanescent phenomena, gradually acquires the habit of looking for them and observing them. Short-hand is like a lens that brings to the consciousness of the observer many minute but most important points, that would possibly otherwise escape him. The often-quoted words of Bacon, that "writing maketh an exact man," acquire a fuller significance when the writing is short-hand writing.

But the use of short-hand does not stop at the record of observation. "It is equally available," says Dr. Gowers, "with the same saving of time and labor, in the processes of comparison of observations, of epitomizing the facts observed by others, and in all the preliminary work of composition. Indeed, I have frequently written the final copy in short-hand; typewriters transcribe it with accuracy."

It may be thought that these remarks have little application to the work of the practitioner, but, on the contrary, the value of short-hand in medicine finds, perhaps, its greatest expression in the aid it can give to the practitioner. "Without the use of writing, the facts

that pass before him will leave only a transient furrow on the sands of unaided memory, vanishing for the most part when new facts disturb the surface, or at most leaving but a slight modification in mental tendency. The vast effect of unrecorded—and therefore unconsidered—'experience' is too often a warping of judgment by the influence of some striking but exceptional fact, conspicuous in vague outline in the memory, while the conditions essential to its interpretation are forgotten. Only habitual, immediate record can preserve from these dangers the 'personal science' on which depends the work of the practitioner and the welfare of his patients. For this result the record of that which is observed must of course be utilized, and so arranged that its value shall not be lost. Yet the mere process of record gives, as we have seen, precision to observation, and secures retention not otherwise to be obtained."

Of course, there are objections that may be urged against the use of short-hand, but the drawbacks are slight in comparison to the advantages of the accomplishment. The contention that note-taking weakens the memory is an objection that applies equally to the taking of long-hand notes. Few men, if any, have a memory that never plays them false; and, moreover, it is the experience of most people that writing down a fact helps to fix it in the memory. Another objection, and really the only one of any real force, is that neither the student nor the practitioner can spare the time necessary for the acquirement of a ready knowledge of short-hand. But anyone can learn to write with sufficient rapidity, say three times that of long-hand, by practising two hours a day for two months, and the one hundred and twenty hours thus spent will be saved and repaid several times over in the next two years. Short-hand is illegible is another objection urged against it. But the experience of those who use it is that it is not illegible when written carefully and at a moderate speed. The notes of a stenographer making a verbatim report of a political meeting may perhaps be illegible to all but himself; but short-hand can be written with three times the speed of long-hand and be fully as legible, not alone to the writer but to all phonographers, as long-hand.

Dr. Gowers deserves the thanks of all who are interested in the advance of medical science and of individual progress for his disinterested labors in promoting the diffusion of a knowledge of short-hand among members of the profession, and we hope that he will find his reward in the prosperity of the Society which he has founded, and which has honored itself in choosing him as its first presiding officer.

Dr. S. Arthur Bosanko, of Leadville, Colo., died in that city on November 23d, of pneumonia. Dr. Bosanko was born in Aurora, Canada, November 25, 1855. He received his medical education at the University College of Victoria and the University of Toronto, receiving degrees from both colleges. After practising for a time in Michigan he removed to Colorado, where he resided up to the time of his death. He leaves a widow and one son.

News of the Week.

Medical Staff of the Board of Fire Commissioners.—The Medical Staff of the Board of Fire Commissioners of New York City, consisting of four gentlemen, have resigned, and a new set of physicians have been appointed. The salary for these positions is $2,000 a year. The following are the new appointees: Dr. Fred. A. Lyons, Dr. Edwin B. Ramsdell, and Dr. Francis M. Banta.

Microscopical Diagnosis of Infectious Diseases.—The city of Paris has gone a step further than the city of New York, and has decreed that the diagnosis of all diseases due to known micro-organisms shall henceforth be undertaken at the bacteriological laboratory of the city, and that any practitioner can send his specimens there and have the examinations made *gratis*.

The New York School of Clinical Medicine, located at 328 West Forty-second Street, and modelled after the Berlin Docenter Verein, has just issued its first announcement. An important feature of the new school is the fact that the classes being small and limited, the matriculates act as assistants and have an opportunity to personally study the cases under the guidance of the teachers. The names of most of the faculty are familiar, having been connected with the leading hospitals and schools as professors and instructors. Those thus far appointed are—Professors, Beck, Bushe, Dessau, Garrigues, Goelet, Gottheil, Oppenheimer, Skeel, Valentine, Weiss, and Zemansky; Associate Professors, Louis Fischer, George Lindenmyer. The secretary of the faculty is Dr. Ferdinand C. Valentine.

Dr. Charles W. Allen's Article on "Erysipelas," in our issue of November 23d, was not read before the American Medical Association, but at the recent meeting of the American Dermatological Association.

Adulterated Boots and Ulcerated Throats.—Adulteration has spread to everything, and it has not even spared the shoe. According to a London contemporary there are such things as "adulterated boots." Certain classes of cheap boots are said to be made up with a kind of spongy diaphragm of shavings and sugar between the inner and outer sole. This spongy diaphragm, once damp, never gets dry, and as the result, people who wear these shoes are liable to sore throats, rheumatism, colds, and so forth.

Maragliano Serum.—We learn from the *Boston Medical and Surgical Journal* that an Italian physician of this city, who attended the recent Medical Congress in Rome, brought home with him some of the antitubercular serum prepared by Professor Maragliano. He has used it with, as is claimed, favorable results in three cases. The impression, however, gained from European exchanges, is that this serum is of no value.

Sanitary Science is extending its domain every day. The city of Montpellier, in France, has given peremptory orders that no article of food shall be delivered by the grocers and butchers of that town unless it is wrapped up in clean wrapping-paper, and this new wrapping-paper must not be colored.

A Fee in the hand is worth two in the book.

The Therapeutical Laboratory attached to the ward of the Hôpital Cochin, which used to be under the charge of the late Dujardin-Beaumetz, has been transferred to the Hôpital de la Pitié. It will be under the charge of Dr. Albert Robin.

Dr. Harrison Allen has received the title of Emeritus Professor of Comparative Anatomy in the University of Pennsylvania.

Mr. Young J. Pentland, of Edinburgh, is the only medical man in Great Britain and Ireland who has subscribed to the *Index Medicus*.

Physicians and Euthanasia.—The *Medical Magazine* calls attention to the fact that at a certain Medico-Legal Congress, held in this city last summer, a lawyer read a paper in which he maintained the right of the physician to end the agony of a patient whose recovery was impossible, by giving drugs; and he added that he knew physicians who did follow such practice. The *Chicago Times-Herald*, commenting upon this, said: "It may be conceded that in a few cases, such as acute mania or hydrophobia, where the patient is suffering from a pitiless malady without hope of relief short of death, the physician has taken the responsibility of ending the agony by administering an over-dose of opiates. It is well known that during the war surgeons sometimes gave the *coup de grâce* to tortured victims of battle." The *Medical Magazine* expresses regret that the medical press in this country should not attack the statement with the vigor that they expected, and wonders if American physicians do really thus produce euthanasia. We suspect that the real reason why the American medical press did not notice the discussion referred to was because it did not seem worth while to pay attention to such criticisms.

United Medical Societies.—The Chicago Practitioners' Club and the Doctors' Club have united under the title of the Physicians' Club.

Dr. John S. Billings, United States Army, retired, has been presented with a purse of $10,000 by physicians, in recognition of his valuable services in issuing the *Index Catalogue*.

Thanks.—The New York MEDICAL RECORD has come to our table for so many years that we miss it if it is a day late, and without it something would be seriously lacking in the enjoyment of professional life. We have become so acquainted with the spirit of its editorials that we have found pleasure in alternately agreeing and disagreeing with its utterances. It is so old and so familiar a friend that we at all times feel the most perfect composure and ease in praising and abusing it. While it now takes a seeming relish and pleasure in assailing the railway surgeon, still we have become so educated that its complaining murmurs of disapprobation rather soothe and lull us with the thought: "Oh, it is the Record." We have, however, never doubted its able conduction nor its great capacity for usefulness. It has been a great educator in our country, and while we reproach it at times, still we fully appreciate its greatness.—*The Railway Surgeon.*

The French Congress of Surgery.—This Congress, which met in Paris recently, is spoken of as being a scientific success, but we note from our Paris contemporaries that there were certain phases of the affair that were not entirely pleasant. The visitors complained that the Paris surgeons did not give them good opportunities to see the work in the great city hospitals, and a still more bitter cry went up from the fact that the sessions of the Congress began at eight o'clock in the morning, at which time, we are informed, all good Parisians are in bed. The consequence was that at the time when the scientific work began, only thirty or forty out of the two hundred members of the Congress were present. Eight-o'clock sessions of scientific meetings would certainly not be popular in this country, particularly the day after the banquet.

The organization of the scientific work seems to have been well planned, and the Congress discussed nearly every surgical question, beginning in the head and ending in the toes. The surgical treatment of the lungs, of the heart, of affections of the stomach, of the liver, and of the kidneys, of the urethra and genito-urinary organs, diseases of the joints, fractures—in fact, the French Congress of Surgery spread itself out over the whole human anatomy, and a perusal of the proceedings is suggestive of a systematic treatise on the surgical art. A number of new cases, results of difficult operations in the various surgical fields, were reported, but we do not find any particularly new methods of treatment suggested.

Suits Against Physicians.—A suit for $20,000 damages against Dr. W. O. Roberts, of Louisville, was recently thrown out of court, and in a suit for $5,000, brought against Dr. L. S. McMurtry, the jury awarded Dr. McMurtry a counter-claim of $500 for services rendered the patient.

A New Laboratory for the University of Pennsylvania.—On December 4th, the Pepper Laboratory of Clinical Medicine, connected with the Hospital of the University of Pennsylvania, was formally opened. Dr. J. S. Billings, director of the University Hospital, presented the building to the University in the name of Dr. Pepper, and Professor W. H. Welch delivered the principal address. Drs. Draper, Delafield, and Janeway, of New York, and Drs. Osler and Abel, of Baltimore, were present.

Obituary Notes.—Dr. D. M. MILLER, of Elizabeth, N. J., died on December 3d.—Dr. JOHN A. JONES died at his home in Mansfield, O., on December 3d, aged sixty-four.

The New York State Board of Health and Infected Milk.—The Board of Health of the State of New York has decided to submit and recommend to the Legislature a bill forbidding the sale of milk containing tubercle bacilli. The bill will require those who sell milk to show that their cows are free from the disease in question. A proof will consist of a certificate, issued by the Board or its authorized agents, after an examination made by competent persons.

Bureau of Public Health.—In the House of Representatives, Mr. Mahon, of Pennsylvania, has introduced a bill establishing a Bureau of Public Health in the Treasury Department, to provide measures of security against the introduction of contagious, and spread of epidemic, diseases.

Reviews and Notices.

MEDICAL DIAGNOSIS WITH SPECIAL REFERENCE TO PRACTICAL MEDICINE. By J. M. DaCosta, M.D., LL.D., President College of Physicians of Philadelphia. Eighth Edition. 8vo, pp. 1104. Philadelphia: J. B. Lippincott Co. 1895.

THIS well-known and classical work appears in its eighth edition considerably amplified and altered in its various parts. The general arrangement is the same as in former editions, the diseases being classified in accordance with their more prominent clinical features, rather than arbitrarily arranged in reference to their leading pathological lesions. Nothing is left to be desired by the student who wishes to study salient features in comparison with others common to similar diseases. The lines of distinction are clearly drawn by the hand of a master, and the student is led to that line of broad and conservative reasoning that is in itself a special mental training for a conception of the higher duties of his calling as a discriminative and accurate diagnostician. There is also incorporated whatever of purely bacteriological interest that is valuable for the leading purposes of the talented and broad-minded author. The introduction of a number of additional original cuts gives a special value to this admirable treatise.

THE PATHOLOGY AND SURGICAL TREATMENT OF TUMORS. By N. Senn, M.D., Ph.D., LL.D., Professor of Practice of Surgery and Clinical Surgery, Rush Medical College. 8vo, pp. 709. Philadelphia: W. B. Saunders. 1895.

THE appearance of such a work as the one indicated in this title is most opportune. The well-known capabilities of the author, his large clinical opportunities, and his painstaking investigation of pathological phenomena, eminently fit him for the task he has undertaken. There is no doubting the fact that the special department of surgical pathology of which the volume treats has hitherto been much neglected, and that the time is ripe for its wider consideration and its more accurate study. This condition has been very satisfactorily met by the exhaustive manner in which the whole subject is studied in its broader general aspects, as well as its detailed modifications as applied to special forms. In design and execution the work is such as will appeal to every student who appreciates the logical examination of facts and the practical exemplification of well-digested clinical observation. The general complexion of the work is didactic, and considering its aim to impress leading facts, is excusably reiterative and dogmatic. Scattered throughout the text are italicized sentences and paragraphs that are impressed upon the reader as axioms, and as such serve an excellent purpose. The division of tumors is on a purely histogenetic basis, and their study is conducted on clinical lines as well. The author does not believe in the *de novo* origin of tumors, but very ingeniously and quite satisfactorily proves that they are also due to the development of a matrix of embryonic cells, and that there is nothing whatever in the microbic theories. The broad distinction between the benign and malignant tumors, in that the former is always encapsulated and the latter infiltrating, is impressively stated with many necessary repetitions. Each particular variety of growth is minutely described from histogenetic, anatomical, and clinical stand-points, with a liberality of illustration which creates a most attractive feature. The descriptions of operative procedures are also profusely illustrated, and many show the different stages in a manner that cannot fail to be highly instructive to the practical surgeon. Altogether it is a broad book, full of interesting facts, eminently sound in its pathology, and founded on an exceptionally large experience of a conscientious and painstaking observer.

A MANUAL OF OPERATIVE SURGERY. By Lewis A. Stimson, B.A., M.D., Surgeon to New York, Bellevue, and Hudson Street Hospitals, and John Rogers, Jr., B.A., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, New York. Third Edition. 12mo, pp. 598. Philadelphia: Lea Brothers & Co. 1895.

THIS compact, tersely written manual has been almost rewritten in the laudable effort to note the important changes in the science and practice of operative surgery during the past ten years. A number of the useless operations described in former editions have been omitted, and a number of new ones which have proved valuable have been inserted, notably those referring to the abdomen and cranium. The illustrations are plentiful, and the descriptions of technique are admirable for their clearness.

BULLETIN NO. 8 OF THE HARVARD MEDICAL ALUMNI ASSOCIATION. Report of the Fifth Annual Meeting held in Boston, June 25, 1895.

WE are always glad to read these after-dinner speeches, even if we cannot always laugh where [laughter] is indicated. One can learn much from them, and it is interesting to know just where the Harvard man puts in his applause. The general style of the bulletin is surely attractive and creditable. The Association appears to be in a very healthy state.

SUPPLEMENT TO THE INTERNATIONAL ENCYCLOPÆDIA OF SURGERY. Edited by John Ashhurst, Jr., M.D., LL.D., Philadelphia. One royal octavo pp. 1130. New York: William Wood & Co. 1895.

THIS large volume, corresponding in size with the original ones which comprise the well-known series of the International Encyclopædia of Surgery, forms a becoming and exhaustive supplement of that work in presenting the latest and more advanced views of eminent authors on the various topics of newer interest in progressive modern surgery. No less than forty-eight contributors have written articles on fifty-five different subjects, that have been specially studied with the view of bringing them up to date in all essential and practical particulars. In such a view the work is a good and useful supplement to any treatise on surgery, and as a volume by itself it surveys a field of recent experience that is broad enough to give it a value, essentially and peculiarly its own, as a leading text-book for the progressive surgeon and advanced student. The arrangement of subjects has been judiciously made by the editor, and the spaces assigned to the writers are in accordance with the importance of the subjects on the one hand, and the amount of new material to be digested on the other. Commencing with a well-written digest, by Dr. H. C. Ernst, of the more recent views on inflammations, and more particularly from a bacteriological stand-point, there naturally follows one on Wounds and Wound Treatment, by Dr. Kammerer. This is a thoroughly exhaustive article, and gives ample evidence of a practical knowledge of the subject. The painstaking thoroughness of Dr. Kiliani in his chapter on Diseases Complicating Wounds will be fully appreciated by the reader. The experiences of Professor Conner in gunshot wounds will carry their due weight, giving in small compass the really essential methods of their modern treatment. Dr. Packard, on Poisoned Wounds, presents some new and interesting facts connected with their causes and treatment, especially such as are received in dissection and operation. Dr. Gaston, in his article on Hydrophobia, speaks earnestly, if not convincingly, of Pasteur's preventive method. Dr. Forcheimer, in a short chapter on Scrofula and Tuberculosis, lays the groundwork for the detailed treatment of their numerous manifestations as given by the writers who follow. Dr. Lewis Smith's article on Rachitis lays down those broader principles on which the more strictly medical treatment is founded. Dr. Wharton, on Abscesses and Ulcers, appropriately endorses the value of Thiersch's method as well as that of skin transplantation in selected cases. Gangrene and gangrenous diseases is the topic discussed by Dr. E. M. Moore, in his usually comprehensive and exhaustive style. Dr. Bouffleur contributes an exceedingly practical article on Anæsthesia, which shows wide reading and close observation. The more recent and approved methods of Amputation, special and general, are treated by the scholarly editor. The chapter on Tumors, by Dr. Curtis, is one of the leading features of the work, and is filled with all the newest observations on this always interesting topic. Dr. J. William White, on Venereal Diseases, confines himself mostly to the management of gonorrhœal affections, and leans strongly to the intra-prostatic management of all urethral discharges.

Dr. Sturgis, in treating of the non-specific venereal sore, very properly dwells on the very radical measures for its arrest, while Dr. Van Harlingen, on Syphilis, is equally happy in his clearly presented views regarding diagnosis. Dr. J. Abbott Cantrell's chapter on Diseases of the Skin and its Appendages has a unique value, in that it groups together some of the rarer and more interesting forms of these affections in a way that is eminently satisfactory. Dr. Ashhurst, in an article on Diseases of the Cellular Tissue, gives a very clear account of a set of troubles that are seldom grouped together. Following these are chapters on general and special injuries of the blood-vessels, lymphatics, nerves, bursæ

bones, joints, head, back, nose, ear, face, throat, neck, œsophagus, and chest, by various leading authorities. The articles on Intubation, by Dr. H. W. Wharton, on Injuries and Diseases of the Abdomen, by Dr. Van Der Veer, and on Intestinal Obstruction, by the Editor, are especially worthy of careful reading and earnest study. Dr. Hunter McGuire's Discussion of Diseases of the Bladder and Prostate is short and to the point, especially in so far as he omits all reference to the absurd method of castration for enlarged prostate. Dr. Keyes still leans to lithotrity as the usual method of treatment of vesical calculus, and makes some capital and suggestive remarks concerning the true value of supra-pubic lithotomy. The chapter on Injuries and Diseases of the Urethra, by Dr. Thomas R. Neilson, gives a very interesting account of the principles and practice of urethroscopy as an efficient aid to treatment. The Injuries and Diseases of the Male Genital Organs, by Dr. G. W. Davis, goes very thoroughly into the whole subject, and compresses in a comparatively small compass for easy reference a large amount of practical information. The technique of Abdominal Ovariotomy is presented from the modern standpoint by Dr. Charles B. Penrose, and deserved attention is given to supra-vaginal hysterectomy for uterine cancer. Dr. Robert P. Harris treats very fully of the indications and methods of modern Cæsarean Section and Symphyseotomy. Dr. Theophilus Parvin follows with Injuries and Diseases of the Female Genitals, and among other appropriate things in keeping with the general design of his topic, very clearly describes Tait's new operation for ruptured perineum; Wenckel's posterior colporrhaphia; Martin's elytrorrhaphia; Sanger's perinorrhaphy, and Sanger's substitute for Emmet's cervix operation. Lastly, Dr. Edward Cowles offers some excellent plans for the construction of the larger and smaller hospitals on an aseptic basis. The volume is profusely illustrated from original drawings and contains a well-executed chromo-lithographic plate of ulcerating mammary carcinoma.

History of Epidemics, with Reference to Animal Epidemics. By Dr. B. M. Lersch, Berlin. 1896. Pp. 4855. Published by S. Karger.

The writer says in his preface that the history of epidemics, from the oldest time up to the present, furnishes to the thoughtful physician much instruction upon the hygienic questions of to-day. There is no doubt about this, and we think that the author has supplied us with an extremely interesting and valuable work. The history begins with the references to epidemics in the earliest times in Egypt, Babylon, and China, but the systematic descriptions of epidemics date back no further than the Athenian pest of about 430 B.C. The author goes on from this time, century by century, describing the principal epidemics that have occurred, mainly in Europe. It is a sad record of the sufferings of human beings through ignorance of how to live healthfully, and how to prevent the spreading of disease when it has attacked a community.

A Noble Epitaph.—The scientific record of Pasteur is thus summed up on a marble tablet which was recently set up by order of the Paris Municipal Council in the old laboratory of the École Normale:

Ici fut le Laboratoire de Pasteur.

1837.—Fermentations.
1860.—Générations spontanées.
1865.—Maladies des vins et des
1868.—Maladies des vers à soie.
1881.—Virus et vaccins.
1885.—Prophylaxie de la rage.

A New Journal on Diseases of Children.—We have received the first number, dated January 1, 1896, of *Pediatrics*, a journal that will speedily win for itself the favor of workers in children's diseases, if it succeeds in maintaining the excellence of its initial number. The editor is Dr. George A. Carpenter, of London, and the owner Dr. Dillon Brown, of this city. The staff of collaborators includes such well-known names as Jacobi, Forchheimer, Eve, Boas, Grandin, J. Nevins Hyde, Dawson Williams, Joseph Collins, and Gowers. The contributors to this first number are Jacobi, Fruitnight, Lilienthal, Phelps, Sutherland, Manges, and Collins. The cover of the journal is strikingly original and neat, and the illustrations are very good.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual and Stated Meetings, November 25, 1895.

Egbert H. Grandin, M.D., Later E. D. Fisher, M.D., in the Chair.

Annual Dues.—On motion of the treasurer, Dr. John S. Warren, the annual dues were made three dollars, as usual. The comitia was empowered to expend such money as was necessary to defray the expenses of the Society.

Report of the Committee on Hygiene.—Dr. George B. Fowler read the report. He first pointed out the earnest efforts of the city authorities to keep the streets clean, and the needed aid which the Board of Health had given the Street Commissioner, by allowing him a sum of money to meet a prospective deficiency in his department. The health and hygienic condition of the city was almost wholly in the hands of the Health Department, and with the proper support of the medical profession, there could be no doubt but what it would yet largely control many forms of disease which at present added greatly to the death-rate. During the past twenty-five years the death-rate had been gradually reduced from 33 to 20 per thousand. The new tenement-house work was destined not only to reduce the mortality among the poor, but also to increase the standard of intelligence and citizenship. The importance of the public baths was dwelt upon, the only one in the city having ten baths had been used during the three years of its existence 219,000 times. A number of these were to be erected through the city, fifty by one hundred feet, each to contain eighty-six baths. There were also to be established as many as one hundred public urinals and water-closets.

The next subject touched upon was the use of antitoxin by the Board of Health for the purpose of curing and preventing the spread of diphtheria. The reports from European countries, and from Dr. Biggs, of the Health Department in this city, appeared to show very favorable results from antitoxin, but Dr. Fowler thought they were not yet conclusive. We were not justified in accepting laboratory and special hospital experiments while ignoring the results of vast clinical experience. We had to await further observations, meanwhile testing the value of modern methods in order to keep abreast the times.

The Medical Directory.—Dr. Daniel Lewis, Editor of the *Medical Directory*, read his report. An additional expense had been assumed in publishing the list of physicians in New York State, New Jersey, and Connecticut, yet there was a balance to the credit of the Society of $152. The book had a wider circulation than any previous year. Members were requested to notify the editor of any errors or alterations which should be made.

Address of the Retiring President.—Dr. Egbert H. Grandin, in relinquishing the office of president to his successor, said:

Gentlemen: The Society year which is expiring, it seems to me, may rank with its predecessors in that it has maintained the Medical Society of the County of New York as the leading society in the world holding stated meetings. The membership has been increased by one hundred and one. Death has laid his hand upon us with more frequency than usual, fifteen of the members having passed to their reward, each in his sphere having achieved something for the good of humanity and, in particular, of this community, and each meriting the words "Well done, thou good and faithful

servant." The attendance at the meetings has been of the most gratifying nature. The scientific papers presented have been of a high order of merit, brief and practical, and the selection of the papers has been with the aim of interesting the various special lines of work which are cultivated by the members of the Society. The special meeting held to protest against official folly as exemplified, in particular, by coroners, has borne fruit in that it proved that this Society did not propose to allow indignity to be inflicted on its members without forcible protest. The coroner system, however, is still with us. And yet this office is gradually hanging itself, on which occurrence this community may possess a system worthy of the age in which we live, instead of one which is the constant laughing-stock of the country. Under the revised constitution the legislators at Albany should find no difficulty in abolishing an office which is as useless as it is ludicrous.

Sufficient influence was in control at Albany last winter to side-track your resolution protesting against the wording of the law which prevents a medical man serving as president of the Board of Health of this city. The contention that this clause of the law is unconstitutional appears valid, in that it makes special exemption against the citizen. Further still, it must be obvious that a medical man is from education better qualified to serve as president of a Board of Health than the average bank president, clerk, politician, or what not. A medical president of the Board of Health, were the emolument of the office sufficient to enable a medical man of the right calibre to accept, would not only add lustre to the board, but carry the conviction that political influence could play no part in matters affecting the health of the city, whether it lay in the abatement of nuisances or the selection of competent subordinates.

The suggestions of your standing committees on Ethics and Prize Essay are so fresh in your minds, that I need do no more than acquiesce ; and yet, while referring to this matter of committees, I would state my conviction that the interests of the Society require that the chairmen of the committees on Ethics and of Hygiene should be members of the Comitia, in order that the officers of the Society may be in constant touch and sympathy with these committees.

The report of your counsel proves that, under the law signed by a liberal-minded Governor last spring, the Society is beginning to rid the community of the quacks and the impostors who fatten on the credulity of the populace, too often to its injury, if not death. Abortionists we are as yet unable to reach owing to the difficulty of securing evidence, although the leniency shown these offenders by the legal officers of the county, even though indicted, might well make us sceptical as to the utility of causing arrest, had we evidence. In accordance with instructions received from the Society steps have been taken, and the effort will be continued, to prosecute druggists who, holding no degree in medicine, practise and prescribe over the counter. Of course you appreciate the fact that all this entails the expenditure of considerable money, but the counsel believes that at the end of the year the receipts from fines will practically make the legal bureau of the Society self-supporting. Even if the reverse proves to be the case, the good accomplished justifies the Society in the extra outlay involved. It is to be regretted that in this county we have not the same power as, I am informed, obtains in at least another, of regulating the practice of midwives. Since these women, owing to the nature of our population, must exist, the community should insist that they possess at least the requisite qualifications, such as obtain in Austria, for example. Not only does puerperal sepsis still exist in this city, owing largely to the ignorance of the midwives, but *ophthalmia neonati*, with its frightful consequences, cannot be stamped out. While it is not within my province to make suggestions, I would express the hope that the Society may see fit to endeavor to secure proper legislation, looking to the registration of midwives after suitable examination. The *Medical Directory* of the Society has this year been enlarged, as has been stated by the Editor, so that the necessity for the publication of any other ceases to exist. Just so long as this *Directory* is given free of charge to the members of the Society it is impossible to eliminate what in the opinion of many members is objectionable, that is to say, the advertising pages. To express the opinion of an individual in regard to this question, I think it might be well to have future issues published without advertising matter, and that copies should be sold at as low a rate as will pay the expense of publication.

At the last meeting of the Society action was taken on an appeal from a decision of the Comitia, and the Society endorsed the precedent, that it was responsible for remarks made by its members, irrespective of the nature of the remarks. It would appear to me that this precedent is an exceedingly dangerous one to establish, although, as a member of this Society, I favor as strongly as anyone the protection of the rights of the members. The way out of the difficulty is for the Society to hold executive sessions, where the greatest possible latitude of speech would be allowable ; at any rate, members should be instructed to remember that, under the By-Laws, the officers of the Society, constituting the executive committee, should be consulted in reference to matters which might lead to litigation before such matters are introduced in public meeting.

At the same meeting a temperate protest against what many members of the Society deem an outrage, was presented and accepted by practically an unanimous vote. The matter of the protest is one which allows of honest difference of opinion, and yet it is one which, speaking from the stand-point of an unprejudiced individual, was bound sooner or later to force itself on the attention of this Society. In my address on the occasion when I assumed the position of high honor which I am on the point of relinquishing, I endeavored to show you how, if you each exerted your influence, you could most effectively and powerfully mould public opinion in the direction which, as professional men, you wish. I endeavored to point out to you that one reason why you carried little influence was because you little realized your power in obtaining your rights by, as a body, insisting upon them. Now that I am about to make the parting words in my career from a position of public honor and of great trust, you will pardon my frankness if I go further and tell you that outrage is inflicted upon you, and you do not gain what you deserve, because you do not act together for the good of one another. In the fifteen years that I have lived and practised among and with you I would have you believe that it has not been with closed eyes, even as I assert that it has been on an entirely independent basis. I naturally feel, therefore, that the conclusions I have reached should be definitely stated, even though not one of you here present to-night can agree with me.

In the years I have spent in this city I have seen the gradual evolution of a monopoly in medical circles such as, if it be not strangled, will render it difficult for all but the favored few to secure a livelihood out of the practice of medicine and of surgery. I have seen the dispensary arise in all quarters of the city, supposedly endowed for the care of the worthy poor ; I have seen hospitals stretching out their tentacles so as to include even the care of the worthy rich, although, under the ground of their endowments, they were only entitled to help the needy. Meantime the general practitioner—the bone and the sinew of our profession —has seen his income dwindle and his patients grow beautifully less, his panacea being the reading of the glowing annual reports of dispensary and hospital, showing the good done supposedly to the worthy poor, and to these alone. I am far from deriding the value

of both hospital and of dispensary; on the contrary, were I rich beyond the needs of those dependent on me, I might be tempted to open and to endow both hospital and dispensary. Conducted, however, they would be on the following cardinal principles: Only those entitled by reason of poverty could gain entrance, and the physicians and the surgeons and the internes who cared for these poverty-stricken sick would receive remuneration for the services rendered. The laborer is worthy of his hire, even though he be a medical man. When, if it so happened, the medical staff had dispute with Boards of Governors, right and equity being on their side, I would not tolerate, in the event of resignation for principle, the prompt filling of position by other medical men, giving rise to the utterance on the part of Boards of Governors, "the places are easily filled!" I would expect the colleagues of those who resigned to stand up for the principle at stake, and to make Boards of Governors the servants instead of the masters of medical men. On the medical man falls the labor, the anxious nights and days full of the greatest of all responsibilities—that of human life! Why, pray, should the medical man bear the trying burden only to receive that treatment which even the dumb animal would protest against? Stand together, therefore, brethren, where principle is at stake, and do not so quickly fill the places left vacant because of principle.

So much for the solution of the dispensary and the incorporated hospital abuse as viewed by a man who can talk freely because he is untrammelled.

Next, as regards the public hospitals of this city. The sympathy of this Society is certainly with the cause of higher education. Whatever will tend to turn out a better class of medical practitioners will ever receive the sanction and the active support of the Medical Society of the County of New York. As members of this Society and of the profession of medicine, we are proud of the record of our institutions for medical instruction. We realize that this city is destined to become the chief centre of medical instruction in the world; toward that end we all labor. But as members of the medical profession, can we rest satisfied with seeing a monopoly grow up in our midst, a hydra-headed trust against which our ancestors long ago protested? We are all tax-payers, are we not entitled to equal representation? When I say *we*, I mean the general practitioner.

Who is it that earns his living, often literally, by the sweat of his brow? It is not the successful hospital surgeon or the professor in the medical school, whose salary suffices to lift him above anxiety about the bread and the butter of his wife and his little ones. It is the general practitioner, and what with the illegitimate lending of aid to the well-to-do by hospitals and dispensaries, and the filling of private rooms in the former by those whose means and positions do not lend justification; and what with the passing of the charity hospitals beyond the reach of the average practitioner, who needs the experience there to be secured and the éclat of the titles, and who is just as solicitous for the well-being of the wards of the Commissioners of Public Charities as his more favored brother, the professor, can possibly be; if this sucking of everything into the maelstrom of monopoly goes on, what, I would ask you, is to become of *you*, the general practitioner?

From my stand-point, again an unbiassed one, for I have given up teaching and hospital appointment, each and every one of you should have the privilege of competing for positions in the public hospitals, so that you as well may acquire experience and do that which the minority are now alone able to do—show your ever-present solicitude for the health and the well-being of the wards of the city. Further still, as individuals, it seems to me you should exercise your undoubted influence in securing the appointment of Commissioners of Public Charities who, in matters which concern the entire medical profession, should seek the advice of the many instead of being under the domination of the few. The unselfish aim of the many is a safer guide than the self-seeking aim of the few. The entire profession feels a live interest in, we will say, the welfare of the babes on Randall's Island, and the voice of the entire profession might well be raised in protest against existing abuses, whether these abuses be due to parsimony or to negligence.

The utterance of these stray thoughts will be pardoned, I trust, in the face of the fact that I would deem myself dishonest did I not express them. I am not placing myself at variance with the opinion of any other to whom I willingly grant the credit of honest difference of opinion. I only crave exactly the same indulgence.

Gentlemen, for the favor shown me, for the cordial co-operation granted me, for the indulgence extended me, I tender my thanks. Whatever has been accomplished this year, the credit is yours.

You have chosen as my successor in office a man who has ever proved faithful to trust, and therefore he will serve you well. You have selected a man who has earned deserved reputation, and therefore he will add lustre to the records of the Society. Fearless and impartial, he will maintain you where I trust I have left you—on the topmost wave of prosperity and of renown.

It remains for me to declare the adjourned annual meeting adjourned *sine die*, and to introduce the President, Dr. Edward D. Fisher.

Address of the President-Elect.—Dr. Edward D. Fisher, in assuming the duties of presiding officer for the current year, thanked the Society for the honor which it had conferred upon him. He mentioned briefly the objects of the Society and the duties of the officers. The influence of the Society was great, and should not be thrown with undue consideration on either side of any question of importance which might be presented to it. We must resist being carried away by impulse. Papers presented before it should be of general interest, touching directly upon general medicine.

Committees.—Dr. Fisher appointed the following committees: On Hygiene, Drs. J. W. Brannan, E. S. Peck, E. Le Fevre, G. W. Jacoby, Dillon Brown; on Ethics, Drs. T. E. Satterthwaite, J. B. Tuttle, B. J. Knapp, N. E. Brill, H. Stern; Prize Essay, Drs. W. H. Katzenbach, D. B. Delavan, J. E. Weeks; Auditing, Drs. V. P. Gibney, George Woolsey.

Some Intra-nasal Causes of Headache.—Dr. James E. H. Nichols read the paper. A study of the causes of headache as given in the text-books on general medicine failed to reveal an adequate conception by general writers of the frequent etiological bearings which nasal disease had on this distressing affliction. Sinkler and Wood were quoted; also Foster's Dictionary. On the other hand, rhinologists and laryngologists frequently saw cases of headache in which the cause was a disordered or diseased condition of the structures within the nasal cavities. Attempts had been made to localize the disease by the area in which pain was felt, in most cases accompanied by tenderness on pressure. After quoting Head on these areas, he said that while they were undoubtedly present, they were not sufficiently definite to be of much value in diagnosis.

Ethmoidal disease was much more common than we had been apt to suppose, and longer and more obscure in its course. It was not necessary that there should be a profuse nasal discharge to indicate ethmoidal disease, but the situation of the exit of pus, and its intermittency and persistency were the points most valuable in clearing up such cases. A woman, aged twenty-seven, had suffered nearly twenty years from periodically recurring headaches of an extreme type, coming on nearly every week. The day following the crisis of the attack there would be a discharge of thin muco-pus, not

of large quantity, and not malodorous, and then there would be comparative freedom until another attack. Examination at the time of the attack showed the right middle turbinated hyperæmic and pressing hard on the septum, muco-pus coursing down. The head pain was over nearly the entire right side. The anterior extremity of the middle turbinated body was removed, and the ethmoidal cells entered. These were broken down, irrigated, and the frontal sinus was also washed out. Immediate relief was experienced, and after further treatment she was cured. He had notes of several similar cases, in all of which the headache disappeared as soon as the passages were opened and exit given the retained secretions. The headaches, he said, were not sympathetic or referred pains, but were due to pressure of the retained secretions, and were purely of mechanical origin. The author accepted the theory that the seat of pain in headache was not in the cortex, but in the meninges, and was due to vascular dilatation, producing intra-cranial pressure and compression of the dura.

Several cases were cited, showing disease of various localized areas in the nose, in all of which the chief symptom was headache. In one, the headache disappeared after removal of a piece of spongy, syphilomatous tissue springing from the septum and obstructing the superior meatus. In another case a school-boy had suffered from continued headache on the right side, which disappeared on removing a spur of bony tissue springing from the septum, projecting into the middle turbinated, of traumatic origin. This, the author said, could be recorded as a case of hyperæsthetic congestion induced by mechanical pressure. The next case was one of recurrent attacks of nasal stoppage, followed by profuse discharge of viscid fluid from right nostril, due to cyst of the inferior turbinated, removal of which cured attacks of severe frontal and orbital headache, most marked on same side.

Such of the very obscure causes of pressure as myxomata, hypertrophied turbinated bodies, and extreme deviations of the septum, need hardly be mentioned, but the obscurer cases of disease of the accessory sinuses must be thoroughly searched out. Of the latter kind the author related two cases.

It was a conclusion from his observation that headaches were more frequently of nasal origin than was generally suspected; that they were in the main of congestive variety, and due to interference with the circulation of the dura mater by pressure at some point in the nasal cavity, or accessory sinuses, induced by retained secretions and by hypertrophies of the membrane or abnormalities of osseous structure. The pressure was generally on some branch of the ophthalmic vein. Abnormal conditions in the inferior meatus induced free pains, but not cephalalgia. Headaches in which the area of intensity was about the orbit were most apt to be due to disease of the ethmoid cells and antrum. Successive attacks of a similar nature were generally of nasal origin.

Dr. Andrew H. Smith thought the explanation of headaches given by the author was hardly broad enough to cover the entire field. It was well known how often headache was reflex in origin from a distant centre; why not sometimes from a nearer point, as the nasal passages. All were probably familiar with the headache which was sometimes produced very suddenly by irritation of the nasal membrane on passing into the cold air, and he thought this was of reflex origin rather than of obstructive origin as described in the paper. Headache from pungent odors was another example of reflex rather than obstructive headache.

Regarding the seat of the headache, he recalled the case of a gentleman in whom it was in the occipital portion, while the cause was disease in the frontal sinus. The headache ceased with discharge of fluid from the frontal sinus.

Dr. A. Edward Davis made some remarks and confirmed the diagnosis in one of Dr. Nichol's cases, and the discussion was continued by Drs. Mayer, M. L. Foster, and Meyerhof.

Report of Special Committee.—The special committee appointed at the last meeting to present the resolutions then adopted, condemning the new arrangement for appointing medical boards in the public hospitals, to the mayor and to the commissioners, reported that copies of the resolutions had been sent the gentlemen, but no answer had been received, and the mayor had declined to see the subcommittee which had called upon him. The report was received and the committee discharged with thanks.

Civil Service and Hospital Appointments.—The following notice had been printed on the card announcing the meeting:

Resolved, That the Medical Society of the County of New York respectfully urges his honor Mayor Strong to place all appointments of visiting and assistant physicians and surgeons, and all salaried resident medical officers to all the hospitals, asylums, and other institutions now governed by the Commissioners of Charities and Correction, under civil service rules.

Dr. N. E. Brill moved the adoption of the resolution.

Dr. F. R. Sturgis seconded the motion. He said we did not come here as sore-heads because we had lost positions. The Commissioners of Charities had a perfect right to make the dismissals. But we wished to protest against the mode of making the new appointments. The old method had at least a semblance of fairness. Every member of the profession could present himself as a candidate under that method, although it was well known that the question of whether he be given the position depended not a little upon political influence. Under the new method no man who was not favored by his connection with one of three medical schools stood more than one chance in four of getting the slightest consideration in his desire to serve the city and reap the benefit of hospital experience. In the matter of the recommendations from the fourth division of Bellevue, supposed to represent the general profession, the Commissioners could hardly be expected to act impartially. It was said the change had been made in the interests of medical education. If this was the purpose of the Commissioners, they had transcended their functions. As a matter of fact it was made in the interests of a medical monopoly, and was planned by a few men connected with colleges, which in the past had done all they could to prevent the advance of medical education by opposing laws providing for a State Board of Examiners and regulating the practice of medicine. Forty years ago a society was formed in this city by a few medical men, whose aim was to control all hospital appointments and consultation practice. If the general profession to-day did not give heed to the warning, they would find their practice pass into the hands of this limited circle, or engulfed in the public dispensaries and hospitals.

Dr. Warden opposed the adoption of the resolution, more especially because if it were adopted the present appointees could not be removed.

Dr. A. P. Dudley opposed it for the same reason, and also because the demand would not be heeded, and our position would be worse than if it had not been made.

After a few more remarks the resolution was adopted.

Dr. J. Blake White moved that a committee, consisting of Drs. Roosa, Pryor, and R. A. Murray, be appointed to present a copy of the resolution to the mayor. Carried.

The Correspondence of the Insane.—The Assistant Postmaster-General has given the opinion that the authorities of Insane Asylums have the right to withhold letters from patients when it seems necessary to do so.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, November 28, 1895.

HENRY C. COE, M.D., CHAIRMAN.

A Contribution to the Study of Lactation Atrophy of the Uterus.—DR. H. N. VINEBERG read a paper on this subject. It was singular that in this country lactation atrophy of the uterus had received no attention; indeed the condition seemed here to have escaped observation. The opinion commonly prevailed that the uterus never returned after childbirth to the virginal size, unless as a result of pathological change.

The condition under consideration was not that which was usually known here as hyperinvolution. It was the form of super- or hyperinvolution accompanying lactation, with or without amenorrhœa, in which the reduction in size was temporary only, the return to the normal size being in some cases dependent on return of menstruation, in others on regeneration of tissue while lactation was still going on.

The author's attention had been drawn to the condition a few years ago, at the Mt. Sinai Dispensary, where he was struck by the small size of the uterus found in a great number of nursing women. In the majority there was no indigestion, malnutrition, trouble with lactation, or other disturbance. Further observation taught him that the atrophy was only temporary, the uterus again increasing in size. With the return of menstruation conception was likely to occur again, and in some it took place before recurrence of menstruation.

The two principal European writers on the subject were Engström and Thorn, and they were at variance as to the causation, the former attributing it to atrophy, similar to what occurred in constitutional diseases, like syphilis, while the latter regarded it as a normal process usually, and occurring even in robust women with hygienic surroundings. Dr. Vineberg's observations tended to confirm Thorn's views. Regarding what should be considered an atrophic uterus, the bearing organ should measure 7.5 to 8 ctm. Falling below that, it could be regarded as atrophic, and surely so when it fell below half the size of the nulliparous uterus, as he had known it to do.

Two varieties of atrophy had been recognized, the eccentric and the concentric, but they were really differences in degree. According to his observation the process affected both the body and cervix, and when the cervix was larger than the body it was apt to be due to some pathological change, such as that produced by laceration. He could not in his cases demonstrate noticeable changes in the size of the ovaries. Regarding how soon lactation atrophy might show itself, it had been demonstrable even as soon as the twenty-first day, his own measurements showed it present at a period from seven weeks to twenty months. Bimanual palpation by an experienced man gave more reliable information than the sound alone. In fact in eccentric atrophy the sound was apt to indicate the depth of the normal uterus. In his cases the minimum depth of the uterus was 4, the maximum 8 ctm.

These women were not anæmic; out of fourteen cases in which the blood was examined the number of red blood-cells fell below the normal only in one. Anæmic women were more likely to have subinvolution. The degree of atrophy in phthisis had commonly been over-estimated. Dr. Vineberg had seen a number of instances of conception take place during lactation, without intervention of the menstrual flow.

Our views of the anatomico-pathological anatomy of the uterus had to undergo a change in the light of recent research. Several authors were quoted, but in general Dr. Vineberg agreed with Saenger. Muscular fibres of the uterus did not completely disappear during involution, but simply atrophied, the function of lactation promoting this physiological process. Just how it did so was a matter on which opinions differed, but it was probably through nervous influence. The progress could be carried too far, yet out of at least two hundred cases of lactation atrophy seen by Dr. Vineberg there had been only two or three instances in which there had been permanent hyperinvolution. He recalled one case in which the atrophied uterus required twenty-five months to regain its normal size.

In the treatment of lactation atrophy keep up good nutrition, and do not allow the patient to nurse the child longer than the usual period. Dr. Vineberg thought many of the disturbances following pregnancy could be avoided if the physician would make it a rule to see his patients once a week, or two weeks, for three or more months subsequently.

In calling for discussion, the CHAIRMAN mentioned two practical points: the duty of the physician to see the patient several weeks after delivery; and the treatment of hyperinvolution.

Mothers, Nurse your own Children.—DR. RALPH WALDO said it was his custom to urge upon his patients the necessity for nursing their own children, not only for the benefit of the child, but because it hastened involution. When mothers did not nurse their own children the uterus was apt to remain in a state of subinvolution.

The CHAIRMAN remarked that subinvolution was supposed usually to follow laceration of the cervix; yet, as the author had shown, the uterus was sometimes unusually small, and a little further explanation of these cases might be well.

DR. VINEBERG said it was true that often where there was marked laceration of the cervix the body of the uterus was small, although the cervix might be large, even larger than the body of the organ. But where there was no laceration the cervix atrophied in proportion to the body. Dr. Waldo's remarks coincided with the point made in the paper, that it should be the earnest desire of the accoucheur to bring about this hyperinvolution. A uterus which was the size of the normal organ by the twelfth week of lactation had not undergone the full degree of involution.

Venous Thrombosis as a Cause of Sudden Death in the Puerperium.—DR. ELIZABETH CUSHIER read the paper, giving the histories of two cases of sudden death from thrombosis or embolism some days after delivery, and collating a number of others. Her own two cases were seen in 1878. The first was in a stout woman, who had entered the infirmary for her sixth confinement. The labor was normal, but a few hours after labor she experienced a severe pain and the uterus was found at the umbilicus. No clot was discovered. Ergot was given. The temperature at no time exceeded 99.5° F.; pulse, 80. The temperature, pulse, and respiration were about normal on the ninth day, and she was permitted to sit up. About eleven o'clock Dr. Cushier was sent for in haste; the patient had fainted. She found her unconscious, eyes fixed, pupils dilated, pulse full and regular, violent respiratory efforts. Consciousness soon returned, but soon the heart ceased to beat, and the patient gasped for air; the faradic current restored consciousness for a little, and she spoke intelligently, then turned on her side, when the heart and respiration ceased. The attack had lasted not longer than half an hour. Autopsy, four hours after death, showed venous clots in uterine and ovarian vessels, also clot occluding the pulmonary vein and causing distention of the right ventricle.

The other case was similar, but the patient had been under observation from the fourth month of pregnancy, and the urine had contained some albumin, the quantity increasing toward the end of gestation. Labor was slow, tendency to uterine relaxation, small child, not much loss of blood, rather free lochial discharge, and rather tardy diminution in size of the uterus, otherwise the lying-in was normal. The patient sat

up for a short time on the ninth day. On the morning of the tenth Dr. Cushier was called in haste, and on arriving found the patient dead. She had risen, sat on a vessel, uttered a cry, fallen over, and died in a few moments. Autopsy was made under difficulties, the kidneys were large and pale, but microscopic examination was not made owing to the fact that by accident they were placed in wrong fluid. The uterus was rather large, but the only clots found were in the saphenous vein of the leg and in the pulmonary artery, extending as far as its second division.

The object of the paper was to emphasize the importance of a knowledge of the facts connected with these cases with a view to their prevention. The cases collected by Sperling and by herself were used to show the frequent association of the accident and thrombosis of distant veins; that venous thrombosis was the result of changes in the blood; and that the blood coagulation might be prevented. The factors which favored blood coagulation in the veins of the puerperal woman were several: changes due to exhaustive hemorrhage; to septic material in the veins and lymphatics; formation of thrombi in the uterine sinuses previous to labor, as a result of partial separation of the placenta, when hemorrhage, instead of being controlled by contraction of the uterine fibres, must be arrested by coagulation of blood. The cases quoted from Sperling, about thirty-five in number, and those collated by herself, about twenty in number, showed one or more of these factors present as a rule. The frequent association of phlegmasia was to be especially emphasized, as it was present in at least twenty-eight or fifty per cent. of the number collated.

In analyzing the cases with reference to the possibility of foreseeing, and perhaps preventing, this accident of childbirth, note, 1, pre-existing infection; 2, association of the accident with premature separation of the placenta, and probably formation of thrombi in the uterine sinuses preceding labor; 3, general conditions which tended to interfere with normal retractility of the uterus, and the danger of powerful uterine contractions where inertia had previously existed.

The Chairman, on calling for discussion, remarked on the fact that sudden death in these cases occurred not immediately after labor, but several days after; also on the custom of some of letting the patient rise within twelve hours after labor, and the possible bearing this might have on the accident, or at least upon the responsibility reflected upon the physician.

Dr. Vineberg had seen none of the cases under discussion. He thought we should be guided by the condition of the uterus in deciding upon the time when the patient should be allowed to get up, and not follow any fixed rule as to time, say the customary one of the tenth day. He had sometimes allowed the woman to sit up before he thought it was advisable, on account of the condition of the uterus, and nearly always some trouble had followed. Where phlegmasia alba dolens had occurred his impression had been that there was some form of infection. His custom was to examine the uterus frequently to see that contraction had occurred and that involution was going on satisfactorily.

Dr. Ralph Waldo had observed that in Dr. Cushier's two cases the uterus had remained large. Like in many obscure subjects, he thought there were a number of etiological factors here. In many cases of labor there was a tendency to thrombosis, especially in the extremities, and thrombi becoming dislodged might go to the lungs and prove fatal. In view of the obscurity of the cases he thought we were hardly justified in making a diagnosis of thrombus of the pulmonary vein unless proven by autopsy. He would insist upon keeping a patient abed as long as the uterus was large, or there were thrombi in that organ or the veins. He believed the notion that a woman should always get up by the ninth day had cost many lives. The patient should be allowed to get up and go about only after having returned to normal condition, just as after some disease.

Dr. George W. Jarman said that when he was hospital interne he had seen a number of cases of phlebitis after gynecological operations, and a few of these patients had died, not of the phlebitis, but of sepsis, which was believed to have caused the phlebitis, but out of the entire number he could recall none in which there was thrombosis of the pulmonary artery. He would ask why this should be if in pulmonary thrombosis or embolism during the puerperium it was due to breaking away of clot from the veins of the extremities. He mentioned a case seen with Dr. Kennedy in which pulmonary thrombosis following labor was suspected from sudden collapse, cyanosis, rapid pulse, etc., but the breathing was different, and on inquiring for the cause he found that the untrained nurse had injected a solution of carbolic acid into the rectum instead of into the vagina, as directed by Dr. Kennedy. As soon as he introduced his fingers and let it flow out, the patient rapidly recovered.

The Chairman recalled a case in which symptoms similar to those described by Dr. Cushier occurred twice on giving intra-uterine douche about the fifth day after labor.

Dr. Cushier said that formerly she did not keep patients abed as long after labor as at present, and some unpleasant symptoms were to be attributed to that fact; but she believed in going by the condition, not by the day. Regarding Dr. Jarman's question, she did not attempt to answer it in full, but stated that sometimes in phlebitis not associated with the puerperium infarction of the lungs occurred.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 23, 1895.

George P. Biggs, M.D., President, in the Chair.

Fibro-adenoma of the Liver.—Dr. Warren Coleman presented such a specimen. The tumor was removed from a man, aged sixty-eight, who died in Bellevue Hospital, and its presence was not suspected until the liver had been cut into. The liver was cirrhotic and fatty, and markedly bile-stained. Its left lobe was very large—so large, indeed, that it led during life to the assumption that a tumor existed in this situation. It measured 19½ ctm. in its vertical diameter, 6.25 ctm. in its antero-posterior diameter, and 13 ctm. from its left edge to the transverse fissure. The fibro-adenoma was situated in the right lobe of the liver, near to its posterior surface, and in the region of the larger bile-ducts where they converge to form the right hepatic duct. It was spheroidal in shape, and measured approximately 3 ctm. by 3 ctm. It had a solid, white, somewhat translucent appearance, and a dense, hard feel. Its relation to the blood-vessels and bile-ducts made it seem as if fibrous septa ran off into the surrounding liver tissue. It cut hard at the autopsy, and the diagnosis lay at first between primary carcinoma originating in the bile-ducts and gumma. Microscopic examination, however, showed the tumor to be a fibro-adenoma. There was nothing noteworthy in the appearance of the section, except that portions of the liver substance had been inclosed by outlying bands of connective tissue. The gall-bladder was full, the left hepatic duct having remained open. The common duct was also open, but somewhat obstructed by an enlarged pancreas and adjacent lymphatic glands. The heart weighed twenty ounces. Its walls were soft and the cavities dilated, though the valves were normal. There was a thrombosis in the right auricle. The lungs contained dark liquid blood. The first division of the pulmonary artery going to the upper lobe of the left lung contained an embolus

which blocked its lumen, while the first division of the pulmonary artery to the lower lobe of the right lung also contained an embolus. The pleural cavities contained a small amount of clear liquid.

The patient's history, while in the hospital, was closely followed. Only such portions of it, however, as relate to the specimen were given. The heart and lungs were reported negative on physical examination. The liver was enlarged and extended below the free border of the ribs for one and a half to two inches. Its edge was sharp. The left lobe was more enlarged than the right, extending two-thirds of the way from the ensiform cartilage to the umbilicus. The consistency of the liver was firm. The patient died suddenly. The nurse had taken his temperature and had left him comfortable. In passing the bed a few moments later he found the patient suffering from intense dyspnœa and his pulse imperceptible. Death occurred within a few minutes, and was to be explained by the pulmonary embolism.

Dr. Coleman said it had been impossible for him to consult the literature of the subject, and the books at his disposal gave but a reference to adenomata of the liver. Welch states, in Flint's "Practice of Medicine," that adenomata of the liver present themselves in two forms—either as a vascular hyperplasia of the liver substance or as an atypical growth of bile-ducts in a nodular form. So far as his personal experience went, the speaker said adenoma of the liver had been rare, this being the first instance he had met with. He desired to express his thanks to Dr. E. P. Shelby, Jr., for preparing the sections of the tumor.

The President said that he had only seen one adenoma of the liver, and that very recently. In this case, at autopsy, a small primary tumor had been found in the right lobe, projecting slightly above the surface, and measuring about 1½ ctm. in diameter. It was whitish in color and distinctly outlined. The cause of death had been puerperal septicæmia, the subject a young adult. Microscopical examination had shown the growth to be a pure and simple adenoma of the liver tissue.

Dr. Coleman said that in his case there had been no suspicion during life of the existence of such a tumor in the liver.

Multiple Rupture of the Liver.—Dr. George P. Biggs presented portions of a liver. Three distinct ruptures were found. The specimen had been removed from a man who, while intoxicated, had fallen from a height of thirty or forty feet, and had struck on his right side. That evening he had become nervous; his temperature had been 99° F., and his pulse 76. Toward evening of the following day his temperature rose to 103.2° F., the pulse was 76, and the respirations 36. He then presented pretty well-marked symptoms of delirium tremens. Sedatives had but little effect. Shortly before death his temperature rose to 109° F. His death was evidently due to delirium tremens. Examination during life showed no fractures of bones, and no distinct evidence of internal injury, excepting, perhaps, a fracture of the base of the brain. The autopsy presented no fracture of the base—only œdema of the brain. About a teacupful of blood was found in the peritoneal cavity, distributed in every direction. It was firmly coagulated and quite adherent to the intestinal wall. The source of this hemorrhage was found to be the liver, which was considerably enlarged and very fatty. The longest rupture was in the upper border of the right lobe; it measured 8½ ctm. in length by 1¼ ctm. in depth. The line of rupture was covered over with a firm fibrinous coagulum which had checked the hemorrhage completely. Another rupture was found on the under surface of the right lobe. It measured 3 ctm. in length by ¼ ctm. in depth. This also was covered over with a very firmly adherent blood-clot. The third and most extensive rupture measured 7½ ctm. in length, and 2 ctm. in depth. It began in the right lobe of the liver just at the junction of the gall-bladder with the liver substance, and midway between the neck and the fundus of the gall-bladder, and extended along the side of the gall-bladder nearly to the neck, then across the portion of liver tissue between the fissure, the right and left lobes, and the fissure of the gall-bladder. The walls of the gall-bladder were everywhere infiltrated with blood, the blood having been confined for a time beneath the peritoneum, and dissecting its way out to the gall-bladder. This rupture was also covered over by a firm blood-clot.

The case is of interest, for if the man had not died of delirium tremens he would have, in all probability, recovered from his fall in spite of the three ruptures in the liver.

Ruptured Ectopic Gestation.—Dr. Biggs then presented a specimen of ruptured ectopic gestation. Death had been due to internal hemorrhage, the true condition not having been recognized at all until the autopsy. The patient was a Scotch woman, who first came under observation on October 15th. She had had three children and one miscarriage. Six days before coming under observation, while two months pregnant, she had experienced pain in the back and abdomen, and had gone to bed. She expelled some "red lumps" from the vagina, and thinking it was a miscarriage she had had no medical treatment. The pain in the abdomen had, however, continued, and there was constant, though moderate, bleeding from the vagina. Her condition becoming serious she was taken to the hospital. On admission her temperature was 100° F.; pulse, 70; respirations, 20. She was very anæmic, supposedly from the amount of blood discharged from the vagina. She complained of pain in the abdomen and tenderness over the hypogastric region. The abdominal wall contained a thick layer of adipose tissue, precluding anything being learned by palpation. On the evening of her admission to the hospital the uterus was curetted. The cervix was sufficiently dilated to admit of the entrance of the curette. The uterus measured three and a half inches. A small quantity of odorless material was removed by the curette, and a strip of iodoform gauze was placed in the uterus. The temperature fell to 99° F. after the curetting. On the following day the temperature was 99° F., the pulse, 120, and the respirations, 40. She had passed a very restless night. That evening the temperature was 101.2° F., the pulse, 144, and the respirations, 40; and on the following day the temperature was 102.2° F.; pulse, 146 and thready, and respirations, 36. She was supposed at this time to have septic peritonitis, originating in the uterus or from a ruptured tube. An ice-coil was applied, and the packing in the uterus removed, and found to be perfectly odorless. At noon of the second day in the hospital the temperature was 104° F. She was given an intra-uterine douche, without any effect on the temperature. She vomited almost constantly. The dext day the temperature was still high, and the distention of the abdomen had increased. She died the following morning. At the autopsy the abdominal cavity was found completely filled with blood. It was estimated that eight pints of fluid blood were taken out of the abdominal cavity. In addition to this the entire hypogastric and pelvic regions were filled with a firm coagulum of blood, which appeared to have been at first partially confined. The ectopic gestation was found to have been in the upper portion of the left Fallopian tube, and the remains of the fœtus were visible in the interior of the sac. The sac, distended with the hemorrhage, measured 7 ctm. in length, 5 ctm. transversely, and 3½ ctm. vertically. The uterus was 9 ctm. long, 5½ wide at the fundus, and 3½ ctm. at the cervix.

Dr. Henry Power said that he had looked up the literature of the subject of rupture of the internal viscera, and had found that the late Dr. B. A. Watson

had experimented on one hundred and sixty-two dogs, with the idea of injuring by concussion the spinal column chiefly. He had allowed the animals to drop from a height. His observations showed no injury to the brain and spinal cord, but a large number of ruptures in the kidneys, lungs, spleen, and other organs.

Dr. H. S. Stearns asked if these ruptures referred to by Dr. Biggs had not been really quite superficial, and if the greater part of the apparent depth were not due to ecchymosis. There was an unusual amount of repair considering the short time that had elapsed between the injury and the man's death.

Dr. Biggs said that certainly two of the ruptures were quite superficial.

The Society then went into executive session.

Clinical Department.

DEPRESSED FRACTURE OF THE SKULL; TRAUMATIC AMNESIC APHASIA; RECOVERY WITHOUT OPERATION.

By GEORGE H. WILLIAMS, M.D., M.R.C.S. ENG., L.R.C.P. EDIN.

FISHKILL-ON-HUDSON, N.Y.

On October 2d, J. M——, a young man, aged nineteen, was hit on the left side of his head by a stone, during an altercation with another man. Two days later he was brought to the Highland Hospital by Dr. Sutton, of East Fishkill, and placed in my charge, pending the result of his injury. The patient was able to walk from the station, some half-mile distant. Dr. Sutton reported that on the afternoon of the injury he was called, and found the patient in an unconscious condition, with a slight hemorrhage from the left ear, and was informed that the blow was followed almost immediately by a convulsive attack lasting nine minutes; patient was in this unconscious state some four hours, recovering slowly, and seemingly much dazed. On admission to hospital, October 4th, the patient, a powerful young man, seemed still dazed and heavy mentally, and was unable to answer questions. There was an effusion on the left side of the head about two and a half inches above the upper margin of the left ear, there was conjunctival effusion and loss of hearing on same side, watch heard only when pressed against ear. Pressure over the effusion elicited pain. There was some loss of power in the opposite hand. The pulse was slow but regular—44.

Treatment.—Patient put to bed, left side of head shaved and ice-cap applied. Diet—malted milk and beef juice every alternate hour. Five grains of calomel administered and repeated in six hours. Ordered ten grains of potassium bromide every three hours. For the next two days patient's condition remained much the same.

On October 7th, the effusion having somewhat disappeared under treatment, we could make out a decided depression of the external table of the skull over the lower parietal bone involving the squamous suture and the upper temporal region, altogether the size of a silver dollar, with pain on pressure in this region. Patient was unable to tell his name or answer questions; when asked to write his name he wrote it slowly but fairly well; when asked for his friend's name who accompanied him to hospital he could neither tell nor write it; could not tell his home, but muttered something beginning with a B., which I learned later was Cape Breton, N. S.

To-day for the first time I recognized his condition as one of amnesic aphasia. He had been closely watched day and night during his stay here. On this afternoon, the fifth from the injury, I saw him about four o'clock. About an hour after I was hastily summoned by the matron, who told me the patient had had a convulsive attack during my absence, lasting some ten minutes or more; although the pulse was more rapid than when I saw him there were no other fresh symptoms. About 7 P.M. he had another attack, which I witnessed; it was epileptiform in character, the head was turned to the right, the eyes were rolled upward and outward toward the right, pupils dilated but regular, the hands were clenched and the arms strongly flexed, there was a bloody saliva dribbling from his mouth, and inspiration and expiration were short and quick, accompanied by a series of gurgling sounds. This attack was shorter than the last, persisting for only about five minutes. Patient soon recovered and seemed as before. A consultation of the staff was called and the advisability of trephining discussed; it was decided to wait further developments. I left the patient about 11 P.M.; up to this time he had no further seizures.

The night nurse informed me that during the early morning he had three short attacks within an hour, each lasting only a few seconds. The next day patient's condition seemed as before, so the former treatment was continued. On October 9th my friend, Dr. Allison, of the Matteawan State Asylum, saw the patient with me, and corroborated the diagnosis of amnesic aphasia of traumatic origin, probably due to concussion of the cells in the third frontal convolution. On examination this day he was able to tell the time, said "Fifteen," and after a time "twelve," it being a quarter to twelve. Could not read aloud, or tell letters, or name objects shown him, although he said he knew what they were perfectly well.

October 10th.—When asked if he was better, patient said "Yes." This seemed one of the few words he could say. Tells time thus, "Half-past," and after a time, "three." Knew the name of a quarter to-day when he saw it, and said "Ten" when shown a ten-cent piece. Writes his own name well, as from the first; can't tell or write his friend's name. The hearing is better, can hear watch an inch from the left ear. Tongue is cleaner; pulse still slow, 44 to 48. When shown a key and asked what it was he could not tell, but pointed toward the door and went through the motion of unlocking. Could not say watch, or knife, or other articles when asked what they were, but said he knew what they were.

The effusion over temporal region was less, and the depression quite marked at the upper margin; it was three inches above the upper part of the left ear, a little behind the ear, and quite an inch and a half either way. The conjunctival effusion was less.

October 11th.—Answers questions better to-day: otherwise his condition is much as yesterday: when shown the watch could not name it; when asked the time, it being five minutes to twelve, said, "Five," and after some time "twelve." Cannot say to; tongue is cleaner. Complained of feeling hungry for the first time. He was reading the paper at my visit, and said he knew what it was all about, but could not tell me.

October 12th.—Treatment as before; pulse 52. Sleeps well; bowels still sluggish. At my visit this morning patient seemed brighter. The patient in the next bed—singularly enough another case of depressed fracture, but without symptoms—informed me that he had carried on quite a conversation with the man, and found he could answer questions better. On trying him with the watch and asking him what it was, he said "Watch;" asked what time it was, he said "Ten—ten," it being ten minutes to ten. Was able to call a key, knife, and all other objects shown him. Said his friend's name, of whom I had often questioned him, was Jones, but could not write it. Grasp in the right hand is stronger. He does not remember the name of the man who struck him, and acknowledges that he was not altogether sober at the time. From this time on his recovery was uninterrupted. On October 14th

his hearing was normal and his general condition good. A plaster cast of the left side of the head, taken five weeks after, shows the depression still strongly marked.

Remarks.—Injuries to the head are always of interest to the surgeon, and this case had additional interest, presenting as it did decided depression and well-marked amnesia, and goes to show that conservative treatment was the best in this case. Of course, had the convulsive attacks been more lasting one would have operated at once. The *rationale* of the convulsive attacks I cannot explain, but think the amnesia was due rather to concussion of the cells in Broca's convolution than to either a ruptured vessel and effusion, or to embolic plugging in this neighborhood, as the recovery was so speedy and complete. The loss of power in the opposite arm, together with hemorrhage from the ear, I think were certainly due to a ruptured blood-vessel, as the depression in the skull was over the arm and hand centre. An unusual anxiety was added to the case for the reason that in the event of a fatal termination of the injury its medico-legal relation might have become complicated by surgical interference. There was a criminal aspect as well as a medical one to consider, and during the occurrence of the convulsive seizures it was a serious question to determine just how far the responsibility of the surgeon extended. The welfare of the patient was a prime consideration, yet an unusual anxiety must always attend the operative treatment of all severe injuries inflicted criminally, and which may result in the death of the person assaulted.

A CASE OF SPLENIC MYELOGENOUS LEUKÆMIA NOT CURED BY BONE-MARROW.

By CHARLES E. NAMMACK, M.D.,

ATTENDING PHYSICIAN, OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

FLORENCE S——, twenty-three years of age, native of England, was admitted to the hospital March 11, 1895, in the service of Dr. George L. Peabody, who has kindly permitted me to use her clinical history while in the wards. Her previous personal history was to the effect that she had been treated unsuccessfully, for eighteen months prior to her admission, for anæmia. Her habits were temperate. She menstruated regularly and painlessly. Her family history was negative.

The symptoms on admission were headache, marked vomiting, fever, prostration, breathlessness on exertion, and insomnia.

Examination.—Pulse, 112; respirations, 36; temperature, $102\frac{8}{10}$° F., mouth; lungs, normal; heart, accentration of pulmonary second sound; action rapid, but regular and strong. Liver normal. Spleen extends one inch to the right of the median line and to midway between pubes and umbilicus. Urine shows a trace of albumin, also hyaline and granular casts. Blood count shows the red corpuscles to number 2,520,000, and the leucocytes 760,000, a proportion of about 3 to 1. Hæmoglobin, fifty per cent.

Treatment ordered was tablet of protonuclein every four hours, and bone-marrow spread on bread, taken at meal time.

April 4th.—Blood count: red corpuscles, 2,680,000; white, 864,000, about 3 to 1. Hæmoglobin, fifty per cent. Patient is relieved of all symptoms except dyspnœa on slight exertion, although blood examination does not show improvement. Patient feels decidedly better and leaves for convalescent home at Summit, N. J. She remained at Summit for a month, then returned to the hospital and was referred to the writer's class in the out-patient service. At this time her only suffering was from shortness of breath on exertion. She had had one attack of nose-bleed, but no other mucous hemorrhage. The spleen was still enlarged and its notched anterior border extended to the right of median line. Blood examination showed the ratio of white to red corpuscles to be about 1 to 3. It also showed deficiency of hæmoglobin, and the presence of nucleated red blood-cells. The pulmonary physical signs were normal, the shortness of breath being due to deficient oxygenation owing to the oligocythemia. The cardiac apex was not displaced. The liver was not enlarged. The urine showed a trace of albumin. Patient admitted some difficulty of vision, and ophthalmoscopic examination by Dr. Walker showed neuroretinitis in each eye. In the right eye there was a large hemorrhage near the macula. Vision = OD $\frac{20}{30}$; OS = $\frac{20}{30}$. Hearing was acute. Temperature, normal. No enlarged lymph-glands could be found. No œdema. No dropsical effusion. She was ordered Fowler's solution, to be gradually increased to ten drops three times a day, but as this remedy caused vomiting, diarrhœa, and puffiness of face, it was stopped. Through the kindness of a leading drug firm of this city she was gratuitously furnished with bone-marrow, and a friend obtained board for her in the country during July.

It was thought that these measures fulfilled the therapeutic indications, and the outcome was awaited with interest and the hope that the case might prove an exception to the rule, that the disease is almost always progressive despite the most carefully directed treatment.[1] This hope was strengthened by the favorable reports relative to the use of bone-marrow.[2]

Of the cases referred to in these reports, that of Bigger[3] most nearly resembles our case, and is reported by him as a case of leucocythemia apparently cured.

On August 5, 1895, she returned to town and examination showed that the spleen was smaller, that the ratio of corpuscles was as one white to ten red. No nucleated red corpuscles could be found. Hæmoglobin decidedly improved. She then went to live on Long Island, in a locality where malaria prevails. She developed immediately intermittent fever of the tertian type, and on August 29th was readmitted to the hospital for treatment. The digestive disturbance associated with her malarial fever prevented the administration of bone-marrow until October 10th, when its use was renewed. Blood count at this time showed a ratio of one white to nine red blood-cells. During the run of the intermittent fever her spleen had markedly increased in size, and with the subsidence of the fever the organ diminished, until its anterior border extended only to the former position, namely, about one inch to the right of median line of abdomen.

On October 31st Dr. Thomas S. Southworth kindly examined her blood for me, and found hæmoglobin, forty-eight per cent., ratio of white to red cells as one to thirteen, abundant myelocytes, and numerous nucleated red cells.

At the present time she is taking Warburg's tincture, Pearson's solution of arsenic, which seems to be better borne than Fowler's solution, and Caswell, Massey & Co.'s preparation of bone-marrow.

29 EAST TWENTY-FOURTH STREET.

POTASSIUM PERMANGANATE IN OPIUM POISONING.

DR. J. T. M. LINDSAY, of Cuero, Texas, writes: "On the 21st day of October I was called to see a patient, Mrs. Annie A——, of this city, at about 11.30 A.M., who had (as reported) taken nearly a teaspoonful of morphine. I was near the place, making my visits to some sick patients in the neighborhood, when called. On my arrival I found this woman (middle-aged) in a

[1] Osler: American Text-book of Practice of Medicine, vol. ii., p. 226.

[2] Henry Hun: New York Medical Journal, January 12, 1895, p. 35. Allan McLane Hamilton: New York Medical Journal, January 12, 1895, p. 44.

[3] Lancet, September 22, 1894, p. 682.

comatose condition. I had her face bathed in cold water, and kept her in a sitting posture, and at the same time administered potassium permanganate internally. The effect of the morphine was rapidly counteracted, and in thirty or forty minutes I had her walking the floor of the room supported by myself and her husband. I made her drink several cups of coffee, and in an hour's time I had her outdoors, where she could get fresh air and plenty of it, and within three hours after administration of the potassium permanganate she was able to resume her usual occupations."

INTESTINAL ANASTOMOSIS BY THE MURPHY BUTTON.

By MILO BUEL WARD, M.D.,

TOPEKA, KAN.

THE following case may be of sufficient interest to the profession to justify its publication:

Mrs. McC——, Irish birth, aged twenty-nine, mother of one child of seven years, with a history of pelvic disease extending over a period of several years, much of the time incapacitating her from household duties, and under treatment for the same almost constantly for the past five years.

No history of miscarriage was obtained, but her attending physician had suspected gonorrhœal infection to be the cause of the primary infection. There was, however, no positive proof obtainable, which left this feature of the case to rest entirely upon suspiction.

I first saw the patient in consultation with Dr. Munn, of this city, September 29th of this year. At this time she was bedridden, the result of continuous uterine hemorrhage, also extreme tenderness of the abdominal organs, making it quite impossible to remain in the upright position. Upon examination, I found the pelvis completely filled with solid exudate, entirely obliterating the outlines of the uterus. The patient's suffering was intense. A very careful bimanual examination caused great pain. She was reduced to complete invalidism. The pulse was very rapid, and the temperature from 100° to 101° F. There was serious bloating of the intestines much of the time, but the bowels had been kept open by the frequent use of saline laxatives. The diagnosis reached was chronic endometritis, very serious in character, and salpingo-ovaritis, with probable intestinal complications. The patient was brought to my hospital on the following day and hastily prepared for surgical interference.

On the morning of October 1st, under ether anæsthesia, and assisted by Drs. Munn and Frankenburger, of this city, and Dr. W. G. Vest, of Montezuma, Ia., who was visiting my hospital at that time, I did the following operation: With the patient in lithotomy position, the uterus was dilated with Goodell's dilator, and with the sharp curette the endometrium was thoroughly curetted, irrigated, and packed with iodoform gauze. This completed, the patient was placed in dorsal decubitus for the purpose of removing the pelvic masses. The omentum was found universally adherent, requiring forced separation from the pelvic organs. The intestines were firmly adherent to the fundus of the uterus and pelvic tumors. After they were separated, it was found that several inches of the sigmoid flexure was greatly thickened and nearly gangrenous, and severed almost completely in one place, being only held by the mesentery portion. Two oval-shaped holes were also found in this portion of the gut, about one-half inch in diameter, extending through the serous and muscular coats, resembling a punch-hole in sole leather. The wall of the intestine was one-half inch thick at the point where it had broken in twain. Hot towels were applied to the intestine outside of the abdomen during the removal of the pelvic masses. The enucleation of these tumors was more difficult than words can describe, and can only be appreciated by those who have been so unfortunate as to deal with this character of disease. The bleeding was very profuse, causing great shock to the patient, and giving us much concern, for fear that we would not be able to keep her alive long enough to reach her bed. Hypodermic injections were quite freely used, and, after irrigating the peritoneal cavity with normal salt solution, the patient seemed to rally enough to justify an attempt to complete the necessary surgery. I packed the pelvis with iodoform gauze, which controlled the bleeding, while I turned my attention to the intestine. My first plan was to attempt to unite the intestine, after repairing the ragged and almost gangrenous edges by the Lembert suture method. But owing to the great thickness of the wall and also the holes above mentioned in other parts of the intestine, it was found impossible to proceed in this manner. A large-sized Murphy button was immediately brought, and six inches of the intestine resected and an end to end anastomosis made. The wall of each end of the intestine, where it was severed, was about one-third of an inch in diameter, making the introduction of the button extremely difficult. It would perhaps have been much easier to have removed more of the intestine in order to have reached a point where it was more nearly normal in thickness, but it did not seem advisable to sacrifice more of that portion of the gut if possible to avoid it. Contrary to the usual custom, and the advice of Dr. Murphy, I sutured around nearly the entire intestine with silk, believing it would afford additional support. The pelvic gauze was then removed, intestines replaced, and thorough irrigation with a very warm salt solution was again resorted to. I then thoroughly packed the pelvis with iodoform gauze, and closed the upper angle of the incision with silkworm gut sutures, completing the entire operative procedure in one hour and twenty minutes. Without knowing the exact time occupied in doing the anastomosis, it is at least safe to say that not more than fifteen minutes were occupied in this part of the operation. The patient was placed in bed and restoratives used, but she did not react satisfactorily for twenty-four hours. Twenty-two hours after the operation I removed the pelvic packing, which had served the double purpose of controlling the hemorrhage and draining the abdomen. A small quantity of iodoform gauze was again introduced into the incision and carefully forced down toward the pelvis, the gauze not being removed for forty-eight hours. The dressings were from this time on removed and fresh gauze introduced every twenty-four hours, allowing the incision to heal by granulation. The first ten days were spent in extreme anxiety, but at the same time the patient had so many favorable, intermingled with unfavorable, symptoms, that there seemed good reason for hope of her final recovery.

A review of the daily record relative to the care of this patient would be too lengthy to publish in this connection. After ten days had elapsed, the patient seemed to give promise of certain recovery, and had no untoward symptoms from this time on. The button was passed on the eighteenth day, following the administration of a generous dose of castor-oil. The incision was entirely healed in four weeks, and she returned to her home in five weeks after the operation, being able to walk off as sprightly as ever before in her life, and says she is entirely well. Her appetite and digestion could not be more perfect. She was permitted to have regular diet after the button made its appearance.

The special features in this case, making it one of unusual interest, are: the danger of procrastinating surgical interference in cases of such severe chronic disease; the great gravity of the pelvic operation causing so much shock that the doctor in charge of the anæsthetic expressed the fear that she would die on

the table before the pelvic masses could be completely removed; and the anastomosis of so thick an intestinal wall.

If there are surgeons who question the value of this wonderful device, Murphy's intestinal button, a knowledge of this one case ought to convert them without further controversy. It is the writer's opinion that no other method would have resulted satisfactorily in dealing with this abnormally thickened intestine in connection with such trying circumstances.

Therapeutic Hints.

Atrophic Rhinitis.—In atrophic rhinitis the diluted peroxide solution serves a double purpose, eliminating the stench by breaking up the decomposing matter, and helping—by the liberation of the gas and the consequent formation of bubbles—to loosen the crusts. The cotton-tipped probe is of the greatest service in dislodging these dried masses and wiping away strings of tenacious mucus.

Eczema of Nose.—In eczema of the nose occurring just at the junction of the integument and mucous membrane, and associated with an interstitial keratitis, the effects of the sirup of the iodide of iron in appropriate doses are most striking. Such cases, which are so frequently met with in a dispensary practice among children of low vitality, are rarely benefited by local applications alone.

Alumnol.—Alumnol, in two per cent. solution, either alone or combined with menthol, and in certain cases with a small percentage of cocaine, is extremely serviceable in relaxed conditions of the larynx.

Rhinitis.—Cod-liver oil, the hypophosphites, etc., will do more for the cure of rhinitis in scrofulous children than any simple local application.

Itching in Eczema.—Fluid extract of jaborandi locally applied.—G. W. Robinson.

Diabetes.—Boric acid, seven grains, thrice daily.
—Mockton.

Sciatica.—Salol, gramme 0.5 to gramme 1.0.
—Aschenbach.

Chlorosis.—In true idiopathic chlorosis, where iron is ineffectual, sulphur will produce a marked amelioration. After using sulphur, iron can again be resorted to, and it becomes very beneficial.—Schultz.

The Analgesic Antithermics.—The following conclusions were drawn at the French Congress of Internal Medicine: 1. The numerous remedies which compose the rather ill-defined group of analgesic antithermics are characterized by their protoplasmic action—their action of the blood, and especially their nerve-action. 2. The preponderance or the exaggeration of the one or the other of these actions is connected with their chemical constitution, and determine the differences of their therapeutic effects and the accidents that they may produce. 3. They are only employed, in the great majority of instances, against a single symptom—elevation of temperature or pain. 4. As antithermics, or rather antihyperthermics, they may have, in certain cases, a favorable action. Most often they are useless or dangerous. 5. As analgesics, they occupy an important place and one which is incontested in the treatment of pain.—Schmitt, *Gazette des Hôpitaux*, September, 1895.

Chopparro Amargoso, belonging to the same order as quassia, a thorny bush growing in Texas, of which a fluid extract is made, is said to be tonic in small doses, stimulant in large, and a palliative remedy in dysentery.—Mixon.

Uterine Inertia can at times be remedied by a glycerine suppository.—Cowan.

Lavage.—1. Stimulates the gastric glands in cases of chronic gastric catarrh, especially in those instances which are associated with excessive secretion of mucus. 2. Strengthens the enfeebled gastric muscular fibres in cases of insufficiency or atony. 3. Increases peristaltic action. 4. With the improvement in the tone of the walls of the stomach, associated intestinal disorders such as constipation may also be overcome.
—Joseph.

Vomiting of Pregnancy.—The medicines recommended for persistent vomiting are numerous and varied, including alcohol, alkalies, tincture of iodine (5 to 10 drops in water), tincture of nux vomica, pepsin, ingluvin, cannabis indica, orexine, purgatives, belladonna, ipecac, lavage of the stomach, chloroform, menthol, cocaine, potassium bromide, opium, caffeine, chloral, strontium bromide, oxalate, carbonate, or valerianate of cerium, ether, serum, inhalation of oxygen, blisters over the epigastrium, ice to the spine, and ether spray to the abdomen or spine. Blood-letting has done real service in some cases. Electricity has often been applied, and is now becoming very popular. Among the medicines employed by the author are calomel in small doses, creosote, pyroligneous acid, tannin (20 ctg. daily), smoking of tobacco, resorcin, phosphate of calcium, and mercury. Rectal enemata are useful when the patient becomes very weak. The local treatment consists in scarification of the cervix, leeches applied to the cervix, the introduction of a small sound for 5 to 6 ctm., cauterization of the cervix by nitrate of silver (1 to 10), and correction of retroversion if that condition be present. If all of these means fail, and the patient is losing in weight every day, it is justifiable to produce an abortion, or premature delivery. In the severe cases this procedure should not be delayed too long, otherwise the patient may be too weak to rally after the operation.—Demelin.

Neurasthenia.—

Leucorrhœa.—A leucorrhœa inodorous, or of mild odor, persisting during the climacteric, accompanied by increasing hemorrhage, is suspicious, and demands investigation. A leucorrhœa profuse, of peculiarly fetid odor, grumous, excoriating, appearing early or late during the climacteric, with profuse hemorrhage, is reasonable evidence of cancer of the cervix. A leucorrhœa, moderate in amount, ill-smelling (the peculiarly fetid odor of cancer of the cervix being absent), accompanied by hemorrhage, suggests cancer of the corpus uteri. A leucorrhœal discharge with hemorrhage, containing material like the washings of meat, is said to indicate sarcoma. A watery discharge, as a rule, occurring during menstruation, odorless or of little odor, persisting, accompanied by profuse hemorrhage, indicates fibroids; with little or no hemorrhage, polypi. Profuse bloody discharges coming on gradually with declining menstruation, ceasing usually with the menstrual flow, point to fibroids. Persistent profuse discharges of blood occurring spontaneously, arising from sudden exercise or coition, occurring, as a rule, after the menopause, indicate cancer.—Mish.

Typhoid Fever.—Whenever the thermometer registers 102.2°, or over, the bath is resorted to, and again in half an hour; if below 102° and above 101° F., it is repeated in an hour; if below 101° and above 100°

it is repeated in two hours; if below 100° F., the patient is put into the bath again in three hours; but whenever 102.2° F. is reached, the bath is repeated, and so on until the temperature does not go above the bath point.—Tyson.

Cascara Sagrada is useful in rheumatism.

—*Vanderbilt Clinic.*

Rheumatism.—The author does not believe that the changes in the joints in the cases of rheumatism examined by him are caused by direct bacterial invasion. He considers that they are caused by the action of toxic substances, which, under certain conditions, exert their influence on the joints, and he believes that we must consider as causative factors not only the toxins of those micro-organisms which we regard as the infective agents, but also those chemico-toxic substances which are produced indirectly by bacterial activity.—Choostek.

Hypertrophies.—1. Hypertrophies due to obstacles in the heart itself. This condition is typically represented by lesions of the valves. 2. Hypertrophies due to increased resistance in the vascular system. 3. Hypertrophies due to diseases of the heart muscle itself, from infection, overstrain, degeneration, etc. 4. Hypertrophies due to affections of the nervous system. —Whittaker.

Alleged Reflex Causes of Nervous Diseases.—1. The essential feature in the production of many neuroses is the neuropathic state—the degeneracy—of the subject. 2. In hysterical subjects suggestion plays an important part both in the development and cure of the symptoms. 3. Disease of any organ may give rise to referred pain in some definite area, but not to other nervous disturbances, except as a secondary result of local disease of the organ. This local disease manifests itself by the ordinary local symptoms, and the nervous phenomena are due to exhaustion, anæmia, intoxication, etc. 4. In a few rare cases injury of a sensory nerve may give rise to epileptiform seizures. 5. Surgical operations for the relief of nervous symptoms should never be performed unless there are clear indications, apart from such symptoms, for an operation. —Knapp.

Yeast Nucleins in Tuberculosis.—1. In cases of pulmonary tuberculosis with cavities it does no good. 2. It may retard the progress of long-standing cases, so long as secondary infection with pyogenic germs does not occur. 3. A temporary cure (the cases have not been long enough under observation to say more) may be obtained in early cases of small area. 4. It has proved satisfactory in urinary tuberculosis. Finally, the nucleins in other substances may act equally well as yeast nucleinic acid.—Vaughan.

Faith.—Dr. Mackay, in his work on "Popular Delusions," relates that, when the Prince of Orange was besieging the town of Breda, his army became so seriously afflicted with the scurvy as to be threatened with annihilation. When all legitimate remedies failed he caused a decoction of chamomile, wormwood, and camphor to be made, and announced it to his army as a wonderful remedy brought from the East with much danger and toil, and that a single drop of it, mixed with a gallon of water, was an absolute specific for their disease. The result equalled their expectation, and the measure of success was exactly equal to the measure of the faith.

Tonsillitis.—If you find that the patient cannot open the mouth you may almost invariably exclude diphtheria, and suspect one of the inflammatory non-diphtheritic forms of angina.—Massei.

Chronic Enlargement of the Tonsils will be benefited by painting every other day with a mixture of one-third compound tincture of iodine to two-thirds glycerine.

Typhoid Fever.—The tympany of enteric fever can often be favorably influenced by rectal injections of from five to six ounces of ice-water, retained for some time in the bowel.

Peritonitis.—1. Mechanical irritation of the mucous membrane by which it becomes abraded, or its vitality lowered, as by indigestible food or foreign bodies; and, in the latter case, by strangulation from a band or a hernia. 2. Chemical poisons, both organic and inorganic, by their injurious effects tend to lower the resisting power of the lymph tissue to the invading germs, provided the poison be not directly fatal to them. 3. Retardation or obliteration of the normal intestinal peristalsis, preventing the gut from casting out its invaders. A great increase in the number of bacilli by which the lymph-cells are overpowered, or a diminished number of the defending cells, or their low vitality enable the bacilli to pass into the peritoneal cavity, and by reproducing themselves in sufficient numbers cause a general peritonitis. That the foregoing is the etiology of many cases of peritoneal inflammation is now a demonstrated fact.

—Childs-Macdonald.

A Brave Physician.—The latest addition to the roll of gallant actions performed by medical men is that of Dr. Charles Toller, of Ilfracombe, who, during the recent heavy gale which raged on our west coast, and at the imminent risk of his life, descended by means of a rope a cliff on the Lee Bay Rocks, which are one hundred and fifty feet in height, in order to apply restoratives to an apparently drowned person. Strenuous efforts were made by Dr. Toller to restore animation, and the patient partially rallied, but expired a few minutes before being landed at Ilfracombe in the lifeboat which had been sent to the rescue.—*The Lancet.*

New Instruments.

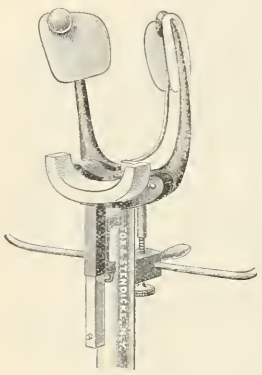
A HEAD REST FOR THE JAVAL OPHTHALMOMETER.

By FRANK D. SKEEL, M.D.,

NEW YORK.

The following is a description of an experiment made with a view to improving the present form of head-rest in the Javal ophthalmometer.

Some time ago I suggested to Messrs. Fox and Stendicke that some such improvement should be made, and this engraving will show the results of their efforts. Two supports are provided, against which the forehead rests, each carrying a small screen which shields the eye from cross lights. The distance between these supports is adjustable and is regulated by a screw shown above. The eye-screen is mounted on a curved arm and swings from side to side to cover either eye. The details can be readily seen in the engraving.



41 East Twenty-third Street,
November 15, 1895.

LONG FLEXIBLE DOUBLE-CURRENT TUBE FOR HIGH IRRIGATION OF BOWEL, ALSO DOUBLE-CURRENT IRRIGATORS FOR INFANTS.

By ROBERT COLEMAN KEMP, M.D.,

NEW YORK CITY.

This flexible irrigator is a modification of the soft-rubber rectal irrigator described in the Medical Record of December 7th. The outer tube is of soft rubber—diameter, $\frac{5}{8}$ of an inch—the inner longitudinal tube is of linen. The linen tube is riveted in a hollow tip, and this tip unscrews from the outer tube. To clean the instrument unscrew the tip, and withdraw the central tube. The outer cap, etc., is similar to that in the instrument previously described. This irrigator is twelve inches long. It can be made longer if desired. The Ford Instrument Co. also make a short rectal irrigator similar to this, a flexible double-current irrigator—diameter, $\frac{1}{4}$ of an inch; length, 8 inches—is made for infants; also a short flexible irrigator four inches long. There is also a hard-rubber irrigator, and one of soft rubber—diameter, $\frac{1}{4}$ of an inch—in construction, similar to those described December 7th. In these small irrigators, however, the conducting tube is of metal-copper. They may be plated or made of silver or aluminum, which would increase the expense. I have found that in these small tubes the hard-rubber conducting tube cannot be made sufficiently small enough and of internal calibre to furnish a good current. Note, however, the linen tube, which can be substituted for metal. In connection with this article I mention an adult rectal irrigator, external tube of soft rubber, internal tube of copper. It can be bent to suit operator, is soft, and yet under his control.

Correspondence.

EXPERT TESTIMONY IN LUNACY CASES.

To the Editor of the Medical Record.

Sir: My attention has been called to an editorial in your issue of November 23d, entitled "The Commissioner of Lunacy as an Expert," which, if permitted to stand uncorrected, would do me a great injustice, and which, in view of my pleasant personal relations with the editor of the Medical Record, I must assume was written under a misapprehension as to the law and the fact in the matter rather than in a spirit of unfriendly criticism.

The law relating to the "commitment of the insane by criminal process" provides, among other things, in substance, that whenever any person accused of the crime of arson, murder, or attempt at murder, or highway robbery, shall have been acquitted on trial upon the ground of insanity, the jury shall bring in a special verdict to that effect, and so state in its finding, and the court before whom such trial is had shall order such person to be committed to some State lunatic asylum, there to remain for observation and care until such time as, in the judgment of a justice of the Supreme Court, founded upon satisfactory evidence, it is safe, legal, and right to discharge him.

From this it will be clearly apparent that the Commission in Lunacy has no power either to prolong the detention or cause the discharge of a person committed to an asylum pursuant to the statute cited and held on what is known as a "criminal order." A discharge from custody in such a case can only be made by a judge of the Supreme Court, who, upon receipt of notice from the superintendent of the asylum that the patient is restored to his right mind, must determine if it is safe, legal, and right to discharge him. The only possible jurisdiction the lunacy commission would have over a so-called criminal case would be to interfere in his behalf if it had reason to believe that he was cruelly or negligently treated. Furthermore, the views of judges, as well as of governors of the State, respecting the relations of the Lunacy Commission to such cases may be inferred from the fact that these high officials have frequently designated the medical member of the Commission as a special commissioner to determine the mental condition of persons charged with crime, and in whose behalf a plea of mental unsoundness has been made.

Carlos F. MacDonald.

The Cambridge, 334 Fifth Avenue,
New York, December 3, 1895.

[We give place to this communication from our distinguished correspondent with an acknowledgment on our part that the article was written under a misapprehension of the law as it now stands and cheerfully disavow any motive for unfriendly personal criticism.—Ed.]

LENGTH AND POSITION OF THE APPENDIX.

To the Editor of the Medical Record.

Sir: Contributions to the subject of the anatomy of the appendix vermiformis, like that of Dr. Byron Robinson's to the Medical Record for November 30, 1895, are so valuable that their authors are presumably glad to have any possible source of error pointed out. In making observations, it will be observed that appendices become lax and elongated after the period of rigor mortis has passed, and Dr. Robinson's measurements were made without reference to, or at least statement of, that point.

It is also probable that the post rigor-mortis relaxation of the bowel allows the appendix to hang into the pelvic cavity much more after than it does in life. All of us who are engaged in abdominal surgery find

the appendix in the pelvic cavity occasionally, but in operative work, or in palpation of normal appendices through the abdominal walls, I do not find nearly so large a proportion of appendices in the pelvic cavity as Dr. Robinson finds in the post-mortem examinations. In making accurate palpation of the normal appendix through the abdominal walls, it is necessary to carry the cæcum quite high in order to roll the appendix out, so that we can press it against the psoas and iliacus muscles for fixation, and this movement may lift some appendices out of the pelvis; but certain it is that there are few normal appendices which cannot be found behind the cæcum when we are ready to fix them against the pelvic wall for palpation.

ROBERT T. MORRIS, M.D.

NEW YORK, December 1, 1895.

LIMITATION OF SERVICE IN THE CITY HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: At the annual meeting of the County Medical Society the discussion that took place in reference to the appointments in the city charitable institutions, a gentleman who was for some time in the service of the city hospital remarked, that formerly the field for an appointment was open to everybody, but admitted that the candidate must have had political influence. That distinctly proves that the field was not open to everybody; that the candidate must have been and continue to be the tool of a political wire-puller. He further remarked that at present the appointments are controlled by a medical trust, and only friends and members who have served the trust's purpose are open for appointment. In comparing the two I rather prefer (although I believe it is unfair and unjust) that the appointment should be in the hands of the medical trust than those of the politicians. I consider the appointment of civil service just, but some restrictions should be made; that is, a candidate for examination should be an American citizen, and at least a resident of the city of New York for three or five years, and practice medicine for five years. Then the service of visiting and assistant physicians and surgeons should be limited to a term of five years and only be permissible to serve two terms, as this service is only for the purpose of gaining experience. Five years is ample for that purpose, and by limiting the term of service it will give an opportunity to a greater number of the medical profession to gain this valuable experience.

LEONARD LANDES, M.D.

NEW YORK, November 30, 1895.

CHLOROFORM AND ETHER WITH OXYGEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Cole, in the MEDICAL RECORD of October 12th, reported some observations on the use of oxygen and ether in combination. In the issue of November 2d, Dr. R. C. Newton says: "The valuable and instructive paper of my friend, Dr. Cole, in your issue of the 12th ultimo, will doubtless set many other surgeons to experimenting with oxygen combined with ether." Several years ago it occurred to me that such a combination would be most desirable, for the reasons given by Dr. Cole. To satisfy myself of the correctness of my supposition I obtained a cylinder of pure oxygen and administered it in combination with chloroform to several private patients. In one or two instances it seemed to work admirably, but in others it was not as satisfactory as chloroform alone. However, I was satisfied that the principle of the combination was correct, so I demonstrated before some of the surgical staff of the Orange Memorial Hospital. Ether was the anæsthetic used on that occasion. The comment was, after the new process had been carefully watched for some time, "When you get through experimenting with the new combination, we will have the patient etherized and proceed with the operation." It was not a flattering success.

The three principal objections to the use of the combination, according to my experience, are. 1. The length of time it takes to satisfactorily anæsthetize a susceptible patient, the time being longer, as a rule, than when no oxygen is used. 2. Its utter inefficacy in many instances. 3. The danger of depending entirely upon the quantity of oxygen in the combination as a trustworthy heart and lung stimulant.

Respectfully,

JOSEPH WILLIAM STICKLER, M.D.

ORANGE, N. J., December 2, 1895.

Typhoid fever	26	7
Scarlet fever	63	3
Cerebro-spinal meningitis	2	0
Measles	224	16
Diphtheria	282	22
Small-pox	1	0

Color-blindness and Atavism.—A recent writer, M. Dubois, throws out a suggestion that will probably be new to most of our readers. It is recognized by astronomers that there are three classes of stars—first, the bluish-white stars, of which Sirius and Regulus are examples. More than half of all known stars belong to this class. In these stars combustion is at its maximum, and their atmosphere consists of superheated hydrogen and certain metallic vapors. The second class, of yellow stars, has for typical representatives Capella and our own sun. They are less hot than the first class, and the hydrogen lines in their spectrum are not so conspicuous as in the case of the white stars. This class contains about 33.5 per cent. of all known stars. The third class are the red stars, and of these Betelgeux is the representative. They are in a later stage of cooling than the second class, and the violet rays are deficient. This class includes about eight per cent. of known stars. From these known facts it is conjectured that color-blindness (or insusceptibility to the red rays of light) may possibly be a case of atavism—a "negative inheritance from that time long ago when the eye of our ancestors was not yet sensitive to red rays, which were almost entirely wanting in the white stage of the sun." This is a startling theory, but it suggests a plausible explanation of what is such a mysterious fact—viz., that color-blindness should so uniformly take the form of insusceptibility to the red rays. Atavism is without doubt a principle of wide application, and may be fairly relied upon to explain many apparently inexplicable facts. We will not venture to pronounce upon the correctness of its application in the present instance, but at least the theory is a bold and ingenious one, and, if accepted, would tend toward that unifying of knowledge which is the aim of science. Color-blindness, regarded as an isolated phenomenon, is mysterious, but if it be a case of atavism it takes its place in the scheme of ordered knowledge.—*The Lancet.*

The Edinburgh Royal University has received legacies to the amount of $375,000.

Treatment of Electrical Injuries.—The numerous deaths among the staffs employed in the electrical lighting works in Paris has attracted the attention of the Minister of Public Works, who has asked the Academy of Medicine to draw up directions concerning the treatment of those injured by contact with the wires, and also concerning the technical precautions to be taken. The medical treatment formulated by the Academy is the same for injury from electrical shock, no matter what the nature of the current inflicting the injury may be. But the technical precautions differ according to the nature of the current. If the person injured remains in contact with the electrical conductors, the assistant who extricates the injured person must be careful before commencing operations to have dry hands and wear a pair of thick flannel or stuff gloves, and not to take hold of the injured person by a region in perspiration. In non-interrupted currents the electrical conducting wires must not be cut. When the wire is cut it must be cut in two places. The medical treatment consists of placing the injured person where there is plenty of air, loosening the clothes, rhythmic traction of the tongue, rubbing the body, etc. M. Dupuy Dutemps has forwarded these directions to the prefects, urging them to make them known, especially among engineers and staff of the Ponts et Chaussées entrusted with the electrical lighting of streets, to the directors of electrical stations, municipal authorities, medical men, and dispensing chemists. The instructions corresponding to the respective currents will be pasted on the wooden structures to which the poles are fixed.—*British Medical Journal.*

The French Army Medical Service.—There seems to be a great deal of trouble in connection with the medical services of the armies and navies of civilized nations. The fundamental difficulty in all cases, is the antagonism between the regular army officers, who wish to control everything, and the medical officers, who wish to have independent control and authority over the branches of work for which they are responsible. The latest disturbance has developed in France. Dr. Noel has written to the *Bulletin Médical* a protest against the new methods adopted for the French medical service of the army. By recent orders, control of the whole of the personnel connected with the *Corps de Santé* has been turned over to the military officers proper, and the authority is taken away from the medical and sanitary officers. Dr. Noel says that in armies that are still dominated by the feudal spirit, where caste sentiment persists, and where the militant officer regards himself as a superior being, ambulances are commanded by cavalry officers. This occurs, for example, in Germany, Austria, and Russia. In the more modern armies, in which the organization is not modified to suit this peculiar traditional spirit of caste, such is not the case, and he instances the armies of Italy, Switzerland, England, and Japan. Dr. Noel does not place the army of the United States among those in which the feudal spirit has been extinguished, and he is, we presume, justified in holding such an opinion. He protests, in the strongest terms, against a rule which imposes upon the medical officers duties, but does not give them the authority to discharge them.

Strychnine in Pneumonia.—In the report of the Surgeon-General of the Navy, Commodore J. R. Tryon, of a year ago, mention was made of the apparently favorable results of the hypodermic injection of strychnine in the treatment of lobar pneumonia. In his report just issued, Dr. Tryon says, that the favorable opinion entertained of the value of this drug in the treatment of pneumonia has been further strengthened by the experience of its use during the past year. Forty-five cases of acute lobar pneumonia were treated in the Naval Hospital in Brooklyn during the past two years, with but three deaths, a mortality of only 6.0 per cent.

NEW BOOKS RECEIVED.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A CONTRIBUTION TO THE STUDY OF HEREDITARY CEREBELLAR AND HEREDITARY SPINAL ATAXIA, WITH THE HISTORY OF AN ATYPICAL CASE OF THE FIRST-NAMED DISEASE.

BY JOSEPH COLLINS, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE CITY HOSPITAL (NERVOUS DEPARTMENT).

DURING the past few years there have appeared many contributions to the literature of that constantly increasing class, the family and hereditary diseases of the nervous system. A class that now includes Friedreich's disease, Thomsen's disease, hereditary chorea, the various forms of familiary and hereditary spinal, myopathic, and neurotic muscular atrophy, hereditary spastic spinal paralysis and diplegias, a form of progressive bulbar palsy, diabetes mellitus, and perhaps other diseases. None of these contributions are of greater interest than those which have been grouped under the caption of hereditary cerebellar ataxia. Like a number of other diseases that have recently been raised to a separate entity, examples of this family disease, hereditary cerebellar ataxia, have been seen from time to time in the past, but they have been looked upon as non-conforming or atypical cases of hereditary spinal ataxia or Friedreich's disease, and as such have not been subjected to the careful scrutiny and examination which they deserved.

The first cases carefully observed were by Fraser, who recorded them in the *Glasgow Medical Journal*, page 90, 1880. On one of his cases a careful autopsy was made by the renowned pathologist, Joseph Coates. Fraser's cases are now considered among the fundamental observations of the disease.

It was Nonne's[1] great merit, that he, finding himself in the presence of three such cases, all of the same family, recognized the necessity of separating it from hereditary spinal ataxia, not only because of radical points of difference in its symptomatology, but of variance in time of development and in the mode of its occurrence. An autopsy of one of his cases showed that this autonomy was established by the pathological findings, which differed materially from those constantly found in cases of Friedreich's disease. A year later a paper by Sanger Brown,[2] containing a large number of observations of family ataxia, included a report of no less than six cases of this disease. To this paper of Brown were appended valuable remarks by Ormerod, of London, and Bernhardt, of Berlin. A point of great value in these commentaries was the emphasis both writers laid on the necessity of considering many of Brown's observations as cases entirely apart from Friedreich's disease. Since that time reports of cases have been made by Klippel and Durante,[3] by Brissaud and Londe[4] and by Londe[5] in which the symptomatology has been so definite as to lead observers to place these cases unreservedly in the category of hereditary cerebellar ataxia.

In addition to these a number of cases have been reported which will be mentioned farther on in this article, in which the symptoms were intermediary between hereditary spinal and hereditary cerebellar ataxia, or which included symptoms outside of these two diseases. These latter cases furnish great opportunity for study, reflection, and investigation.

Two years after the publication of Nonne's paper, Marie, in discussing the former's cases in connection with the interesting series of cases reported by Sanger Brown, and the cases of Fraser, and of Klippel and Durante, suggested the name hereditary cerebellar ataxia in contra-distinction to hereditary ataxia, which is the name universally given to the disease first described by Friedreich[1] in 1863. A name which is associated anatomically and historically with lesion in the spinal cord. And this for two reasons: in the first place, because the constant attending lesions of this disease are spinal, and secondly, because Friedreich described, and for a long time considered, these cases as anomalous forms of tabes or locomotor ataxia. And although the anatomical investigations of Schultze,[2] Kahler and Pick, and others soon attested the incorrectness of Friedreich's view, they at the same time put the disease on a firm anatomical basis.

The name hereditary cerebellar ataxia, its sponsor considered, would not only indicate the important clinical manifestation, the ataxia, but would impress the kind of ataxia, viz., cerebellar, while it would also suggest the *sine qua non* of its genesis: heredity. Furthermore, it was suggested by the fact that in the cases of this disease that had come to autopsy the most manifest lesion was in the cerebellum. Although Marie's designation is a satisfactory one thus far, it should not necessarily be considered a permanent one, as there have already appeared observations to show that a strikingly similar condition (if not quite the same) may develop without any hereditary antecedents or consequences.

These cases will be referred to later. In fact it is probable that heredity, in the proper and literal interpretation of the term, is not an absolutely necessary antecedent. If it be granted that the case reported herewith is an example of this disease (an atypical example), the occurrence of the disease without defective heritage must likewise be admitted. That is, no such or analogous condition existed in the immediate antecedents extending back as far as the grandparents. That it is a family disease, however, is indicated by the occurrence of it in all the children of the family, viz., two.

It does not seem necessary to dwell on the distinction between familiary and hereditary diseases. That a disease may occur in a family without being in the strict sense hereditary, must be conceded. It is believed to have been proven that the germ plasm may be defective in its primary constituent, or during its development, without the source of its origin being diseased.

The name hereditary cerebellar ataxia is applied, therefore, to a class of diseases in which heredity is the

[2] Ibid., vol. lxviii., 1887.

genetic factor, ataxia the clinical, and the cerebellum the seat of the most important pathological change. The name is the same as that given to Friedreich's disease (hereditary ataxia) with the interposition of the word cerebellar. The latter, indeed, may be called hereditary spinal ataxia, the former hereditary cerebellar ataxia, while those cases which conform to neither type, the cases described by Nonne as transition forms, and with which the cases of Menzel, Erb, and my own may be reckoned, may be considered as cerebello-spinal hereditary ataxia, or hereditary cerebro-spinal ataxia. The latter name especially when psychical and other symptoms pointing to cerebral defect are prominent.

It is more than probable that such cases will be found to exist and Nonne's recent contribution,[1] in which he describes six cases, would seem to point in this direction. Hereditary cerebellar ataxia differs from hereditary spinal ataxia not only in its symptomatology, but in its etiology and course. The former seems to develop in the period extending from late youth up to maturity, although it may develop in earliest infancy.[2] In this it differs very materially from the spinal form in which the great majority of the cases develop during the cycle between childhood and adolescence. That the former may develop in infancy is shown by Fraser's cases, in which the disease began in the third or fourth year. As Fraser's cases were the first on record and with autopsy, this fact is important. So far as any conclusions may be drawn from the small number of cases published, it would seem that the former had been observed oftener in males than in females, the proportion being relatively similar to that of hereditary spinal ataxia. This is in keeping with a fact which is generally conceded, that in all of the family and hereditary diseases of the nervous system males are more frequently affected than the opposite sex. As in hereditary spinal ataxia the familiary or hereditary element is all that we can find bearing on the occurrence of the disease.

Like in a great many other protal or teratological diseases, an antecedent or coincident history of tubercle may be discovered in the family. This can have no other significance than a general one, viz., the prevalence of this infectious disease and the greater vulnerability of those handicapped by inheritancy or by acquisition. The fact that a tubercular history has been found relatively more frequently in the antecedents of hereditary cerebellar ataxia than in hereditary spinal, is in keeping with the universal knowledge that tuberculosis is much more common during the epoch when the former occurs than it is with the latter.

Factors which may be considered incidental have been remarked by some reporters, such as psychical trauma (Nonne), the occurrence of infectious disease (Londe, Marie), etc. Naturally, such conditions may precipitate or aggravate incipient symptoms so as to render those previously unnoticed quite perceptible.

In none of the cases reported thus far has parental syphilis played any part. The entailment of neurotic inebriety has, however, been noticed as it has in hereditary spinal ataxia.

The etiology of hereditary spinal ataxia is practically similar to this, with the exception that direct inheritance has been traced only in a few instances, while the familiary occurrence of the disease is rarely, if ever, absent. Moreover, it is supposed by many to be not only familiary, but congenital. Nevertheless, Friedreich himself, and recently Schultze,[3] have stated that the familiary character may be absent.

The difference in the symptomatology of the two diseases is set forth in the following parallel columns:

Hereditary Cerebellar Ataxia.	Hereditary Spinal Ataxia.
1. Gait: Uncertain, reeling; gait of one inebriated. Patient frequently walks with body bent forward and the head thrown backward, and the feet wide apart.	1. Gradual impairment of co-ordination, first in legs, afterward in arms. Later in the disease the patient may reel as if under the influence of alcohol.
Does not have to watch the feet. Feet wide apart.	A quick backward and forward balancing movement.
2. Station: Romberg symptom absent.	2. Station: Closure of eyes, as a rule, increases the unsteadiness; this may be absent.
3. Titubation and inco-ordination and loss of dexterity in the upper extremities. Choreiform movements exaggerated on voluntary effort; "intentional."	3. Titubation of upper extremities very uncommon. Irregularity in voluntary movements of arms and fingers.
4. Not infrequently oscillations or jerky movements of the head, less often of the trunk.	4. Frequently jerky, irregular movements of head and neck. Sometimes like an irregular tremor.
5. Exaggerated contraction of the mimetic muscles on speaking.	5. Mimetic muscles do not show ordinarily over-contraction.
6. Ataxia is very much less, or disappears when the patient is lying, but the inco-ordination persists.	6. Ataxia is not so great when the patient is lying.
7. Speech: Hesitating, abrupt, explosive, ataxic, defective.	7. Affection of speech may be absent; when it does occur is a late symptom, and consists of an eliding of syllables and an occasional hesitation.
8. Eyes: Twitching of the eyeballs very common, but not nystagmus. Optic atrophy, progressive choroiditis, paralysis or paresis of the external recti sometimes.	8. Nystagmus is a very common symptom, but it may be lacking.
9. Myotatic irritability increased; reflexes exaggerated, such as knee-jerks; often ankle clonus.	9. Myotatic irritability is lost. Knee-jerks may be present in the beginning of the disease, but they soon disappear. Ankle clonus is never present.
10. Mental shortcomings varying from slight psychical disturbances up to a considerable degree of dementia.	10. Mentally, normal. Very rarely any defect.
11. Deformities of the extremities and spine, such as pied bot or scoliosis, do not occur or are most rare.	11. Deformities of the extremities such as pied bot and spinal curvature, very common.

These are the principal symptoms of these two familiary diseases. There are additional symptoms, but they do not occur with sufficient regularity to justify considering them a part of the clinical picture. It will be seen that, even in parallel columns, the symptomatology of the two diseases does not appear to be so radically different. This will convey some idea of how similar some of the cases seem in reality. They are both family and progressive diseases. There is practically the same titubation in the gait, the same instability, and the same loss of co-ordination and choreic movements of the hands, and perhaps, also, of the face. The appearance of the face both when in repose and on speaking furnished a minor point of difference: in hereditary cerebellar ataxia there is a look of astonishment habitual to the features, and over-action of the mimetic muscles when the patient speaks or betrays emotion. This has not been considered a phenomenon of Friedreich's disease.

It is in the condition of the deep reflexes that these two diseases differ materially. In the former they are always present and frequently exaggerated; in the latter they are often absent, at least after the disease is developed, and no typical case has been recorded in which they were found increased. The presence of even the slightest clonus of the foot indicates a spastic condition to which the anatomical conditions existing in Friedreich's disease are inimical. To show the great importance that is attached to the state of the tendon reflexes as a diagnostic factor, it may be permitted to quote from Brissaud, who, lecturing on a patient with hereditary cerebellar ataxia (in whom there

[1] Archiv. f. Psychiat., etc., vol. xxvii., part 2, p. 479.
[2] Besold: Zeitschr. f. Nervenheilk., vol. v., pp. 2 and 3.
[3] Zeitschr. f. Nervenheilk., vol. v., parts 1 and 2.

were no visual troubles and the presence of scoliosis), said, "En somme, si j'ai éliminé la Maladie de Friedreich, c'est pour la seule raison que les reflexes rotuliens sont exagérés."

The remaining symptomatology in which they differ materially are the ocular and the mental conditions. Whereas such ocular symptoms as diplopia, dischromatopsia, achromatopsia, contraction of the visual field, and loss of light and accommodative reaction, all pointing to optic nerve lesion, have been found in several cases of hereditary cerebellar ataxia, these are most uncommon manifestations in hereditary spinal ataxia. In fact, it must be said that, whereas cases of the latter disease have been reported in which there has been diplopia and loss of light reflex, optic atrophy never occurs.

Cases of hereditary cerebellar ataxia in which there has been no real involvement of the optic nerve have been reported, so that, although it constitutes a very important line of demarcation between cerebellar and spinal ataxia, its absence should not convey the non-existence of the former disease. Marie, and following him Brissaud,[1] have both laid undue stress on the eye-symptoms in hereditary cerebellar ataxia, the former going so far as to say that if the eye-symptoms are lacking the diagnosis cannot be made with certainty.

Londe, whose monograph on the subject aims to encompass all that has been written on the subject of hereditary cerebellar ataxia up to the date of its publication, emphasizes the belief that visual disturbances, ocular, motor, or sensory, which Marie considers pathognomonic, do not constitute an essential feature of the disease, and that in typical cases the symptom picture may be reduced to its simplest expression: general inco-ordination, with conservation or exaggeration of the tendon reflexes.

A careful examination of the records of the reported cases shows that in some there were no ocular symptoms, and in others very slight departures from the normal.[2] Brissaud proposes to call these cases in which ocular symptoms are wanting, variétés frustes of hereditary cerebellar ataxia. We do not admit the necessity or propriety of such subdivision.

The history of the case which I wish to communicate is as follows: A boy eleven years of age, of mixed English and Irish parentage. The parents are living and in good health. There is no history or manifestation of syphilis in either parent. No disease like the one from which the child is suffering, nor any symptom complex resembling it, can be traced in any of the ancestry. His paternal grandfather and grandmother both died of consumption. Five paternal aunts died in childhood, all with some tubercular manifestations, and his only paternal uncle has hip (tubercular?) disease. Thus it will be seen that there is a most pronounced tendency to the transmission of a constitutional condition favorable to tuberculosis. There is no history of defective mental or physical development, or the possession of morbid atavistic traits in any of the patient's immediate family. He is the second of two children. The fact that the mother has not conceived in the past eleven years, although she and her husband are apparently normal and vigorous, indicates relative unfecundity which bespeaks degeneration. The child born previous to the patient was a girl, who died at the end of her second year. The parents say that she had a "sort of a paralysis," that her eyes "danced" continually, that she was very "backward," never having learned to say words, to walk, or to use her hands. She had two or three attacks of convulsions, and finally died during an attack. The child did not look natural, the back of the head was flat and the forehead was bulging. This is quoted practically verbatim from the account given by the mother, and can be taken, I believe, to mean that the first child was defective in a way similar to the patient here described, only that the defect was greater and showed itself earlier. The "sort of a paralysis" spoken of by the mother was in all probability extreme inco-ordination of the extremities, which prevented it from learning to creep, to walk, or to use its hands. The fact that the child could move all four extremities speaks in favor of this view and against the supposition of any real paralysis. The "dancing" of the eyes indicates that nystagmus was very marked, just as the "backwardness" implies defective mentality.

Between the first and second pregnancies there was a space of two years. The pregnancy with the present patient terminated with a normal delivery. The child never had spasms; the teeth began to appear at the proper time, and when he was a year old he began to walk. The mother says that he began to walk and talk at about the customary time. Since his third or fourth year it has been remarked that he was "stiff in his joints," that he took "short steps" and was "continually tumbling;" "but he was always a great runner and walker," but was not able to climb like other boys. When he was four years of age it was noticed that he was short-sighted, a condition which was on the increase, and since then he has worn glasses. He has had measles, pertussis, and scarlatina, all in a very temperate form and without the slightest after-effect from any of them. When he was five years of age he began going to school, but in the following six years he has not been able to progress beyond the grade in which he started, except after the first two years he was once promoted, but later he had to be put back, and now at eleven years he is still in the baby class, or was until a short time ago, when he was returned with the advice that it was impossible to make any progress with him.

In April, 1894, in his tenth year, the mother says he had an attack in which he was unable to use the left side of the body. Although he could move the extremities, the left arm and leg were very clumsy and the hand lost all its dexterity. At this time speech was very indistinct. This seeming exacerbation of inco-ordination has recurred a few times since then, two or three times under my own observation; sometimes on one side, sometimes on the other, but more frequently on the left. And more than once has it been diagnosticated as St. Vitus's dance. The hands and fingers are often blue and extremely cold, and slight depressions of temperature make him very cold. It is quite impossible to keep him warm in winter. He complains of general fatigue, and of numbness and occasional cramps in legs; but not of pain. About a year ago, after having returned from a walk with his father, he felt ill and vomited a great amount of clotted blood. The hæmatemesis continued for three or four days. Some months ago he had a fall from a flight of steps and since then they think he is worse.

Examination. — A moderately tall, anæmic boy. Face has an aged, astonished, or frowning appearance which is heightened by the powerful convex lenses which he wears. Face looks somewhat asymmetrical, the right side being slightly more innervated than the left. Under the influence of the emotions, particularly those of depression, there is over-activity of the mimetic muscles, the face becomes a mass of wrinkles and takes on an elf-like expression.

He stands with the body bent forward and the chin pushed out, and with the feet wide apart. Station is quite as well preserved with the eyes closed as open. No Romberg. The gait is shambling, uncertain, titubating. This is most conspicuous when he endeavors to walk within a narrow space or to avoid successive obstacles. He falls with the greatest readiness. Lack of co-ordination is very manifest on attempts at purposive movements with the hands, worse with the left; while with the right hand there is a great deal of titubation. When he attempts movements requiring some dexterity, such as picking up successively a number of

[1] Leçons, Salpêtrière, 1893–94.
[2] Oulmont: Mercredi Med., No. 9, 1895.

coins and retaining them in the hand, grasping and holding a pencil to write, etc., clumsiness and incoordination are particularly manifest, while the ataxia of the upper extremities is seen distinctly when he puts the tip of the finger on the apex of the nose. This is more marked with the left hand than the right. Defective co-ordination of the lower extremities is seen

Fig. 1.—Facial Expression.

best when he attempts to go upstairs, to run, and to step over anything. When he lies on his back purposive movements with the lower extremities are much more accurate. The tendon reflexes are all more active than normal. The knee-jerks are exaggerated and there is varying ankle clonus on both sides; sometimes this latter is well marked, while at other times it cannot be brought out. The triceps reflex is lively, and muscular contraction to mechanical stimulus is pronounced, such as is obtained by tapping the extensors of the forearm. The lower extremities resist somewhat passive motion. There seems to be an inability on the part of the patient to relax the contraction of the muscles, which gives an impression of passive rigidity. Then the contraction will disappear. So it cannot be said that there is real spasticity. The muscular strength of the upper extremities is very considerably diminished, especially the extensors, and the grip of the hands is very slight, he being scarcely able to make the dynamometer register. The muscles of the back and thighs are also weak, and this is strikingly manifest when he attempts to rise from the completely prone posture. He gets up very like a patient with dystrophy of the pseudo-hypertrophic type, except that the crawling up the thighs and trunk is not so pronounced. The muscles feel flabby and pultaceous; when the tissues on the back of the forearm are pinched up there is none of that characteristic muscular resistance, and the mass lifted up is perfectly translucent, yet the contour of the extremities is well rounded, and there is no atrophy of individual parts of the body.

Careful examination of the sensory sphere fails to reveal any constant deviation from normal. The mother says that sometimes in the morning he complains of headache, and is excessively sensitive to touch on being handled or rubbed, but it has been impossible for me to corroborate this. There is no vesical weakness, and aside from slight constipation the bowels are normal. Muscle sense intact. The disturbance of speech is most striking, but a somewhat difficult one to describe. The sound is abrupt and the articulation defective. The linguals and labials are often not sufficiently constructed to be recognizable. When he attempts long words or tries to say several words, one after the other, they get jumbled up and it is quite impossible to recognize the words. There is none of the scanning of multiple sclerosis, but rather abrupt, forcible ejaculation attended by very perceptible effort of the muscles of expression. "Explosiveness," "abruptness," and ataxia are the three prominent characteristics.

Examination of the eyes reveals a paleness of the disk which Dr. W. A. Holden, who examined the eyes, considers to be within physiological conditions, and slowly progressing choroiditis. It is difficult to speak positively as to whether there is dyschromatopsia or not, but it is certain that there is no achromatopsia. The pupils are wide, alike on both sides, and respond slowly to light and accommodation. There is a progressive myopia. Forcible side to side movements of the eyeballs are accompanied by slight jerky movements which are not sufficiently rhythmical to be designated nystagmus. The movements of the eyeballs are free in every direction, but outward rotation is much less vigorous and complete than it is normally. There would seem to be no defect in the function of the other cranial nerves except the asymmetry of the face, which has already been mentioned, the exaggerated condition on display of the emotions, and the fact that he cannot whistle. This last does not seem to be due to inability to pucker the lips, for that he can do, but to the lack of reciprocal action between the muscles of the lips, the cheeks, and the respiratory muscles. It is also worthy of remark that until a year or two ago he could whistle. There is an irregular tremor of the tongue. Senses of smell, taste, and hearing are apparently intact.

As has been said before, he is deficient mentally, but he is not demented nor idiotic by any means. He would seem to have receptive faculties and a considerable capacity for memory; but in power or process of association he would seem to be entirely lacking. He has rational likes and dislikes, and has, apparently, ideas of right, of wrong, of possession, etc. He answers questions rationally, and also asks questions becoming a child of much fewer years. Yet, withal, he has never been able to put letters together so as to form words, nor to develop sufficient faculties to write simple sentences, although he could write his name. He has a bad temper, is easily provoked, does not like to be contradicted, and can be led more easily than dominated. He has no capacity for attention. One may try in the most forcible and praiseworthy manner to hold his attention, but after holding it for a moment it flits. There are no objective sensory troubles.

The genital organs are extremely undeveloped, the penis like an infant's, and only one testicle can be felt. The skin is dry, the hair falls out more than normally, and it is said that he does not perspire. He becomes fatigued rather easily, and oftentimes he is very drowsy and will sleep in the day. There is a deformity of the right foot, a typical so-called pied-bot, which is shown in the accompanying illustration. This deformity has not yet been noticed by the parents, nor is it to be remarked in the patient's gait. The shoes that he wears are of a pair.

The course of the disease has been a progressive one even since the patient has been under my observation. The fact that when the parents first brought him for treatment it was stated that symptoms dated from the fall already mentioned, may be taken as evidence that the disease has made a considerable progress in that time. It is unnecessary, probably, to add that fall was incidental to the disease, and not *vice versa*. The defective formation of bodily heat; the consequent depressed vitality; the increasing inco-ordination of gait, of movements, of speech; the retrogression of mental acquisition; the increasing loss of muscular strength, all go to show that the anatomical conditions at the

bottom of his disease are not only preventing anything like normal somatic and mental development as had gone on up until three or four years ago, but that there is an actual retrograde process at work. The muscles respond to the galvanic and faradic current, sluggishly of course, considering the pronounced lack of development, especially of the extensors, and there is normal

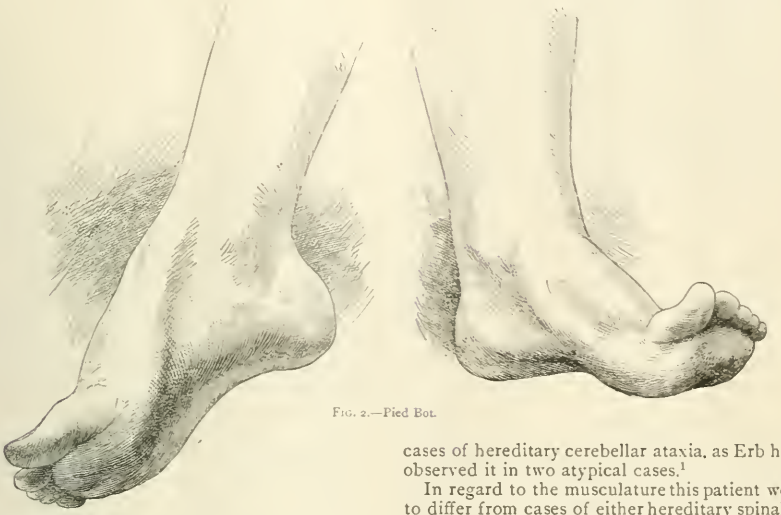

Fig. 2.—Pied Bot.

polar relationships. Faradic irritability of some of the nerves, notably the musculo-spiral, is diminished.

To recapitulate briefly the salient points of this case: 1. Absence of direct hereditary transmission. Evidence of its being familiary, a sister, in all probability, suffered from the same disease. 2. Onset in early childhood. The accompanying photograph is evidence that in infancy the child was free from the manifestations of the disease. 3. Disturbance of co-ordination manifested in all four extremities. Titubation of the hands and feet. 4. Gait: feet wide apart, reeling, inco-ordinate. 5. Increased tendon reflexes; exaggerated knee-jerks and ankle clonus. 6. Marked disturbance of speech, explosive, inco-ordinate; articulation very defective. 7. Profound deviation of intellect; associative faculties lacking; defective in attention. 8. Absence of sensory disturbance and intactness of the sphincters. 9. Progressive loss of muscular strength and tonus. 10. Shrivelled appearance of skin, lack of perspiration, senile, position of body and staring expression of countenance.

Thus it will be seen that in some points it differs very radically from hereditary spinal ataxia or Friedreich's disease, combined lateral and posterior sclerosis; while other of its symptoms point in no uncertain way to this disease. But the fact is that the case presents characteristics directly inimical to the postulated pathological condition of this disease. In brief these contradictory symptoms are: 1. The exaggerated tendon reflexes, knee-jerks, and ankle clonus. In Friedreich's disease the tendon reflexes are diminished or absent, particularly after the disease has been absent for some time. A case in which ankle clonus was an accompaniment has never been described. 2. The absence of nystagmus. 3. The striking defect of the mind.

The extremely early onset (Friedreich's disease comes on generally between the tenth and fifteenth years), the absence of sensory symptoms, the intensity of inco-ordination in the upper extremities, and the titubation are likewise uncommon concomitants of Friedreich's disease.

On the other hand, this patient shows symptoms and conditions which are found so frequently in hereditary spinal ataxia as to be considered of considerable diagnostic importance. Such is the pied-bot, a form of talipes dependent upon defective action, paresis, and subsequent contracture in the peroneal group of muscles. It is more than probable, however, that a history of this deformity will be found in subsequent reports of cases of hereditary cerebellar ataxia, as Erb has already observed it in two atypical cases.[1]

In regard to the musculature this patient would seem to differ from cases of either hereditary spinal ataxia or hereditary cerebellar ataxia. In the former muscular power is usually normal, even after the ataxia has become well pronounced, and although it sometimes becomes impaired in the course of the disease, the flexors suffer more than the extensors. Wasting of the mus-

Fig. 3.

[1] Neurologisches Centralb. 1890, p. 378.

cles is very slight.[1] In the latter disease Londe,[2] in his analysis of all the cases on record, reached the conclusion that the subjective sensation of fatigue and feebleness of muscular force is but slightly diminished; and when it is diminished it is but the consequence of hospitalization and prolonged inability to give the muscles their proper stimulation. Nevertheless, in Menzel's case (a so-called intermediary case) there was remarkable diminution of muscular force in the upper extremities. The deficiencies of musculature which are so striking in my case cannot be attributed to the abovementioned factors. To my mind they should be referred to defective formation either in the primary constituent of the muscle fibre, or of later origin. I shall return to a discussion of this later.

On the other hand, it differs from the cases described by Nonne, Brown, Brissaud and Londe, Marie, *et al.*, which have been grouped under the title of hereditary cerebellar ataxia, in that there is absence of direct hereditary transmission, as well as by the early manifestation of the disease. In these latter cases many of them manifested the symptoms first some time after puberty. And as has been previously mentioned, optic atrophy was a frequent accompaniment. Yet it should be conspicuously mentioned that in the first authenticated case on record, Fraser's first observation, the disease began gradually at about the fourth year. When the patient was seven years of age the staggering had become very persistent, and he was obliged to leave school. In this case, moreover, the opthalmoscope showed conditions very subject to the personal element of the observer: pale papillæ, irregularity of their contour with venous congestion in certain points; arteries contracted. Muddy and opaque aspect of the choroid. Except in the absence of oscillations of the head and the mental defect, the case herewith reported resembles very closely the case of Fraser.

There have been a number of cases of familiary ataxia described, notably one by Menzel,[3] another by Seeligmuller,[4] and two by Erb,[5] to which this case has some resemblance. These cases have been referred to by Nonne and others as transition cases between Friedreich's disease and hereditary cerebellar ataxia.

In Menzel's case the disease began when the patient was thirty years of age. Of six brothers and sisters, three were affected similarly to the patient. The prominent symptoms were ataxia of the four extremities; rotation of the head to the right, with associated movements in the face; speech slow and explosive; pupils large and sluggish to light and accommodation; marked Romberg; exaggeration of the knee-jerks; no sensory troubles. Anatomically, there was found degeneration of the posterior columns and roots, as well as atrophy of the anterior roots in the lumbar cord; degeneration of the columns of Goll and Burdach, of the direct pyramidal and lateral cerebellar tracts throughout the rest of the cord and in the medulla. The pons and cerebellum were atrophic, and in the latter Purkinje's cells were very deficient.

The recitation of this case shows wherein it differs from the accompanying observation. It is particularly in the age of the patient, the mental condition, and the severe contractures. Otherwise my patient has in common with it the exaggerated knee-jerks, the slow and explosive speech, and the very nearly normal condition of the eyes. The case, therefore, conforms neither to the type of cases described under the name hereditary cerebellar ataxia, nor to those constituting Friedreich's disease. Furthermore, its symptomatology is quite different from the symptomatology of such familiary diseases as cerebral diplegia, as described by Sachs, by Freud, and by others; from paraplegia ataxo-spasmodic of Gowers, and familiary spasmodic paraplegia which has been described by many writers.

[1] Gowers: Diseases of the Nervous System, vol. i., p. 464.
[2] Loc. cit.
[3] Archiv f. Psychiat., vol. xxii., 1891, p. 161.
[4] Ibid., vol. x.
[5] Ibid., vol. xxvii., p. 749.

It is advisable also to contrast it with the symptomatology of six cases recently described by Nonne.[1] He sums up his conclusions in these cases as follows: "The disease developed in patients without any hereditary condition existing in the family. It may follow a disease of the brain, as we have seen it after a sunstroke. The most important symptoms are: 1. A static and locomotoric, not purely ataxic, disturbance of co-ordination of the extremities, of the trunk and phonating speech muscles, with intact power of mimicry. 2. Insufficiency of the external eye muscles, with normal condition of the pupils and absence of nystagmus and change in the optic nerve. 3. Increase of patellar tendon reflex without accompanying rigidity of the muscles. 4. Absence of disturbance of sensibility and absence of sphincter disturbance. 5. Intactness of (or slight perversion of) the intelligence."

The symptoms in one of the patients which the author details reached a standstill. Nonne is of the opinion that we have in these cases to deal with the sequences of an affection of the brain, the result of some toxic agency of exogenetic origin. He looks upon these cases as still another transition form between Friedreich's disease, hereditary cerebellar ataxia, atrophy of the cerebellum, the cases previously described by him (which Nonne does not consider to belong in the title suggested by Marie, on account of the wide-spread atrophy of the central nervous found in one of his cases), as well as the cases published heretofore as "mixed forms" of these diseases.

The only criticism that will be offered on these last cases of Nonne is, that whereas some of these six cases appear to belong properly to so-called "transition forms," some of them, such for instance as the one coming on after sunstroke, can be explained by the previous existence of an encephalitis. They differ essentially in some points from the case herewith reported. Particularly in the intactness of intelligence, the absence of any familiary history. In common with it they have the early beginning, the abnormal liveliness of the tendon reflexes, the absence of eye-symptoms, the absence of sensory and sphincter disturbance, etc.

The symptoms of the patient herein described can be most rationally and logically explained, when more extensive defect of the nervous system is postulated than exists in either hereditary spinal or hereditary cerebellar ataxia. In the former disease there is sclerosis and shrinking of the posterior columns of the spinal cord, and of the columns of Goll and Burdach, analogous to that found in tabes. In addition a similar pathological process goes on in the crossed pyramidal tracts, in Gower's tract, in the direct cerebellar tract, in the medullary bridge of Lissauer; and with these there is a diminution of the cells of Clarke's columns. The lesions in the latter disease are pronouncedly in the cerebellum, and consist of a reduction in weight and volume which is associated with a thinning of the gray layer and a lessening in number of the cells of Purkinje. Naturally, with such a lesion there are others of such fibres or bundles of fibres the neurons of which are situated in the degenerated areas of the cerebellum. The projection fibres of the cerebellum are, happily, now very much better known than they were a few years ago, even although we are still in the dark as to their connections and functions. Therefore, just what these outlying lesions are, or what they will be found to be, cannot yet be said.

The patient, R. L——, has symptoms which cannot be explained by either set of lesions or by both combined. The retrocession of slight mental attainment at the sixth or seventh year, and the lack of mental development in the five years following on that age—years in which children make more radical mental progress than at any other period of their existence; a period when they acquire ideas of spoken and written

[1] Archiv f. Psychiat., vol. xxvii., 1895.

language, of moral and social relationships, when there is an enormous awakening as to their being and function—point unmistakably to lack of cerebral development which we believe could be called a lesion if it were possible to examine it.

The psychical condition of the child at the present time forms an interesting subject for study. His possessions and lackings in this line have before been commented on in some detail, but it may be well to repeat that it is the neural processes underlying attention, association, and complex memories that he is strikingly deficient in. These qualities of the mind we believe to be subserved principally by the great system of association fibres or tracts. And the fact that these mental attributes are deficient and undevelopable is in evidence that the neural processes on which they are dependent are lacking. Other symptoms, such as the decided exaggeration of myotatic irritability, the lack of readiness in the relaxation of muscular contraction, are explained most naturally by defect in the system of long projection fibres, which interrupts in part the inhibitory activity of the cerebrum on the former and interferes with the conductivity of impulses necessary to the latter.

Taking the symptoms which this patient presents in their entirety, it seems to me that they bespeak a defective formation of the nervous system, not of any individual portion such as certain parts of the cord or the cerebellum, but of the entire cerebro-spinal and sympathetic nervous system. In fact, if we take our perspective from the broad view-point of the development of the nervous system, it is not difficult to conceive how some perversion of the germ plasm destined for the portion of that part of the epiblast from which the nervous system is to develop, may cause a deficiency in the proper development of the nervous system. Such a defect, by very virtue of its protal origin, would not be limited to any individual part of the nervous system, but would be manifested throughout it. That is, it would not be alone in the central neuron, in the projection and association fibres which are built from them, but in the peripheral neuron as well.

The condition of the musculature of the patient R. L—— I consider of no small importance in bearing on the process underlying his disease. As has been said, the contours of the extremities are quite normal in appearance. There is neither apparent atrophy nor hypertrophy. The fact that the musculature is deficient is conveyed by what has been said concerning the way in which he rises from a lying posture. Then, when it comes to an examination of the muscles, it is seen that in some parts of the body, such as on the back of the forearms, they are strikingly deficient, as is shown by the translucency of the parts when the tissues are pinched up, by the extremely small amount of muscular tissue which can be recognized by the touch in these parts and by the rapidity with which the upper extremities become fatigued.

That the muscles exist, and that there is no degeneration in the muscles, is shown by their behavior to the electrical tests. That is, it would seem that some groups of muscles are represented in miniature. This is not the result of disuse, or of disease of the muscles themselves, but is, I believe, the result of defective formation consecutive to deficient protal distribution of peripheral neurons. I am aware that this theory leaves unexplained the integrity of the sensory system, but the fact that it is intact should not prevent an attempt at furnishing a rational explanation of existing defects.

The absence of sensible perspiration, the condition of the skin and appendages, to which attention has been called, bespeak shortcomings in the performance of its duties by the sympathetic nervous system. We have, therefore, in this case symptoms which, although partaking of the symptomatology of both hereditary cerebellar and hereditary spinal ataxia, has in addition certain conditions which are dependent upon a more extensive defect in the nervous system than either of these two diseases has been found associated with. The purpose of this report is to show that cases such as this cannot be encompassed by unvarying boundaries.

It also, I think, goes to show, as Nonne has pointed out, that there exist clinically cases which vary in their clinical manifestations from the picture produced by cerebellar atrophy, through the category of his original cases, through the cases described under hereditary cerebellar ataxia, to the many transition forms that have been described, and that these cases can be differentiated clinically from hereditary spinal ataxia.

I deem it a privilege to thank Professor C. L. Dana, in whose clinic at the Post-graduate Medical School this patient was found, not alone for the consent given to study the case, but for valuable suggestions made while studying it.

43 West Thirty ninth Street.

A CHEMICAL AND EXPERIMENTAL RESEARCH ON "ANTIPHTHISIN" (KLEBS'S).

By E. L. TRUDEAU, M.D.,

AND

E. R. BALDWIN, M.D.,

Saranac Lake, N. Y.

In spite of the ill repute into which Koch's tuberculin so quickly fell, many investigators, struck with the specific and selective influence which it exercises on the lesions of experimental tuberculosis, as well as with some favorable clinical observations noted in certain types of the pulmonary disease treated by tuberculin, have persevered in its further study and have attempted to analyze its constituents, to do away with the manifestly dangerous products contained in liquid cultures of the tubercle bacillus, and if possible to separate some pure substance which might favorably influence the tuberculous process, or produce in men and animals a certain degree of immunity.

Koch,[1] shortly after his announcement of the discovery of tuberculin, published the result of his attempts to purify this substance, claiming, however, for the product he obtained no therapeutical advantage over crude tuberculin. Kühne[2] made a chemical analysis of its component parts, and found that the active substances present in it are of the nature of albumoses.

Baumgarten[3] obtained temporary cures of eye tuberculosis in the rabbit by treatment with tuberculin. Trudeau[4] demonstrated, by the treatment of the experimental disease in the rabbit's eye, that the substances which bring about reaction and, under certain experimental conditions, even temporary cure, are to be found in the filtrate of liquid cultures, and not in a solution or suspension of the washed bodies of dead bacilli, and that the heat used in making Koch's tuberculin precipitates some of the proteids present in the cold filtrate. The studies of Hunter[5] and Klebs[6] were directed more particularly toward the separation by chemical methods of the injurious from the possibly curative elements of tuberculin.

In a communication made in 1892,[7] and in an exhaustive and more recent publication on this subject, Klebs claims, by chemical methods which he describes, to have separated from tuberculin, and later from the filtrate of over-ripe liquid cultures, a product which, owing to its specific germicidal action, is capable of killing the tubercle bacillus even when intrenched in

[7] E. Klebs: Die Causale Behandlung der Tuberculose, 1894, pp. 578–81.

the living tissues of infected men and animals, and thus curing the disease.

According to Klebs's observations, the cure is brought about, not, as Koch thought, by the power of the specific product to incite a reactionary effort on the part of the body cells, but directly and solely through its germicidal influence on the tubercle bacillus. Klebs, having observed that tubercle bacilli in cultures die when a certain period in their cultivation is reached, holds that they perish because they produce toward the end of their existence in the culture medium a peculiar germicidal substance which destroys them; that, by the chemical processes he describes, he has obtained this specific substance freed from the poisonous alkaloids and albumoses also produced by the microbes during their growth, and present in tuberculin; that he has succeeded in separating from over-ripe cultures this germicidal substance, which he calls "sozalbumose," and that it is the natural specific for this dreaded disease.

Such deductions, if proved correct, would have so important a bearing, not only upon our existing knowledge of the tubercle bacillus and of the treatment of tuberculosis, but upon the etiology and treatment of many other bacterial diseases as well, that a study of the claims made for "antiphthisin," both from the chemical and experimental stand-points, and of the theory upon which these claims are based, was undertaken by us at the Saranac Laboratory for the Study of Tuberculosis, and an answer to the following questions sought:

1st. *Can a specific substance, differing chemically from the albumoses already known to be contained in the filtrate of liquid cultures of tubercle bacilli, be separated from such cultures in a state of purity by the chemical methods proposed and described by Dr. Klebs?*

As the directions given by Dr. Klebs for the preparation of "antiphthisin" were evidently intended to be sufficient for the guidance of others who might desire to prepare this substance, we preferred not to limit our chemical study to an analysis of his own product, but to include in our research a test of the chemical problems involved in the process of manufacture as laid down by him.

In order to ascertain the nature of "antiphthisin" we prepared large quantities of it according to the directions given, which were closely followed.

"Antiphthisin" is stated by Klebs to resemble "tuberculocidin" (the name given to a former preparation), but is made directly from the fluid filtered from the over-ripe bouillon cultures without heat, instead of from crude tuberculin, as is the latter. The same method is used in both, but the "antiphthisin" presumably contains more of the active albuminoid substances, because some are removed by heat in the manufacture of tuberculin, from which "tuberculocidin" is made.

Kühne[1] examined 100 c.c. of Klebs's "tuberculocidin" and found a small amount of deutero-albumose and traces of peptone as the ingredients, excepting the phenol used to preserve it and inorganic salts. The albumoses, etc., resembled those contained in the peptone of the culture medium, though possibly derived from the bacilli. The important step in making these modifications of tuberculin is said by Klebs to be the removal of harmful, fever-producing substances by precipitation with sodium-bismuth-iodide (a reagent used to separate alkaloids) in acetic acid solution. The useful germicidal substances are assumed to be retained in the filtrate, which is then treated with NaOH to remove the bismuth. This being filtered off, absolute alcohol is added to the filtrate. The resulting precipitate collected and dissolved in water is called "antiphthisin." This is preserved in 0.2 per cent. trikresol, and is made of $\frac{1}{2}$, $\frac{1}{5}$, or $\frac{1}{10}$ bulk of the original culture fluid.

[1] Kühne: Loc. cit., p. 252.

We first procured some potassium-bismuth-iodide through the kindness of Professor C. E. Colby (Columbia College, School of Mines), and with this made several samples of "antiphthisin." Later, with sodium-bismuth-iodide prepared by ourselves, we made larger quantities.

Seven flasks containing 900 c.c., covered with thick pellicles beginning to sink, and all showing a rich growth of ripe, pure cultures grown from December 20, 1894, to February 18, 1895—eight and a half weeks—on peptone-bouillon, were filtered free of bacilli, and 12 c.c. of trikresol, twenty per cent. solution in glycerine, added as a preservative. After standing twenty-four hours sodium-bismuth-iodide was added until no further precipitation occurred, the reagent being first treated with sodium acetate and acetic acid. To avoid great excess, the quantity of the precipitant needed was first closely determined by titration three times with 5 c.c. of the culture fluid. The bulky, red precipitate was settled and filtered; the filtrate tested gave no further precipitate with $NaBiI_4$; NaOH (norm.) added until reaction just alkaline; warmed, settled, and filtered, free of $Bi(OH)_3$; to the clear filtrate absolute alcohol added until no further opalescence produced. The final precipitate, washed with absolute alcohol and dried, was readily dissolved in 70 c.c. distilled water.

EXAMINATION.

Color—light straw (resembled "tuberculocidin" obtained in market).
Odor—none (without trikresol).
Reaction—slightly alkaline.
+ heat = O + acetic acid = O (absence of albumin).
+ NaOH + $CuSO_4$ = rose color distinct (indicative of albumoses or peptones).
+ $(NH_4)_2SO_4$ (saturated) = opalescence (albumoses?).
+ NaCl (saturated) = O + acetic acid = opalescence (deutero-albumoses?).
+ $PtCl_4$ (excess) = opalescence (not found by Klebs).
+ $NaBiI_4$ + acetic acid = precipitate (the first was evidently incomplete—not found by Klebs).
+ HCl + H_2S (warmed) = O—(absence of Bi).
+ HNO_3 (conc.) + starch paste = O (absence of I).

The above reactions and others indicated that we were dealing with an albumose, or peptone-like body, which was incompletely precipitated by the first treatment with sodium-bismuth-iodide. The whole quantity remaining was therefore again treated with sodium-bismuth-iodide in acetic acid. This time there was much less "antiphthisin," and by a third treatment it was possible to completely remove all of it—no proteid being left.

These results show the absence of any substance different from the albumoses already described by Kühne as deutero-albumose, produced by the bacilli in very small quantities.

Klebs thinks this substance to be elaborated by the bacilli in growing. To test this point we treated some unplanted bouillon by the same method above described.

Two hundred and fifty cubic centimetres gave a residue identical in appearance and reactions with that obtained from the cultures. It was, however, less in quantity than that obtained from cultures of same bulk.

As it was evident that some of the albumoses, etc., in the original culture—*i.e.*, contained in the peptone or meat extract—might be in the product called "antiphthisin," we prepared some from peptone-free cultures, grown on the asparagine fluid suggested by Schweinitz.[1] 475 c.c. of this gave a trace of antiphthisin," which from its reactions resembled a deutero-albumose. Obviously this must have been derived from the bacilli, because a control experiment with the culture fluid gave nothing. A second treatment of the presumably pure "antiphthisin" with sodium-bismuth-iodide completely precipitated the proteid substances.

Some experiments with deutero-albumose were next made to determine whether this is incompletely precipitated by sodium-bismuth-iodide. This substance

[1] Schweinitz: New York Medical Journal, February 3, 1894.

was prepared in a fairly pure condition from Witte's peptone by the method of Kühne and Chittenden. It was then made up into the usual bouillon culture medium mixture, being substituted for the peptone in like proportion. When treated with sodium-bismuth-iodide, etc., a small residue, identical in its appearance and chemical reactions to the "antiphthisin" obtained from ripe cultures, was found to be present.

A similar proteid residue was obtained from a mixture of Liebig's extract of meat, sodium chloride, and glycerine in the usual proportions for culture media. Meat extract is known to contain a small quantity of albumoses.

Some experiments with the object of determining the reason for this incomplete precipitation of albumoses, particularly deutero-albumose, incline us to think it due to several causes. It may be due partly to the presence of neutral salts in which these albumoses are very soluble, and possibly because of slight solubility in excess of the reagent. The amount of acetic acid present seemed to bear no relation to the amount of "antiphthisin" produced. By careful precipitation it was possible to remove all the albumoses in the first treatment.

The components of tuberculin, so far as known, can be best compared with those of "antiphthisin" by the following table:

Tuberculin (crude)
- From the culture medium unaltered.
  - Glycerine.
  - Inorganic salts.
  - Extractives from meat.
  - Albuminat.
  - Albumoses (proto-, hetero-, deutero-)
  - Peptone.
- From the bacilli as a result of growth.
  - Albuminat (?) (doubtless a nucleo-proteid).
  - "Acroo-albumoses" (Kühne).[1]
  - Deutero-albumose (small amount).
  - Peptone (possible trace).[1]
  - Alkaloids (?).[2]
  - Protein (?) from bodies of the bacilli.

"Antiphthisin" and "Tuberculocidin."
- Inorganic salts.
- Deutero-albumoses (*very* small amount and partly from the culture medium).
- Peptone (?)
- Trikresol.

Many animal tests were made with "antiphthisin" of one-tenth volume of original culture fluid. Doses from 0.5 c.c. to 3 c.c. seldom produced appreciable effects on tubercular guinea-pigs and rabbits when administered at various stages in the disease. In doses of 5 c.c. elevation of temperature was produced, and one pig was killed by that dose, showing characteristic tuberculin-reaction lesions. Ten cubic centimetres caused marked congestion in the tubercular eye of a rabbit, with a temperature rise of from 102° F. to 105° F.

The effects of large doses of "antiphthisin" were similar in all respects to those produced by small doses of tuberculin.

It is interesting to note in this connection that Mathes[3] found that deutero-albumose (and others) made from Witte's peptone, produced effects on tubercular animals identical to those of tuberculin when given in sufficient quantity. We have confirmed this.

2d. *Has "antiphthisin" any germicidal action on the tubercle bacillus in vitro?*

Six cubic centimetres of a suspension of a virulent culture of tubercle bacilli on serum having been made in water, 0.5 c.c. was injected subcutaneously in the thigh of four control pigs. Three cubic centimetres of the same suspension were now mixed in a little sterilized beaker with 3 c.c. of pure "antiphthisin" prepared by us as stated above, allowed to stand six hours at the room temperature, and 1 c.c. of the mixture injected into five pigs in the same manner as in the controls. All the animals died within two months.

The average life of the controls was fifty days. The average life of the test animals receiving the cultures which had been left six hours in contact with "antiphthisin" was thirty-nine days. The lesions of the test animals differed in no appreciable manner from those noted in the controls.

3d. *Do "tuberculocidin" or "antiphthisin" exert any curative influence over the course of experimental tuberculosis in the guinea-pig?*

Twelve guinea-pigs were each inoculated in the inner aspect of the thigh, subcutaneously, with 0.5 c.c. of an emulsion made from tubercular glands and peritoneal tubercles taken from a rabbit dead with acute tuberculosis. Six were kept as controls, and treatment of the other six was begun by injecting subcutaneously on the following day, in each, 0.25 c.c. "antiphthisin" one-tenth conc.

Injections were continued every second or third day and the dose gradually increased, so that within a month the animals were receiving each 1.5 c.c. "antiphthisin." The dose was then reduced to 1 c.c., and injected at intervals of two or three days until death.

The average duration of life for the control animals was thirty-nine days; for the treated, thirty-three days. In two of the treated animals the extensive tubercular lesions found in all showed bluish congestive areas such as are usually seen in tubercular guinea-pigs injected with Koch's tuberculin. Otherwise the post-mortem appearances were about the same in both sets of guinea-pigs.

A similar experiment was also made with "tuberculocidin" purchased in open market, with materially the same results.

4th. *Is the death of the germs in over-ripe cultures due to the formation of a specific germicidal substance in such cultures, or to some other cause?*

Dr. Klebs's observation that if a culture medium in which tubercle bacilli have once developed be replanted no growth will occur, was several times confirmed by us. In testing carefully, however, such a medium before planting, and after the germs have ceased to develop on it, it was observed that its reaction had become markedly changed.

Peptonized glycerinated bouillon ready to plant with tubercle bacilli should be either neutral or faintly alkaline, but after an abundant crop of the bacilli has developed on its surface it may be noticed that its reaction has become more or less markedly acid, according to the depth of the culture medium in the flask and the richness of the growth. Whether this acidity is brought about merely by the abstraction from the medium of some of its alkaline constituents for the needs of the growing germs, or by the addition to it of an acid substance produced as the result of the microbes' metabolism, has not yet been accurately determined, and the cause of this acidity offers a subject for further study; but as "antiphthisin" is alkaline, no germicidal influence can be claimed for it on that ground. It seemed to us not improbable that the failure to obtain a second growth on such a medium, if replanted, might be due simply to its acid reaction alone, and the following experiment to determine the correctness of this hypothesis was therefore made:

Having grown cultures of tubercle bacilli on peptonized glycerinated bouillon for seven weeks, until the thick pellicle formed by the germs began to look humid and sink at the sides, a few drops of a sterilized solution of NaOH was added to the culture fluid until the acid reaction found to be present in it was changed to a perfectly neutral one. This neutralized medium was then filtered through a previously well-sterilized Kitasato filter into small sterilized flasks. Fresh plants of actively growing tubercle bacilli were made in all of these, and the entire lot placed in the thermostat at 39° C. No contaminations occurred, and, as is not un-

[1] Kühne: Loc. cit.
[2] Crookshank and Herroun: Journal of Physiology, vol. xii.
[3] Mathes: Deutsch. Arch. f. Klin. Med., S. A., 1894.

commonly observed in the cultivation of the tubercle bacillus, but little growth took place during the first two weeks. From that time, however, the pellicles began to spread and thicken in the usual way, and five weeks from the day of planting the entire surface of the flask was covered with a rich growth.

Conclusions.—1. The substance made according to Klebs's published method, and called by him "antiphthisin," resembles deutero-albumoses in its chemical reactions, and can be precipitated by sodium-bismuth-iodide. Hence it has no peculiarity of behavior to that reagent to distinguish it, and as a similar substance can be obtained from unplanted bouillon, it cannot be considered an altogether specific product of the tubercle bacillus.

"Antiphthisin," prepared according to Klebs's published method, is practically highly diluted tuberculin, and its physiological effect on animals, when given in sufficient doses, is the same as tuberculin.

2. "Antiphthisin" possesses, under the conditions stated above, no germicidal power on the tubercle bacillus which can be demonstrated *in vitreo*.

3. When applied to animals, as stated above, neither "tuberculocidin" nor "antiphthisin" had any curative influence over the course of experimental tuberculosis in the guinea-pig.

4. Since cultures of the tubercle bacillus become acid as they grow, and, furthermore, since the addition without heat of a little alkali to a filtered culture medium upon which bacilli have ceased to grow renders it again fit for the development of a second crop of germs so long as any nutriment remains, it may be inferred that the limitation of the growth of the tubercle bacillus in such a culture medium is most likely due to the acidity induced in the medium, rather than to any specific germicidal substance produced therein.

A PRACTICAL METHOD OF MEASURING AND REGISTERING THE TRUE THERAPEUTIC DOSE OF INDUCTION-COIL CURRENTS.

By S. H. MONELL, M.D.,

BROOKLYN, N. Y.

A FORMER paper by the present author described a new induction-coil apparatus with a number of original improvements designed by me to increase precision and efficiency. In this second paper I now present to the medical profession my method of dose measurement and registration, which, so far as inquiry discloses, is the first practical method with a scientific basis.

I am met at the outset of my proposition to measure and record induced medical currents by the curt remark that it cannot be done. With this declaration before us, let us review a group of contemporary statements upon the subject of faradic dosage. The authority for each will be easily recognized by all familiar with the literature of electro-therapeutics.

1. "A bar to the progress of faradism is the impossibility of satisfactory therapeutic measurement. Edelmann's faradimeter is incomplete and, I must even add, misleading as a physiological or therapeutic measure."

2. "The Edelmann faradimeter, which is not by any means, as was intended, a measure of faradic electricity, is too complicated and expensive for the practitioner, . . . and is merely a deceptive snare for physiological or therapeutic purposes. The strength of the current would be far better approximated by indicating the nature of the coil and the resistance offered than by the volt scale of this faradimeter."

3. "Unfortunately we have no means of measuring accurately the dose of faradism, the only means at our command being the millimetre scale placed at the side of the coils. This is a very rude method, indeed, but it is all we have at present."

4. "It is much to be regretted that we have no means of accurately measuring the therapeutic dosage of the faradic current."

5. "The old attempt to measure the faradic dose by a coil movable over a primary core, on a graduated scale, was so unscientific and inadequate as to be ridiculous."

6. "It is the ability to record the doses of the current to which must be ascribed the rapid progress of galvanism. To give the necessary impetus to faradism we must obtain this same precision, . . . and toward this end my efforts have been directed ever since I realized how seriously this valuable remedy was affected by its vagueness and uncertainty; and as early as 1886 I sought to approximate dosage by a defining and precising of details."

7. "The precise measurement of the faradic current for therapeutic purposes has not as yet been satisfactorily attained. The method heretofore in vogue, of measuring on a scale the distance the secondary coil is advanced over the primary, is inaccurate and delusive—in fact, means nothing—since the battery current varies with use; and no estimate is taken of the variable resistance encountered in the external circuit, which is altered by the location of the electrodes, by their size, and by the distance between them. The fact that this current possesses the same two qualities as the galvanic current—pressure and volume—makes it evident that we must in some manner estimate the relative voltage and amperage of the current employed in order to arrive at a practical conclusion of its comparative value."

The striking remark of Engelmann's, which closes the second comment cited above, although not observed by the writer previous to the preparation of this article, foreshadows what is substantially accomplished by the method to be described in this paper, and which was originated by me, January 29, 1894. My method also takes into account what is suggested as necessary in comment number seven, but before proceeding with descriptive details, certain relative facts require to be understood. These are as follows: No automatic meter or measuring instrument is required to select the proper dose of faradism for a patient, or to adjust it to the needs of therapeutic use. Direct currents need such an indicator, but induced currents do not. The educated skill of the operator regulates the dose, and does it adequately. The existing need is for a standard system of recording the dose administered, and thus impart uniform value to the reports of clinical cases, and introduce precision and definiteness into the special literature of the subject.

The accepted dose measurer of the constant current is the milliampèremeter, adopted universally within half a decade, and which in general estimation has lifted the galvanic current from empiricism and placed its therapeutics on a scientific basis. Let us, therefore, note exactly what the milliampèremeter accomplishes and what part it plays in the dose record, in order that we may better understand the problem before us in attempting to measure and record the dose of induction currents.

To enable separate observers to compare and repeat results in clinical cases treated by galvanism, we should take into account every factor which affects the action of the current. A comprehensive record must necessarily inform us then, on the following points: 1. Surface area or type of electrodes—which range from needles, sounds, tips, etc., to small or large pads, or water-baths, or may be clay, copper, zinc, carbon, platinum, steel, tin, brass; or covered with sponge, cotton, felt, etc., determining conducting power and density of the current. 2. Situation of both positive and negative electrodes during treatment. 3. Tissues treated and their pathological state, symptomatic conditions, etc. 4. Time and frequency of administration. 5. Reading of the milliampèremeter, or current volume.

Clinical reports of these particulars, with results of treatment, would be complete; and while of the various factors the meter furnishes but one, it supplies the last essential to the dosage of galvanism.

When we enter upon the problem of faradic dosage we find the factors no fewer, but differing in character. These are now: 1. Character of the current, as determined by the coil employed. 2. Description of electrodes and their situation during treatment. 3. Rate of current interruption. 4. Tissues treated, condition, etc. 5. Current strength. 6. Time and frequency of application.

The missing link in our clinical record is a means to state the current strength. We can sufficiently indicate the rest. How shall we measure the current strength? Now, certain features enter into the measurement of a constant current which are eliminated from the case of an interrupted or alternating current. The therapeutic requirements of the two are inherently dissimilar. The galvanic current is silent in its flow and physiological activity. Without observing the deflection of the galvanometer needle, or making other test, we may be in doubt whether or not the battery is in action until the current is strong enough to be felt by the patient, and as a guide to treatment the patient's sensations are incompetent. The predominating quality of the direct current is volume—its voltage being relatively small in medical uses—and "volume" cannot be determined by the eye or ear of the operator. On the other hand, the induction apparatus, through its break-piece, which is the essential, the very life of this form of electricity, gives forth to the ear and sight unmistakable evidence of action; and its current is one of predominating force, of insignificant volume, chiefly mechanical in its physiological effects, and nearly devoid of chemical properties. It therefore requires no peculiar safeguard, like the milliampèremeter, against an excess of electrolytic or cautery action within the tissues. Moreover, owing to the feeble power of dissociation possessed by the constant current, an enormous range of uncertainty enters into every galvanic application without a meter in the circuit; for the actual current strength — *i.e.*, dose — from the same number of cells and with the same electrodes will vary greatly with the degree of resistance of the skin, etc., so that similar conditions of E. M. F. are no guide whatever to similar doses and effects. With the galvanic current, with either 5, 10, 20, or 40 cells E. M. F., and with the electrodes in a glass of water, I can cause the meter to vary from 2 to 250 M. A., without altering the electrodes or the battery, simply by lessening the resistance of the water.

The nature of the induction current, however, is such that little of this great variability occurs in clinical applications when similar conditions of treatment are repeated. A given E. M. F. will produce a definite current strength from a given induction coil, and repeat it under the same conditions as often as desired. The influence of slightly varying skin resistances of different parts of the surface of the body is insignificant in the case of the higher voltage and penetrating capacity of currents from induction-coil apparatus. We have, in fact, but two practical conditions of resistance to consider in faradic therapeutics, viz., the greater general resistance of the skin in external treatment, and the lesser resistance of the moist, mucous surfaces of the cavities of the body. Thus presented, we observe that the problem of faradic dose-measurement, or means of record, is much simpler than was that of the now solved problem of galvanic dose-measurement; for if we can by any means indicate the electrical or mechanical energy of our induced currents under conditions identical with their clinical administration, we are assured of obtaining the same energy for therapeutic uses and repeating it upon patient after patient with substantial accuracy. A standard indicator of current strength will accordingly serve as a subsequent dose-register for future applications from all similar apparatus.

The methods so far suggested for measuring the dose of induction-coil currents are as follows:

1. A strip of suitable material, wood, celluloid, or vulcanite, is placed at the side of the coil and marked in fractions of inches, or of the decimal scale. The current increases in strength as the coil overlaps the primary, and the dosage is taken to be the extent of overlap during the séance. The capabilities of measurement are exhausted when the overlap is complete, and the record must be alike for one or four cells, or No. 36 or No. 16 wire coils. It is not surprising that this attempt to measure current strength by a foot-rule was never scientifically successful.

2. The graphic method of marking the current waves; a purely fanciful idea adapted for black-board illustration of certain currents characterized by sufficient amperage to operate the tracing-pencil, but neither practicable outside of the expert's hands, nor capable of demonstration at all with the currents of higher tension and frequency and consequently smaller amperage now performing so much of the therapeutic work of improved induction apparatus.

3. The Edelmann faradimeter.

The name faradimeter is felicitous and suggestive of a proper method, but it has never reached a more practical stage of development for ordinary use than have ships for navigating the air. It is a complicated, expensive, though highly scientific, meter for the voltage of the current in short circuit; and since therapeutic applications involve the interposition of body tissues this instrument has no relation whatever to a physiological unit.

4. Micro-coulombs were asserted to be the electrical unit by which to express faradic measurement, but when we turn to the coulombmeter for aid we are practically where the faradimeter left us.

5. Voltmeters, ammeters, and wattmeters that fill successfully their proper places in measurements of large commercial currents, do not supply us with any means to meter the small currents of medical coils. If a miniature wattmeter could be made to work it would be too expensive for general use.

6. Rate of interruption.

It is assumed that if this is stated in mathematical terms a certain amount of precision will be secured. Other factors, however, affect the question of dosage too materially to place dependence solely upon knowing the frequency of the periods.

This brings us to consideration of the method proposed and successfully employed by me for upward of a year. It is a method which, in my hands, has passed beyond the nascent stage of hopeful theory into the practical demonstration of constant and satisfactory use. The method was first made possible when I introduced my non-inductive fluid current controllers into the secondary circuit. They easily supersede in value all previous methods of regulating current strength.

The switch board of my induction apparatus presents a rapid interrupter (vibrations of 10,000 to 30,000 per minute); a slow vibrator capable of adjustment from about two thousand periods per minute down to less than one period per second; a cell selector throwing into circuit from one to six cells at will; an eight-button compound coil selector; a pole reverser and a metallic rheostat governing the primary current. This consists of a perpendicular column seven inches in height, wound with German-silver wire of definite resistance, making twenty turns to each inch of column. Attached to it is a registration scale to denote every wind of wire from zero to 140, and permit a record of position in every degree of use. This scale is also an advance in accuracy of record, first suggested by me. But the peculiar novelty introduced in this apparatus is the author's secondary circuit rheostat, which con-

sists of the glass tubes seen at the left of the switch-board and marked respectively 1 and 2. They contain prepared fluids of great resistance (much greater than water), and are the first competent controllers successfully applied to the secondary current of a medical induction battery. The capacity of the first (one megohm) is sufficient to control the full coil, high-tension current, and reduce the perception of it to zero in the most delicate external applications to a patient.

The second tube possesses a much lower resistance, for currents of less penetrative force. Each tube is scaled in ohms of their actual resistance, measured and calibrated for me by Professor F. B. Crocker, of Columbia College, New York. The rationale of my method is now extremely simple. The fluids in one or both tubes, and at certain heights of the movable contact rod, varying with the primary E. M. F. and current density, entirely nullify the patient's perception of the activity of the induced currents, *i.e.*, control them, and reduce their physiological and therapeutic manifestation to zero, and afterward regulate them to any strength we desire. What resistance to the energy of any given current does it require to do this? The answer to this question is the solution of faradic dosage.

The scale referring to tube No. 1 shows the total resistance of its four and a half inches of fluid column to be one megohm. As the movable electrode descends in the tube the resistance lessens until it is only 900, 800, 600, 400, 200 thousand ohms, and so on down to the minimum, when the electrodes of the rheostat are nearest contact. The great resistance of this tube is designed to regulate the higher tension currents of the compound coil, which, in this apparatus, I have caused to be placed invisibly behind the switch-board and fixed in complete overlap upon the primary helix. This coil is immovable and does away with former sledge methods of sliding coils on and off, while it generates at all times the maximum of inductive influence.

Tube No. 2 is of much lower resistance, ranging from 55,000 ohms down to a residual resistance of 4,000 ohms, and is suited to the regulation of currents of small voltage, from short, coarse coils, or other applications where great tolerance exists, as within the pelvis. An additional turn of a switch also cuts out these secondary rheostats and furnishes all currents direct from the coils, in case this is desired. The metallic rheostat in the primary circuit then regulates the dosage by altering the E. M. F., but this rheostat takes no part in my special method of dose registration.

In my method, in applying a given current strength to a patient, it is simply considered that the energy at first wholly absorbed within the secondary rheostat, when perception of the current is nullified on its passage through the rheostat to the patient, is transferred from the controlling grasp of the rheostat to exert an equivalent energy within the tissues when the descent of the movable rod in the tube reduces resistance proportionate to its descent, and in exact proportion raises the current strength in the part of the circuit between the applied electrodes. In other words, as the restraint of the current falls in the rheostat its released energy rises in the patient, and by measuring the degree of restraint we find the equivalent of the released energy.

"Things which are equal to the same thing are equal to each other," and knowing the graduated resistance in electrical units of ohms interposed and removed from the secondary circuit at will, our knowledge of Ohms's law substantially defines for us the values of therapeutic dosage. We have only to let a portion of the measured rheostat substitute itself for the patient's tissues while we at first test the degree of energy to employ, and next to pass on the same current value to the patient, to arrive at a very practical measure of the dose administered. The resistance of the body is compensated in the process and causes no error, and the battery E. M. F. is unaltered during the dose regulation.

Before describing further the details of my method, it is proper to cite the authority for the electrical measurements which constitute the scientific basis of accuracy claimed by me above.

"NEW YORK, December 17, 1894.

"DR. S. H. MONELL. DEAR SIR: I return herewith the two tubes containing liquid resistances which you submitted to me. I have calibrated each tube and provided it with a scale which shows its electrical resistance in ohms for every position of the movable electrode. My opinion in regard to these devices is as follows: 1. A liquid resistance is a very simple and convenient means of obtaining very high resistance for medical use. 2. By changing the liquid the range of resistance may be varied from several megohms to a fraction of an ohm. 3. The screw adjustment of the electrode enables the resistance to be gradually varied to any value, without the sudden shock which occurs when resistance coils are cut out. 4. The resistance is non-inductive, hence there is no reaction against or distortion of the current, which is very important in connection with induction (faradic) coils. 5. A short circuit cannot occur, the electrodes being arranged so that it is impossible for them to come in contact, whereas there is serious danger of short circuit in resistance coils with high-tension currents. 6. The resistance is practically definite and constant, provided the temperature remains nearly the same. With the small currents ordinarily used the heating effect is small, but if necessary the temperature can be tested by a small thermometer and kept constant or allowed for. 7. The effects of polarization and electrolysis are insignificant, since the potential is high and the current is alternating in the case of induction-coils, with which these resistances are to be used. 8. The liquid does not appear to be affected by the action, or to change in any way, but it is of course impossible without actual trial to tell what effect might occur in a long period of time. Any difficulty of this kind might be overcome by renewing the liquid occasionally.

"Yours truly,
"F. B. CROCKER,
"*Professor of Electrical Engineering, Columbia College.*"

While therefore the once proposed scale of fractions of inches was a purely fictitious and ridiculous travesty upon scientific dose-measurement, the author's method is a comparative record of the current strength and not a mere fragment of a tailor's yard-stick. As such a resistance register and rheostat is of general applicability, and may be placed by all instrument-makers upon high-grade batteries and properly standardized for clinical use, it may be fairly claimed that the general adoption of my method would supply the long-expressed need for precision in faradic dose records.

To illustrate the method let us hold, for example, two ordinary electrodes in the hands, select for our coil one thousand five hundred yards of No. 36 wire, and employ very slow interruptions of, say, seventy per minute. We raise the rod in tube 1 to its full height and switch four cells into circuit. Gradually lowering the contact rod, we note the point where the current becomes first perceptible to sensation. It is at 700,000 ohms resistance on the scale. Taking this as our zero unit, we continue to lower the rod until muscular contractions are produced as strong as we desire. The rheostat now indicates but 100,000 ohms, showing that 600,000 ohms of resistance have been removed from the passage of the current into our arm muscles, which feel and respond to the force previously expended within the rheostat. If now I record the facts: Coil, 1,500 yards of No. 36 wire. Interruptions, 70. E. M. F., four cells. Dose, 600,000 ohms, small sponge electrodes in hands, positive in right; I can repeat the exact ap-

plication and muscular effect whenever and as often as wished, even should the cells deteriorate by use so as to require five or six cells to equal the energy recorded. There is no parallel to this precision of record to be found in the literature of faradic electricity. The method allows for all possible variations in treatment.

Again, using a short, coarse coil, one hundred and fifty-four yards of No. 21 wire, for instance, we obtain sensation with a given contact at 36,000 ohms resistance of tube 2; and full tolerance is reached when but 4,000 ohms remain. The given dose is therefore the electrical energy represented in overcoming 32,000 ohms of resistance with the current quantity value indicated by the capacity of the wire in the induction-coil. It is not essential to know the galvanic amperage of different sizes of wire with a corresponding voltage, for we are not dealing with galvanic but with induced currents, in which volume is subordinate to potential and kinetic energy; and our different coils—long, medium, short, fine, and coarse—take on a definite individual identity under habitual use which serves the expert as a practical expression of their quantity values. Our second record reads with electrodes same as before, but a more rapid rate: Coil, 154 yards No. 21; frequency, 300; cells, two; dose, 32,000 ohms.

In the last case the lower voltage is seen to be commensurate with the greater volume conducted by the coarse wire, while the previous high voltage of the long fine-wire current was proportioned to the extremely diminished volume induced through it.

In making a vaginal bipolar application with a very rapidly interrupted high-tension sedative current we use tube 2, with its low resistance, owing to the enormous tolerance of the tissues treated.

An illustrative clinical record reads as follows: Vag. bipolar sedation, coil, 1500, No. 36. Rapid vibrator, E. M. F. 4 cells. Dose, 45,000 ohms, twenty minutes, daily.

If this seems to express a small dose (an inadequate estimate of the great tolerance of the pelvic tissues), it must be remembered that it is the difference between zero sensation and the maximum current strength administered with electrodes applied in actual treatment, which is recorded as the dose, and not the difference between the sensitive nerve-filaments of the hand and tissues whose dulness of sensation and low resistance to current diffusion permits them to accept with comfort and benefit an application which would be painful on the surface of the skin. If the dose was reckoned from a zero obtained in one arbitrary manner, say, by touching the electrodes with the finger or thumb before applying them to the patient, it would bear no genuine relation to the dosage of larger contact areas, of different varieties of electrodes and different parts of the body.

To be a scientific and universal method it must answer for all conditions of treatment, and my method does this perfectly. The use of a single cell, or of any number up to six (the battery contains six cells), will determine the zero at a higher or lower point on the scale, and the same cells, as they deteriorate, in time will alter their E. M. F.; but these variations do not alter the accuracy of my dose record, which is the difference between the minimum and maximum rheostat readings independent of the number of cells it takes to furnish the given inductive force.

The difference, also, in power to penetrate tissue resistance will create a different zero point for each length and size of wire, even with the same E. M. F. inducing force and same electrodes; but with standard coils, a standard method of finding the actual zero point in all cases, with any coil, with any number of the battery cells at any period of their life, my method furnishes a flexible, permanent, and accurate measurement of the true therapeutic dose. Its adaptability to varying conditions of current volume, voltage, resistance, and density removes all sources of error.

This method, carried out in its fullest detail, is particularly applicable to the records of clinicians and other observers whose investigations require an exact comparison of results. In general practice the physician will soon familiarize himself, at least approximately, with the position of the rheostat for various zero readings, just as the skilled book-keeper soon remembers the ledger pages of his accounts; so that actual tests for zero will be unnecessary except, perhaps, in the first treatment of a new case. If the full dose record is considered superfluous for the physician's own records in his ordinary office work, a modification will furnish satisfactory notes for personal reference. In using the modified method which I suggest, we need not repeatedly calculate the actual dose administered, but simply note the conditions under which the maximum current was applied by recording the lowest reading of the scale. For example: Coil, 1000, No. 36. Rapid V.; cells 5; scale 6000; tube 2; vag. bipolar, 20 minutes. There is no expert electro-therapeutist equipped with similar apparatus who, on reading this record, could not instantly apply the same treatment with the same dose, though he were a thousand miles away. The use of initials for full words will, of course, abbreviate the record in our private case-books and be equally intelligible to our understanding.

My resistance scales, therefore, clearly supply to induced currents a dose indicator as practical in their case as the milliametre is in the case of direct currents, and complete the hitherto imperfect record of faradic administrations. Of the other factors requiring report for purposes of uniformity in clinical observations, the character of the electrodes can always be identified by sizes, numbers, or names, as in makers' catalogues. Quantity and quality, the elements of induced currents subordinate to their energy and pressure force, are, as we have seen, sufficiently expressed by reference to the particular coil employed. A more exact description will hardly be required by experts in electro-therapy. As the trained electrician becomes accustomed to the quantitative and qualitative differences in effect between every coil in his apparatus, whether 500, 1,000, or 1,500 yards of No. 36 wire, or 800 or 500 yards of No. 32 wire, down to shorter coils of No. 21 or 18 size, he accurately knows the characteristics of currents from them all, and utilizes their diverse properties with intelligence and precision.

It would add no therapeutic value to his knowledge if the current volume, per wire, was noted by a meter in terms of amperage, or the E. M. F. in volts.

There now remains but one factor of dosage still surrounded by vagueness and lack of precision in theory, although clearly defined enough for practical purposes. This relates to the record of the rate of current interruption, a very important part of the matter indeed. Very low ratio (50 to 300) can, however, be stated in comparative figures, while very rapid interruption does not require a numerical term to express its frequency. Speed, as stated in mere figures per minute, is so involved with other qualities of adjustment, evenness, constancy, length of period, etc., that the advantage of a mathematical record can be greatly overestimated.

I have referred to this in other of my writings, and it is out of place to dwell on this point at present, though it is one of peculiar interest. A closely related feature, however, may claim our attention briefly.

It is the ideal of some who have sought to define faradic dosage by rate of interruption, and who have devoted much time and special thought to the improvement of faradic apparatus, to construct an independent interrupter, actuated by a current separate from that which supplies the inducing force.

The reason for this lies in the fact that every change in the regulation of current strength made in the primary circuit varies the rate and force of the interrupter in instruments as generally made. A prominent

writer has ably argued the advantages of such a method, and states that it can be adapted to every kind of contact-breaker, the motor power for the rheotome being furnished by a single separate cell. The importance of steadfast E. M. F. and unvarying evenness of interruption throughout all gradations of the induced current strength, is so great, so essential to the satisfactory employment of faradic electricity, that no battery not providing for independent secondary current control can be considered as representing the advanced progress of to-day.

Manufacturers of medical batteries, however, do not all agree with the writer who advocates the separate cell for the interrupter, and are well-nigh unanimous in declaring that the mechanical obstacles to the device are insurmountable in practice. The theory is correct, but makers have failed to apply it successfully to the spring vibrators in common use. My apparatus easily surmounts the difficulty; furnishing not alone one cell to actuate the break-piece, but places six at our disposal at will, as independently as any theorist could desire. My former article describing the improved induction apparatus designed by me, referred to this feature at some length, but I wish to emphasize again the far-reaching importance of the secondary rheostats which accomplish this purpose in my battery, and to state further that, were their usefulness and influence restricted to mere regulation of induced current strength, without jarring or irregularity, or change in the primary flow, the advantage they would thus contribute to clinical handling of both patient and battery would alone stamp this apparatus as without an equal in therapeutic convenience and capabilities. That beyond this these rheostats make possible a practical dose record, is proof of their fundamental necessity to a perfect instrument. If still unconvinced that they are indispensable, let us attempt to adjust a slowly interrupted induced current—say fifty periods per minute—to a dosage of strength sufficient to produce powerful but painless, rhythmical, and non-tiring contractions of certain arm muscles, with a gradual and even decrease to scarcely perceptible sensation. With the ordinary interrupter, sliding coil, or primary rheostat, it cannot be done, even with the costliest appliance in the market. With my apparatus it is done instantly and with the most striking success. As an object-lesson in the inadequacy of old methods of current regulation, and of the superior efficiency of my secondary rheostats, it leaves nothing open for argument. Professor Crocker's letter appreciatively sums up the rest.

863 Union Street, Brooklyn.

A Slap at the Bacteriologists.—These are useful assistants, but they are tyrannical masters, and the results of a given treatment must after all be judged, not in the laboratory, but in the hospital ward and the sick-room. A check must be imposed on garrulous bacteriologists who show a disposition to ride the cock-horse among us. We are grateful to them for such assistance as it may be in their power to render to medical science, but we cannot allow them to dictate to us what conclusions we are to draw from clinical investigation. Bacteriological statements are matters of inference, but clinical observations are facts; facts, too, which concern us more nearly than the interesting, but too often contradictory, deductions which foreign laboratory men foist upon us at the point of the scalpel.

A Naval Hospital Corps.—Surgeon-General J. R. Tryon recommends the establishment of a hospital corps for the navy, the limiting of the number of recruiting stations, and establishing a rendezvous at the Brooklyn Navy Yard, and another at the Mare Island Navy Yard.

INFLUENCE OF BILE ON THE PROTEOLYTIC ACTION OF PANCREATIC JUICE.

By B. K. RACHFORD, M.D.,

Professor of Physiology in the Medical College of Ohio.

AND

F. H. SOUTHGATE, M.D.,

Assistant in Physiology in the Medical College of Ohio.

The experiments recorded in this paper were planned for the purpose of throwing some light on the proteolytic action of pancreatic juice, under the conditions which normally exist in the duodenum. In brief, the questions which these experiments were planned to inquire into are as follows: 1. Does the presence of hydrochloric acid combined with proteids influence favorably or unfavorably the action of pancreatic juice on these proteids? 2. Does bile, when added to neutral proteids, influence favorably or unfavorably the action of pancreatic juice on these proteids? 3. Does bile, when added to acid proteids, influence favorably or unfavorably the action of pancreatic juice on these proteids? 4. Does pancreatic juice, acting alone on neutral proteids, have greater or less proteolytic power than when acting under the conditions found in the normal duodenum, that is to say, when acting in the presence of bile and combined hydrochloric acid?

It is claimed for these experiments that they are the first work of this kind which has been done with pure pancreatic juice, and for this reason, if for no other, they are deserving of some attention.

The classic work of Chittendon in this field was done with pancreatic extracts, and for these extracts his work is conclusive. But neither Chittendon, Kuhne, Lea, nor other investigators in this field have attempted any systematic research with pure pancreatic juice.

While it is not claimed that observations made with pancreatic juice are more reliable than those made with pancreatic extracts, it is claimed that these, the first systematic experiments ever made on the proteolytic action of pancreatic juice, deserve some consideration, even though this field has been so ably worked with pancreatic extracts.

Method.—The pancreatic juice was used immediately after it was obtained from the rabbit. One rabbit, as a rule, would furnish sufficient juice for an experiment. The juice was obtained by the method[1] devised by one of us (Rachford), and first published in the *Journal of Physiology* (vol. xii., No. 1, 1891). The proteid used in these experiments was the one recommended by Chittendon, which he describes[2] as "purified and dried-blood fibrin, prepared by thorough washing with water, extraction with cold and boiling alcohol, and lastly with ether. It was then ground to a coarse powder and dried at 100° to 110° C." The digestive mixtures containing the pancreatic juice and other fluids, as noted in the tabulated experiments, were kept at 40° C. for from four to ten hours. These mixtures were then filtered through weighed filters, and the residue (fibrin) left upon the filters

[1] Make an abdominal incision in the linea alba, two and one-half inches long. Bring the duodenum, which is readily found high up in the right hypochondriac region, through this opening, run down the gut to a point where the peritoneum binds it so closely that it will not come through the opening, and just at this point will be found the pancreatic duct, as it runs through a leaf of the pancreas to the small intestine. Resect two inches of the intestine at this point, leaving its mesenteric attachment; tie the cut ends of the intestine above and below, and drop them in the cavity, bringing the resected portion through the abdominal wound. The abdominal wound is now partially closed by stitches, leaving only sufficient opening for the mesentery running to the resected gut. This resected gut is now laid open opposite the mesenteric attachment and spread out on the abdominal wall. The ends of the gut are clamped and its lateral margins packed with absorbent cotton to prevent bleeding. Insert a small glass cannula through the pancreatic papilla into the pancreatic duct, and cover the exposed mucous membrane with absorbent cotton saturated with common salt solution. The flow of juice begins at once and continues from four to six hours. In this manner about one cubic centimetre of jnice, uniform and powerful in physiologic action, may be collected.

[2] This method is described in Chittendon's Studies in Physiological Chemistry, vol. i., p. 77.

was thoroughly dried. After forty-eight hours of drying they were again weighed; the weight of the filter being subtracted from this weight would give the weight of the undigested fibrin. Six grains of the fibrin were used in each experiment, and the difference between this and the undigested residue would represent the amount of fibrin digested, and would therefore measure the proteolytic power of the digestive mixture which did the work.

With this table before us we can now study the questions which these experiments were planned to investigate.

1. Does the presence of hydrochloric acid combined with proteids influence favorably or unfavorably the action of pancreatic juice on these proteids? In answer to this question, Chittendon, working with pancreatic extracts, says:[1] "Experiments made in my laboratory have shown that as soon as free acid, especially hydrochloric acid, is present in a solution containing tripsin, then proteolytic action is at once stopped. When, however, acids, especially organic acids, are present in a digestive mixture containing an excess of proteid matter, so that the solution contains no free acid (or better with the proteid matter only partially saturated with acid), then tripsin will continue to manifest its peculiar proteolytic power, although to a considerable lessened extent." In our experiments we have found that the proteolytic action of pancreatic juice on fibrin is quite as strong in a one-thirtieth per cent. hydrochloric-acid solution as it is in a neutral solution. If there is any difference, in fact, it is in favor of the hydrochloric-acid solution. In only three (1, 4, and 12) of the twelve experiments did the pancreatic juice in neutral solution do more work than the pancreatic juice acting in acid solutions. In two (8 and 9) experiments the same work was done in the acid as in the neutral mixture; while in seven (2, 3, 5, 6, 7, 10, and 11) experiments slightly more work was done in the acid mixture than in the neutral. From these observations we conclude that the proteolytic action of pancreatic juice is not retarded by the presence of a small percentage of hydrochloric acid—such, for example, as existed in our experiments and probably also exists in the normal duodenum.

We are encouraged to publish this observation, iconoclastic as it may seem, because some comparative anatomy[2] studies made by one of us (Rachford) lead to the same conclusion. In these studies it was found that flesh-eating animals had the common opening for their bile and pancreatic ducts very near the pyloris, and that the more exclusively flesh-eating the animal was the nearer to the pyloris was this common opening. If the acid contents of the stomach destroyed the proteolytic action of the pancreatic juice, it is needless to say that the opening of the pancreatic duct would not approach the stomach in the exclusively carnivorous animals, even though such an arrangement might best serve the purposes of fat digestion.[3]

2. Does bile when added to neutral proteids influence favorably or unfavorably the action of pancreatic juice on these proteids? In answer to this question, from experiments made with pancreatic extracts, Chittendon[3] says "the addition of bile to a neutral pancreatic juice (pancreatic extract) causes but little change in its proteolytic action." "A slightly increased action is the only effect produced on the tripsin."

In our experiments we have found that the addition of bile to pancreatic juice very decidedly expedites the proteolytic action of pancreatic juice on neutral fibrin. In one experiment only (4) did the pancreatic juice do more work acting alone than it did acting in the presence of bile, and this result being at variance with all the other experiments was probably due to some unavoidable error of technic. But if we average the results in the other eleven experiments we find that the proteolytic action of pancreatic juice on neutral fibrin was increased one-fourth by the addition of bile. Pancreatic juice acting alone digested, on the average, one and five-sixths grain of neutral fibrin, while pancreatic juice acting in the presence of bile digested, on the average, two and three-sixths grains of neutral fibrin. We conclude, therefore, that bile, in the duodenum as well as in our experiments, materially expedites the proteolytic action of pancreatic juice. This conclusion is sustained by the comparative anatomy research previ-

[1] Digestive Proteolysis. Cartwright Lectures, 1894.

[3] Studies in Physiological Chemistry, vol. i., p. 136.

ously referred to. In this study it was demonstrated that there was a preliminary mixing of the bile and pancreatic juice before entering the duodenum in all flesh-eating animals, and it is not probable that this arrangement has been brought about exclusively by the physiologic laws of fat digestion.

3. Does bile when added to acid proteids influence favorably or unfavorably the action of pancreatic juice on these proteids? In answer to this question, Chittendon[1] says: "In the presence of combined hydrochloric acid, the bile salts produced no effect whatever; the trypsin was entirely without action." Our experiments lead us to the conclusion that bile very greatly aids pancreatic juice in its proteolytic action on acid fibrin. We found in eleven out of twelve experiments, that the proteolytic action of pancreatic juice on acid fibrin was increased by the addition of bile. Pancreatic juice acting alone digested, in the average, one and fourteen-sixteenth grain of acid fibrin, while in the presence of bile, the same pancreatic juice in the same time digested two and nine-sixteenth grains of acid fibrin, a difference of eleven-sixteenth grain. In other words, the presence of the bile enabled the pancreatic juice to do one-third more work on acid proteids than it could have done alone. Here again the conclusions from our laboratory experiments are in accord with those which may be drawn from the fact in comparative anatomy above mentioned, viz.: the more exclusively carnivorous the animal the more closely does the common opening of the bile and pancreatic ducts approach the pyloris.

4. Does pancreatic juice acting alone on neutral proteids (fibrin, etc.) have greater or less proteolytic power than when acting under the conditions found in the normal duodenum—that is to say, in the presence of bile and combined hydrochloric acid? The answer to this question is to be found in the combined answers of the questions which have preceded it. To facilitate conclusions, the following averages are taken from the experiments above outlined: Pancreatic juice digested $1\frac{6}{8}$ grains of fibrin. Pancreatic juice + Hcl digested $1\frac{1}{8}\frac{5}{8}$ grains of fibrin. Pancreatic juice + bile digested $2\frac{3}{8}$ grains of fibrin. Pancreatic juice + Hcl + bile digested $2\frac{5}{16}$ grains of fibrin.

If the propositions in this outline be true, one may read at a glance some rather startling physiologic facts. *a*. A small amount of hydrochloric acid does not retard the proteolytic action of pancreatic juice on proteids. *b*. The pressure of bile greatly increases the proteolytic action of pancreatic juice on both neutral and acid proteids. *c*. Pancreatic juice acting in the presence of bile and hydrochloric acid can accomplish more work in digesting proteids than can pancreatic juice acting alone, or acting in the presence of either hydrochloric acid or bile. That is to say that pancreatic juice + bile + hydrochloric acid can accomplish more work in proteolysis than can any other known pancreatic digestive mixture.

It is an exceedingly interesting fact that although hydrochloric acid does not measurably increase the proteolytic action of pancreatic juice, yet in the presence of bile it enables pancreatic juice to do more work in proteolysis than it could do in the presence of bile alone.[2] In the normal duodenum of the carnivorous animal we find that nature has provided that pancreatic juice shall act under precisely those conditions which we have found, by our experiments, best serve the purposes of proteolytic digestion. That is to say, pancreatic juice in the normal duodenum of the carnivorous animal acts in the presence of both bile and hydrochloric acid.

If the experiments and conclusions set forth in this paper be true, we can understand from the standpoint of proteolytic, as well as from the standpoint of fat digestion,[3] why the bile and pancreatic ducts have not only been united, but have had their common opening placed near the pyloris in all animals exclusively carnivorous.

323 Broadway.

[1] Studies in Physiological Chemistry.

[2] This is in strange accord with the fact demonstated by one of us (Rachford, Journal of Physiology, vol. xii, No. 1, 1891, viz.: Pancreatic juice can do more fat splitting in the presence of bile and hydrochloric acid than it can in the presence of either of them alone.

[3] In the comparative anatomy paper, above noted, the influence which the physiologic laws of fat digestion may have had in determining the arrangement of these ducts has been fully considered.

Progress of Medical Science.

Strabotomy. — Dr. Landolt considers the advancement of the antagonistic muscle a much more valuable surgical procedure for the relief of squint than tenotomy of the squinting muscle. Even in cases of simple insufficiency of convergence or divergence, where tenotomy is admissible, the results of the latter are often unsatisfactory, because a considerable portion of the adducting or abducting power is lost. When the squint is excessive tenotomy is often inconvenient on other grounds. In the operation of advancement the excursions of the eye are always increased, without any loss in the power of the antagonist. Moreover, both convergence and divergence gain more by this operation than by tenotomy. Finally, the operation of advancement never causes any disfigurement. Tenotomy may be considered in cases of motor insufficiency, latent squint, or squint of a low degree, according to most modern opthalmologists; but Landolt believes that in all three classes of cases advancement offers greater advantages. It has never in his hands caused an over-correction of the defect. It must, however, be generally done on both eyes.—*New York Medical Journal.*

Plaster-of-Paris Bandage—To Remove Easily.—In *La Semaine Medicale*, No. 3, 1895, L. Gigli recommends a plan to facilitate the disagreeable task of removing a plaster-of-Paris bandage which is worth considering. After applying the usual layer of cotton around the limb a layer of parchment paper previously moistened and wrung out is wrapped above this and then a large-sized cord well rubbed with vaseline is placed upon this in the direction that one wishes to saw open the apparatus. Over this the plaster bandage is laid on. When, in the course of time, the dressing is to be removed, this cord, whose ends have been tied together, is loosened and one end tied to a thin steel wire which has been nicked at close and regular intervals and the wire drawn through. Each end of this wire is attached to a handle and with a backward and forward motion the plaster is at once sawed through, after which the dressing may be immediately laid off. —*Albany Annals.*

A Judge Scores "Vitapathy."—The following strong denunciation of a so-called "vitapath," who was arrested and fined (by Judge Dustin, of Cincinnati) for practising without a license, has been published. The judge, who was doubtless actuated by the fact that a man was known to have recently died without medical attention other than that of the prisoner, said, in pronouncing sentence: "Men who knowingly go into a sick-room and prevent anything being done for a dying man by silly incantations and laying on of hands are responsible for his death and ought to be on a par with a murderer in the eyes of the law. God help the dying man who relies upon you or any of the so-called graduates of quackery. You speak of vitapathy being of a higher power than medicine, and you say you ordain ministers at the same time you matriculate vitapathic physicians. Your methods are an insult to intelligence, their practice is a criminal abuse of ignorance, and your college a disgrace to civilization."

OLD NATIVE REMEDIES.

DR. HENRY S. PURDON, of Belfast, Ireland, contributes to the *Dublin Journal of Medical Science* an article upon the above subject. He states that in the Belfast vegetable market there is a stall presided over by a herbalist, and that many Belfast citizens still prefer the advice and treatment of this man to that of the registered and qualified physicians. Dr. Purdon makes this fact the text of some remarks upon the value of some of the vegetable remedies that he found at the herbalist's stall, and that are still popular among the people.

Saint-John's-wort is a herb that is recognized by its yellow flower, and is commonly called the "Rose of Sharon." This was formerly used internally in the form of a decoction for colic and gastric disorders, and also for ague. Locally, the leaves were often made into an ointment with lard and used as a dressing for wounds. The *Calamus aromaticus*, or sweet-flag, was once strongly recommended by Dr. Graves as a sheet-anchor in malaria, in doses of from twenty to sixty grains. The common carrot, or rather its seed, is still largely used as a carminative and stimulant, while the carrot poultice is popular as an application in ulcers. The scarlet *pimpernel*, called also the shepherd's-water-glass, is still used in some places as a remedy for chronic or muscular rheumatism. One of the more popular remedies, and one which we find used in this country, is the mountain-sage. Decoctions of this are given to promote perspiration and to cure colds and bronchial troubles. Dr. Purdon says, with a certain amount of *naiveté*, that tansy is still largely grown in cottage gardens, and he noticed it on stall in the market, "it being considered an emmenagogue of much power and largely used by herbalists." We regret to say that it is largely used by herbalists and others in this country also. The herb yarrow is used to a great extent by the poorer class, as an aromatic tonic, and it was formerly given in urethritis. The technical name, *Achillea millefolium*, is derived from Achilles, who is supposed to have learned its virtues from his master, Chiron, the Centaur. The couch-grass, *Triticum repens*, or dog-grass as it is also called, is one of the most useful of the herb remedies, and is still popular in modern hospitals, as well as in country districts. Walnut leaves are sold, and have been sold for many years, to be used in an infusion, internally and externally, for scrofulous affections. The older physicians thought that the walnut had a singular power of healing foul ulcers and sores. Doubtless this is due to the tannin which is contained in it.

A survey of the drugs just mentioned, and their alleged properties, does not give one a very high opinion of the powers of the herbalist. The fact is, that the day of teas and decoctions and infusions and old-woman's remedies of that character is gone by entirely. While we still have some powerful drugs, such as foxglove, among domestic remedies, the vast majority of the herbs sold for various disorders are of slight potency. Used as they often are in the form of hot teas and infusions, they have some value perhaps as stimulants and diuretics, but this value is really very slight. The elder novelists who constructed romances in which some wonderful physician or mysterious witch produces an extraordinary cure by the use of some secret herb, gathered by the light of the moon, would now find their occupation gone if they conformed their tales to any degree of reason and probability. The great secrets of the modern medical art, so far as drugs are concerned, have been brought out by the chemist and physiologist rather than discovered by the botanist or herbalist.

"URANALYSIS" AND "SYMPHYSEOTOMY."

OUR esteemed contemporary, the *Medical News*, has a reprehensible habit of misspelling a good many words and an obstinacy in holding out, even when convicted of error by every other authority as well as by incontrovertible facts. The editor has been quite put to it of late to find a reason for his unreasoning and unreasonable dislike of the two excellent words at the head of these lines, but now he is happy, for he thinks he has on his side the Rev. Dr. Skeat, the author of the "Etymological Dictionary" (which he miscalls *Etymologic* Dictionary). It seems he wrote to Dr. Skeat, asking him what he thought of the coinage of the word *uranalysis*, and received the reply: "I need not say that *uranalysis* means 'analysis of ure;' whatever 'ure' means I do not know." We fear Homer was nodding when he penned that epistle, for surely Dr. Skeat must have heard of οὖρον, οὐρέω, οὐράιη, and οὐραχός. If the Greek language sanctioned the formation of the word οὐραχός, surely Dr. Skeat ought not to make funny over *uranalysis*, of analogous derivation, especially when the word has the sanction of such an excellent and usually reliable authority as the author of Gould's "Medical Dictionary."[1] Even if we had not such good authority for the use of the word, we would prefer it to the wretched hybrid *urinalysis*, half Latin, half Greek, and altogether an abomination. We are sorry to note, however, that in Dr. Gould's dictionary this word (for both are given there) is incorrectly stated to be derived from two Greek words.[2] We wonder what Dr. Skeat would say to that etymology? We trust the editor of the *Medical News* will ask him in his next letter.

As to the spelling of *symphyseotomy* (for our esteemed

[1] Uranalysis (u-ran-al'-is is) [οὖρον, urine; ἀνάλυσις, analysis]. Urine analysis.

[2] Urinalysis (u-rin-al'-is-is) [οὖρον, urine; λύσις, loosing]. The analysis of the urine.

contemporary called for light on this point also), Dr. Skeat is more happy; he writes: "It is not the case that Greek compounds are formed from genitives. They are formed from stems. Every Greek scholar knows all about it; it is not a question of 'opinion' at all, but of simple *facts*." This time, we are glad to say, Dr. Skeat is absolutely right, and we trust our esteemed philologic(al) friend will heed the admonition and spell symphyseotomy with an *e*. The stem of φύσις, we need hardly tell the erudite editor of our esteemed contemporary, is φυσε. The genitive of the word (we mention the genitive, for it shows us the stem from which the compound is formed) was once φύσιος, and that is why we have *physiology*, a word of very ancient coinage. But when *symphysis* was made, the Attic had won a predominance over the Ionic, and the genitive of φύσις was φύσεως, and the stem was, and is, φυσε. That is why it is correct to write *symphyseotomy*. The lexicographer above mentioned, to whose authority we have appealed in the case of uranalysis, seems to have had a confused idea of the presence of an ε in the Attic stem of φυσις, for we find that he gives the preference to such spelling as symphyseal, epiphyseal, epiphyseitis, and the like, but, strangely enough, not to symphyseotomy. We cannot understand the exception as regards this word. The editor ought really to bring the lexicographer to task for his inconsistency.

CRIMINAL NEWS.

One of the features of the new medical journalism is the reproduction of the likenesses of contemporaries who have achieved the distinction of being president of a medical society, a railway surgeon, or a real professor. Another even more interesting phase of this evolution is the medical news column, in which the personal life of the every-day doctor is told with all its tragedies and vicissitudes. The stories are presented with no waste of words, but with conciseness and point that suggest much to the imagination, and yet leave little to add to the reality.

"Dr. B——, of I——, Okla., was fatally shot on November 1st by his fourteen-year-old son," is an example of the modern style of current medical news. "Dr. C——, of C——, Ind., died on November 8th of an overdose of morphine." "Dr. D——, of M——, Ariz., was shot by a sheriff who came to arrest him."

The record continues: "Dr. E——, of D——, Tex., injected three grains of strychnine into his arm by mistake, instead of cocaine—a drug to which he was addicted. He died within an hour.

"Dr. F——, of S——, Ind., was shot by Mr. Thompson, of the same place. Mr. Thompson had spoken derogatively of the doctor's skill, and Dr. F—— had expostulated with him, using a cane.

"Dr. G——, of D——, Tex., was shot by Mr. Hardcastle, of the same place, for causes not stated.

"Dr. H——, of S——, Ky., has been put in jail for intoxication and wife-beating. If he had lived in London he could have gotten off for $3.

"Dr. K——, of N——, Mo., killed a man on October 27th with a gun. The man was a burglar.

"Dr. L——, of L——, Ky., has been arrested for running off with a girl of sixteen, both on time.

"Dr. M——, of M——, Ky., has been sued for $10,000 for breach of promise, but is still practising.

"Dr. N——, of L——, Ark., has been sued for $20,000 for alienating a lady's affections.

"Dr. O——, of the same town, was killed on November 1st for doing the same thing as respects another lady.

"Dr. P——, of C——, Ill., has been arrested and sent to an asylum for announcing that Chicago is the New Jerusalem.

"Dr. Q——, of C——, O., has been arrested for sending to a patient a dun on a postal card."

The news thus gathered from the Mississippi Valley and the region of the Great Divide, shows an unquietness in the life of the American doctor which must startle those who live in the placid regions of the East. Within the space of two months we find records of six murderous and fatal assaults, six criminal arrests or suits, and two fatal poisonings.

Some of our contemporaries print these items as though they represented the news of the profession. We hope and believe, however, that most of the discreditable and criminal acts thus reported relate to men who are not really educated and qualified physicians. It would be better if medical journalism left such matters to the daily press, and confined its news to the records of scientific work.

AN UNKNOWN MEDICAL HERO.

We have often in these columns referred to the injustice which has been done by society to the claims of physicians, as compared with those of persons of other callings. The great memorials in the past have been put up to those who made a name in wars, politics, art, and literature. Measured by the actual benefit done to mankind, the progress in the comfort of life, security, and happiness, the names of many comparatively obscure physicians should stand foremost. Sir Richard Quain voices this sentiment, and in connection with it describes the obscurity into which the name of Dr Snow has fallen. To this physician, says Sir Richard, Great Britain owes, first, its immunity from epidemic cholera for the last quarter of a century, and, of course, for all future time. Through preserving Great Britain from cholera, he has saved millions of lives. In Sir Richard Quain's words, Dr. Snow "made us masters of the deadly plague of cholera. Dr. Snow thereby saved millions of lives. The sole reward which England has conferred upon him is midnight obscurity." "If he had been a soldier," he continues, "instead of a doctor, if he had slain his thousands, instead of saving his millions, every town would have hailed him as a hero, and the nation would have honored his memory with monuments more enduring than brass." Dr. Snow's work, so far as it concerned this point, consisted in his discovering that cholera was a water-born disease. In that discovery lay the secret of its practical extirpation and prevention. As long as people drink pure water they will not have cholera. This simple truth, which modern science has abundantly con-

firmed, was discovered and taught by Dr. Snow. It was, furthermore, discovered, not by accident, but by long and patient research, and the addition of fact to fact and argument to argument. Sir Richard Quain adds that he hopes to live until he has seen a monument erected to the memory of Dr. Snow, and he proposes that the memorial be in the form of a drinking fountain on the Thames Embankment. As the *Hospital* remarks, in reference to this matter, the medical profession is not altogether blameless, so far as Dr. Snow is concerned. We fear that there are really very few of us who do not belong to those who never knew or had forgotten that there was such a man. Furthermore, those who do remember him will perhaps also remember that, in his lifetime, his discovery was opposed by a man of such prominence as the late Sir William Gull.

We are glad to see Sir Richard take up the cudgels in behalf of Dr. Snow, and trust that he will succeed in showing to contemporary civilization the merit of that physician's work.

PHYSICIANS AND THE CONFIDENCES OF THEIR PATIENTS.

The Circuit Court of Michigan has recently decided that a physician is obliged to testify in regard to the ailments of his patients, in a court, if called upon to do so. The question came up over the application of a life insurance company, which had assured the person for $20,000. The company learned after the issue of the policy that the applicant had misrepresented his physical condition, and it began a suit to annul the policy. Courts have often discussed this question, whether physicians shall be compelled to disclose facts regarding the condition of their patients, and various decisions have been made, sometimes one way, sometimes another. The rulings in this State, at one time, were that the physician should be compelled to disclose things that did not, in any way, throw discredit or shame upon the patient, and this seems a reasonable method of dealing with the matter. No reputable physician, in any event, whatever the law, would disclose to the public facts which were confided to him in confidence, and which would reflect injury upon his patient if made public. No human laws could compel physicians to do this, and, therefore, it would be much better to have laws that could be carried out.

An Exploring Trip under the Direction of Two Alumni of the Medical Department of the University of Pennsylvania.—Dr. William H. Furness, 3d, and Dr. H. M. Hiller, both members of the Class of '91, have started for the South Sea Islands, where they will spend at least a year in collecting ethnological and archæological specimens for the University. Should the field prove fruitful, it is probable that their stay may be prolonged to two years. After arriving at San Francisco they will sail for Yokohama, touching at Honolulu. They will proceed to Singapore, and from there will take passage for the Philippine Islands, visiting other groups of the East Indian and South Pacific Archipelagos in a chartered vessel.

News of the Week.

The Improvements in the College of Physicians and Surgeons.—It is reported that the new buildings which are to be added to the College of Physicians and Surgeons of Columbia will be finished by the end of the winter. The additions consist in an extension to the main building of the college, which is to be used for the Institute of Anatomy, and a building to the west of it, which is connected with, and an extension of, the Sloane Maternity Hospital. The Vanderbilt Clinic has been enlarged to twice its original size, and the two upper floors are to be devoted to the study of pathology and bacteriology.

Medical Examiners' Fees.—Our esteemed contemporary, *Puck*, has a very striking cartoon, *à propos* of the Holmes case, upon the subject of insurance companies and their employees. The point of the cartoon is that these companies are so eager to insure everybody and to make money that they are careless in their methods and secure cheap and incompetent men as their agents. The recent general cut in the prices for medical examiners' fees we have already spoken of, and stated that it was, we presumed, a purely business matter, and if they, the companies, could get good men for a lower price they had the right to do so. But, in the light of recent events, it seems that it is not likely they can get good men. Insurance companies had better try and economize in some other way than by cheapening the price paid to their agents for careful examinations of people that are to be insured.

The Sero-therapy Treatment of Cancer. — Messrs. Hericourt and Richet return to the subject of the sero-therapy treatment of cancer. In an article read in September before the Academy of Sciences of Paris, they state that they have continued their method of treatment since their first report in April last, and they have reached the following results: After the injections the pains from cancerous tumors diminish almost immediately, and these pains continue to diminish for a considerable time. The ulcerations become less, and the tendency to hemorrhage also is less marked. The tumor decreases in size, and, in fine, the evolution of the disease is retarded and the general state improved. But, unfortunately, this amelioration does not end in cure. At the end of about two months a gradual return of the symptoms takes place. They therefore say, in conclusion, that while the treatment by sero-therapy does not cure cancer, it does ameliorate the condition to a degree greater than any other known treatment.

Further Gifts to the University of Chicago.— Miss Helen Culver has given to the Chicago University $1,000,000, and Mr. John D. Rockefeller promises $2,000,000. Miss Culver's gift is to be used for biological teaching and investigations. The result of these new gifts will probably be the organization of a medical school.

The Best Symptom in any patient is prompt pay; as, long as it lasts you need not care what else ails him, unless he is likely to die.

Dr. J. Edwin Michael, a well-known surgeon of Baltimore, died in that city on December 6th, aged forty-seven. At the time of his death, Dr. Michael was Dean of the University of Maryland and President of the Medical and Chirurgical Society of the State.

Alcoholism in France.—The question of "alcoholism," which has been much discussed in this city, in connection with Sunday closing, is exciting great attention in France, on much broader grounds. Some of the most prominent scientists and public men in France are directing their inquiries to combating the increase of alcoholism in that country. Their investigations bring out some curious facts. They show, for example, that in England, since 1852, there has been a diminution of the consumption of alcohol from 286 litres per head per year to 270 litres in 1892, and that in Sweden the consumption per head has diminished one-half. If we are not mistaken, the figures show that in this country the consumption of alcohol per head has steadily increased.

St. Luke's Hospital and its Pathological Department.—At a recent meeting of the Board of Managers of St. Luke's Hospital the following resolutions were passed :

"That the matter of the completion of the proposed pathological building and its equipment be referred to the Building Committee with power.

"*Further*, That in the opinion of this Board a sum of not less than $200,000 should be obtained and set apart for the endowment of the pathological department, and that special gifts should be obtained, if possible, for the equipment of this department.

"*Further*, That the matter of endowment of the pathological department be referred to the Executive Committee, with power to appoint a special committee on this subject from the members of the Board."

The hospital has just received $20,000 for the endowment of beds.

An Office Thief.—On Saturday, December 7th, a pocket-case of instruments was stolen from the office of Dr. Ettinger, of this city, by a sneak thief in the guise of a patient waiting for the doctor. He was a man five feet eight inches tall, dark eyes and mustache, slight of build, and with prominent features. Dress was rather shabby ; had a dark derby and overcoat. From appearance and language was born here, of Hebrew extraction.

The St. Louis Academy of Medical and Surgical Sciences.—An association with the above title was organized on November 6, 1895. In order to become a member of the Academy one must possess a good literary and medical education. As evidence of his literary qualifications and ability as a scientific worker he must deposit with his application a thesis, a pathological specimen with descriptive text, a drawing of a normal or abnormal specimen with text, or some other evidence of his worth. The evidence is passed upon by the Committee on Credentials. If the evidence is accepted the ballot is taken. Membership in the society is to be limited to fifty. The following officers were elected for the ensuing year: *President*, Dr. George W. Cale, Jr. ; *Vice-Presidents*, Drs. James Moores Ball and Arthur E. Mink ; *Secretary*, Dr. Emory Lanphear ; *Treasurer*, Dr. Wellington Adams.

Albany Medical College Alumni Association of Greater New York.—A large number of the graduates of the Albany Medical College, resident in this and adjoining cities, met at the residence of Dr. Hanks, No. 776 Madison Avenue, on the evening of December 5th, and organized an association with the above title. The following officers were elected: *President*, Dr. John W. Warner ; *Vice-President*, Dr. Horace T. Hanks ; *Secretary*, Dr. Warren C. Spaulding ; *Assistant Secretary*, Dr. R. F. Macfarlane, of Long Island City ; *Treasurer*, Dr. Allen T. Fitch. The first annual dinner is to be given Thursday, January 9, 1896.

The Loomis Hospital and Dispensary.—Drs. A. Alexander Smith and Henry F. Walker are the consulting physicians of the Loomis Hospital and Dispensary for Consumptives, at 230 West Thirty-eighth Street. Dr. Charles McBurney is consulting surgeon ; Dr. William M. Polk, consulting gynecologist ; Dr. Warren Coleman, pathologist ; Drs. Henry P. Loomis and Charles E. Quimby are visiting physicians ; and Dr. Joseph Carlisle De Vries is house physician. The officers of the Board of Managers are : *President*, Mrs. Richard Irvin ; *Vice-President*, Mrs. Henry Chapman ; *Treasurer*, Mrs. Alfred L. Loomis ; *Secretary*, Mrs. John A. Lowery.

Regulation of Medical Practice in Washington.—A bill has been introduced into the United States Senate to regulate the practice of medicine in the District of Columbia. A Board for Examination and License is provided for.

Dr. Thomas Taylor, of Washington, D.C., has been awarded a gold medal by the International Society of Hygiene in recognition of the value of his investigation of butters, fats, and mushrooms in the United States.

Another Hospital for the Insane in Illinois.—At its last regular session the Illinois Legislature provided for the establishment of a new insane asylum, to be called the Illinois Western Hospital for the Insane. $100,000 has been appropriated for the purchase of a site.

Regulation of Maternity Hospitals in Connecticut.—At the last session of the General Assembly of Connecticut a law was passed forbidding any person to keep a maternity hospital, unless he had previously obtained a license therefor, issued by the Mayor or Board of Health, or Health Officer, where any such place was situated. Records of the inmates and of the births, deaths, discharges, etc., must be kept, and must be accessible to inspection.

The American Medical Review is the title of a new monthly journal published in this city, and edited by Dr. Daniel Lewis. The contents of the first number are well arranged and the general appearance of this new journal is most promising. We wish it every success.

The Medical Department of the Navy consists of one hundred and seventy members when its ranks are filled. There are at this time fourteen vacancies, and nobody seems to want to get in, at least no one who is worth having.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, December 9, 1895.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Bloodless Amputation of Shoulder-joint.—This was the history of a case in which the transversalis colli, suprascapular and subclavian arteries (third division), were tied, under cocaine anæsthesia, with subsequent bloodless amputation of the shoulder.

DR. JOHN A. WYETH reported the case as follows: John S——, aged thirty-one, by occupation a groceryman, with no early personal or family history which throws any light on this case, came under my care, October 2, 1895, in the New York Polyclinic Medical School and Hospital.

In 1889 he had received an injury of the left arm near the shoulder-joint, which he considered a fracture, from which he recovered with some stiffness of the joint. He noticed nothing of interest beyond this until 1893, when, in descending from the deck of a ship, he caught hold of a rope to prevent himself from falling, and severely strained this same arm, and remembers having heard a ripping sound, followed by great pain. The arm has never been right since. Four or five months after this injury he noticed it began to swell. It was not excessively painful, except on sudden motion.

When I saw him first, on October 2, 1895, there was a large, round swelling, which occupied the upper end of the humerus, the deltoid region, and extended somewhat over the end of the clavicle and scapula. On October 5th, under chloroform anæsthesia, I made an exploratory incision for the purpose of getting a specimen for microscopical examination. Cutting directly down through the deltoid muscle, I came immediately into a large, vascular, osteo-sarcoma, which had hollowed out the medullary canal and substance of the head of the humerus, into which I passed two or three fingers very readily. The bone gave way with a peculiar crackling sound, like the breaking of an eggshell, and was followed by profuse hemorrhage, which could only be arrested after rapidly packing the cavity with at least three yards of sterilized gauze; over this an Esmarch elastic bandage was carried. This hemorrhage greatly weakened the patient, and by October 9th I became alarmed about his condition of anæmia, and injected into the right median cephalic vein a pint and a half of hot saline solution, one drachm of salt to a quart of water. This was followed by a rapid improvement in the heart action, fuller pulse, better appetite, and increasing strength. There was, however, considerable hemorrhage whenever the packing in the tumor was changed; so much so that, on October 15th, in order to control this bleeding and to dispense with the packing, which was so tight that it caused him a great deal of suffering, I tied the left transversalis colli and suprascapular, and the left subclavian artery, in the third surgical division. The operation was not easy of accomplishment, by reason of the great swelling of the shoulder, which lifted the clavicle fully an inch higher than the normal position, and prevented the manipulation of the parts, displacing the clavicle and shoulder on account of the great pain. The patient could not tolerate any pressure upon the shoulder. I was afraid to administer ether or chloroform on account of his exhausted condition and, believing I could tie these arteries by the judicious employment of cocaine, it was done. In the entire procedure, twenty-five minims of a four per cent. solution were employed. The operation was quite tedious, and the subclavian artery, when finally exposed, was two and a half inches from the surface of the wound, and deep below the clavicle, where it was caught up by an aneurism needle and tied. The patient lost practically no blood from the incision in the tumor after this operation.

On October 20th, under ether anæsthesia, I made a rapid, bloodless amputation of the shoulder-joint by the method which I first employed in doing this operation in 1889. The operation consists in the insertion of two steel pins about fourteen inches long and less than a quarter of an inch in diameter. The anterior one passes through the skin and part of the pectoralis majoralis muscle, well back behind the level of the shoulder-joint. Not more than one and a half inch of this pin should be concealed by the tissues it perforates. Over the spine of the scapular, well up behind the joint, the second pin is passed, taking hold of nothing but the integument, and, may be, a little of the surface of the trapezius muscle. Around the shoulder, over the clavicle and scapula, and behind the pins, the points of which are shielded by bits of cork, strong rubber tubing is tightly wound four or five times and then tied. The amputation can then be made at leisure, disarticulation completed, and the vessels taken up at will. The operation is entirely bloodless, and the tourniquet need not be removed until the procedure is completed. It is always advisable, however, to loosen the tourniquet before the final suturing in order to see that no important bleeding points have been overlooked.

I have performed three operations of a similar nature by this method, and a number of others have been done by competent surgeons, without hemorrhage in any instance. It was the employment of this method in shoulder-joint amputations which led me to employ it in amputations at the hip-joint, of which I have done seven, with no hemorrhage in any case, and only one death from the operation. The tourniquet remains in position until the operation is nearly completed.

In the present case, it being one of malignant tumor, and as the soft parts up to the level of the joint seemed to be involved, I did not endeavor to cover the joint surface with cutaneous flaps. It was my intention, as soon as the wound began to granulate and the patient recovered sufficiently, to infect it with some septic organism, preferably with streptococci erysipelatis, and on November 19th an injection of five minims of a pure culture of Fehleisen's coccus was made. They were repeated every other day, gradually increasing the dose by three minims until twenty-six minims were injected. So far, however, no regular erysipelas has been precipitated. He has had septic chills, with exacerbations of temperature following, which on one occasion reached 40.7° C. (105.5° F.). These injections have been discontinued for the time being, and, despite the severe ordeal he has undergone, the patient has gained flesh and weight, and does not look like the same individual that came to me on October 2d.

The specimen, which is here presented, shows an osteo sarcoma of the upper end of the humerus. There is no sign of recurrence of the neoplasm.

Carcinoma of the Rectum; Excision by the Kraske Method.—DR. HOWARD LILIENTHAL, in presenting the patient, said the case exemplified the fact that carcinoma of the rectum was not necessarily very malignant. The patient was a man, forty-five years of age, and had had of his knowledge cancer of the rectum for one year. When Dr. Lilienthal first saw him he regarded the case as practically inoperable, for the ischio-rectal fat was involved, together with the rectum extending well up. But the man absolutely refused colotomy and wished the diseased tissues removed. He was an alcoholic, took ether badly, hemorrhage was great, and Dr. Lilienthal was compelled to hurry the operation, with the result that some tissue at the side which felt harder than normal was left, although

it may not have been carcinomatous. The posterior urethra was also involved and was attacked during the operation. In spite of the extent of the operation the patient rapidly recovered, and during the past three months had been working at his trade as a plasterer. The operation was done last June. The bowel moved only once a day, and gave no warning. He complained only of loss of erectile power of the penis, due probably to involvement of the urethra by the disease and the operation. There was one suspicious spot where the anus had been which looked like a recurrence, but it could be removed, with the probability of a long lease of life.

Old Dislocation of Shoulder.—Dr. C. L. Gibson presented a boy, eighteen years of age, who had sustained dislocation of the left shoulder at the age of twelve. There was now very considerable motion in spite of the dislocation. The muscles were markedly atrophied, the ligaments relaxed, so that dislocation could be made to take place in different directions. In view of the fair use of the arm, he doubted whether any of the procedures suggested in these cases would be advisable.

Congenital Dislocation at the Knee.—Dr. Thomas H. Manley presented a case of what seemed an unusual type of congenital dislocation—an infant, born four months ago, forceps used to hasten delivery, no manipulation of the limbs. Everything went well until the child was two weeks old, when the mother observed something wrong about the knee. Examination showed dislocation, falling down of the condyles of the femur into the popliteal space, upward and forward displacement of the tibia. There was no paralysis, no vascular disturbance. The child was able to move the limb forward and backward to considerable degree. Dr. Manley had found but two cases of similar dislocation on record. When the child got older and stronger he would make an effort to get the bones into normal position. It might be necessary to divide ligaments, perhaps also the hamstring.

Aneurism of Subclavian Artery, Probably Traumatic.—Dr. Manley also presented a man, about thirty-eight years of age, who had sustained an injury of the shoulder on board ship two years ago, which laid him up a few days. A month later there was loss of power in the left arm. This improved. A year and a half ago he had pain in the neck and weakness of left arm, and soon noticed a throbbing tumor near the clavicle. The tumor was visible, there was a distinct upward and forward motion of the clavicle with the pulsations; it was evidently an aneurism, probably of the second part of the subclavian artery, and, it was believed, due to the former trauma. There was a specific history, but a doctor had applied treatment by rest for nearly a year and large doses of iodide of potassium. The patient's health became reduced, and when Dr. Manley saw him he decided to try tentative measures, allowing him to go about and apply massage to the tumor in a manner to favor, if possible, formation of clot, and spontaneous cure. The general health had improved.

Supra-malleolar Osteotomy for Flat-foot.—Dr. Willy Meyer presented a girl, aged twenty-three, on whom he had performed supra-malleolar osteotomy for flat-foot in 1893, an operation regarding which he was enthusiastic at that time. In all he had performed it ten times on five cases. This patient was allowed to get up without a support about the thirty-second day, and had a good arch on the left foot, not quite so good on the right, and having no support, she placed too much weight on the left foot and developed pain, calling for further operation about two months later by Dr. Gerster. The right foot remained in good position. Some months later, with the aid of Dr. Whitman, the position of the left foot was corrected, plaster applied, and afterward the Whitman splint was worn. The result had been very satisfactory, and to-day the patient could go about without the splint. Dr. Meyer would now always try physiological treatment, as discussed at the last meeting of the Section, before resorting to supra-malleolar osteotomy in flat-foot, and thought the latter operation would be required only in marked cases.

Weak and Stronger Solutions of Cocaine.—The Chairman said, in relation to Dr. Wyeth's case, that he had used cocaine anæsthesia even in exploratory laparotomy and in gastrotomy. If it were carefully employed it would enable us to dispense with general anæsthesia for operations of considerable severity in patients in whom general anæsthesia was contraindicated.

Dr. David Goodwillie preferred a two per cent. solution to four per cent., as described by Dr. Wyeth, and in operations on the face had found it act admirably.

Dr. Willy Meyer would not like to risk four per cent. solution hypodermically, as he had seen alarming symptoms of poisoning from even small doses. During the past two years he added a one-hundredth of a grain of nitro-glycerine in order to counteract the ill effects of the cocaine on the brain. Such advance had been made in the use of cocaine that now, as practised in Germany, one-fifth to one-tenth per cent. solution was found sufficient. A small amount of morphine could be added.

Dr. Thomas Manley had used cocaine in major operations on the extremities, genital tract, peripheral tumors, etc. Alcohol seemed to increase its analgesic influence and diminish its toxic effect. He used a one per cent. solution of cocaine, and in no case administered more than one grain by injection. It destroyed the pain-sense but not the feel-sense.

Dr. Wyeth said he had been a strong believer in cocaine anæsthesia since its first introduction, and had used it in many hundreds of operations of all grades of severity. He always employed a four per cent. solution, and had seen no toxic effects, but it should be remembered that he employed only one or two minims in one place, and during an extensive operation did not exceed twenty-five minims. The application was made at intervals as the operation proceeded. He had tried weaker solutions, but preferred the four per cent. Dr. Gibson had once tried the weak solution and had to give it up because the nurses and patients complained that it was not efficient in deadening pain.

Dr. Dawbarn said that where cocaine had produced death, respiration had failed before the heart. Nitroglycerine and whiskey counteracted the evil effects of the cocaine by dilating the cerebral blood-vessels, and it was his custom to precede the use of cocaine by a large draught of brandy or whiskey if the operation were of any gravity.

Dr. Lilienthal mentioned the fact that patients were apt to flinch when it came to tying arteries, and Dr. Wyeth corroborated this statement, expressing the opinion that the vaso-motor nerves must carry some sensory fibres.

Dr. Dawbarn, referring to Dr. Lilienthal's case of resection of the rectum, wished to place himself on record as being in favor of inguinal colotomy in every case of cancer of the rectum. The danger was but slight, not more than five per cent. mortality; it would prolong life and make it much more comfortable if the disease below could not be removed. It facilitated healing in operable cases. The colotomy wound would close of its own accord after a time.

Dr. Royal Whitman said, in regard to Dr. Manley's case of congenital dislocation at the knee, that he had seen a good many cases of the kind. Instead of waiting for age, it would be wiser, he thought, to bring the proper articulating surfaces into position at once and try to retain them there.

Dr. Manley said the hamstrings were contracted, and he thought it better to wait until the child was three months old, by which time it would be stronger, before operating.

Dr. Wyeth had not examined Dr. Manley's case of aneurism, but in nearly all cases of supposed aneurism of the first part of the subclavian the real origin was from the ascending or transverse portion of the arch of the aorta, and when that was true the treatment was very different. If only the subclavian were involved, he would tie the artery in its third division. If that did not succeed he would try introducing, and leaving in, pins twelve to twenty-four hours, repeating it two or three times, in order to produce a coagulum. The patient should have explained to him the possibility of embolism arising from it.

Two Successful Hip-joint Amputations, the Second of which was Performed by a New Method.—Dr. F. Tilden Brown read the histories of the cases. The first was one of round-cell sarcoma of the left biceps femoris in a man, aged twenty-two, who was admitted to the Presbyterian Hospital, December, 1894. The origin was in an injury of the knee twelve years before. During the operation the pelvis was brought to the end of the table, and a low sand-bag was placed under the left buttock. Esmarch's bandage was not used, through fear of disseminating sarcomatous elements, but the limb was held nearly perpendicular a few minutes before piercing the thigh with new $\frac{3}{16}$ inch mattress needles, and applying above them the rubber tubing after the adaptation of Wyeth. The Furneaux-Jordan incision was made, and amputation completed twenty-five minutes after commencing the operation. The whole leg was left for leverage during its manipulations by his assistant. The femoral artery was ligated with silk, the other vessels with catgut. The wound was closed without drainage. The patient made a good recovery.

The hæmostatic effect of the rubber tubing, supported by the transfixing needles, was all that could be desired. But an objection to the method was noticed in that the skin and muscles about the joint were made so tense and hard by compression of the tubing that the region was much more inaccessible to instruments and fingers. Even after disarticulation the margin of the cotyloid cavity was difficult to trim up for the same reason. Apparently recognizing this fault, Dr. Wyeth proposed to adopt Lanphear's suggestion to insert the outer pin at a higher point, so that the rubber tubing would be held in the notch just below the anterior superior spine of the ilium.

The second case was one of tubercular osteo-arthritis of the hip in a female, aged twenty-seven, admitted June, 1895, discharged August, 1895. The disease had probably started from a fall four years before. It was proposed to excise the joint if the condition found justified it, otherwise to amputate. July 11th an incision was begun, one-half inch below the anterior superior spinous process of the ilium, prolonged downward in the intermuscular septum between the sartorius and rectus on the inner side, and tensor vaginæ femoris and glutei on the outer. This afforded excellent access to the capsular ligament, with scarcely any bleeding. A cavity with considerable tubercular *débris* was here cleared out. Opening the capsule, advanced tubercular disease was found. The conditions of disease in the joint and muscles, and weakened condition of patient, were not thought favorable for excision. The thigh was held perpendicularly, one jaw of a specially made clamp was passed through the existing incision, guided by the finger, under the sartorius and under the femoral vessels close to Poupart's ligament, the other jaw being outside the wound and bearing upon the cutaneous surface overlying the vessels. As the clamp was moderately tightened and the limb lowered, pulsation in the femoral ceased. The application of the clamp had required but a moment. Its tip had been sheathed with rubber tubing, possibly an unnecessary precaution against injuring the vessels. He then proceeded with the amputation, extending the existing incision along the outer border of the rectus downward to the bone, stripping off remaining attachments to joint and femur. A circular skin cuff was cut and turned back, and the muscles severed to the bone by circular incision. Some of the small branches of the sciatic required the application of pressure forceps, but the femoral vessels and their branches were absolutely dry on their proximal side. The remaining steps of the operation were not unusual. The patient had made a good recovery, although still a victim of pulmonary tuberculosis.

The following were points of merit in this operation: 1. The incision permitted the best exposure of the joint through tissues which contained no vessels or nerves of importance, and the same incision served for the easy adjustment of a clamp upon the femoral vessels before advancing to the critical stages of the operation. 2. The angled shape of the clamp was such that while it securely compressed only the femoral artery and vein between their sheath and overlying skin, it served at the same time as inward retractor for the sartorius muscle, and the instrument was wholly out of the operative field. Esmarch's bandage could be applied up to the groin and yet space remain for the incision and clamp. 3. The continuation of the incision was in a line where there was a minority of the arterial branches of the sciatic. 4. The open wound and its final suture were most accessible to the operator. 5. Belief that this operation, including the period of anæsthesia, could be performed in a shorter time than any of those where the danger from hemorrhage was as thoroughly guarded against.

Dr. Wyeth said he thought the device of Dr. Brown, connected with that particular operation in which there was tubercular destruction of the head of the femur, and in which an exploratory incision had to be made at first, with the possibility of being followed by amputation as a second part of the operation, was very clever. It seemed to him, however, that the same amount of anæmia might have been obtained by simple deligation of the femoral artery and vein. It was a very easy matter to tie the femoral artery under cocaine, and therefore he could see no particular merit in the instrument presented, although it was an ingenious one. In amputation at the hip for tumor below that region, he thought the method was not an advance forward but backward. It did not control a great part of the hemorrhage, and this was now considered a chief cause of shock. The mattress needles and rubber tubing, the needle inserted high up, was the most satisfactory method. He was a very strong advocate of catgut in tying arteries, and had not had secondary hemorrhage therefrom.

Dr. Dawbarn said that in all hip-joint amputations he hamstringed his patients in order to prevent retraction of the muscles and their unequal length and pocketing after division. This saved time spent in suturing them on a common level.

Dr. Brown said the old form of incision in hip-joint amputation would not, as did his, permit of ligation of the femoral vessels, but a second incision would have to be made. He thought a possible objection to the mattress needles and constriction by rubber tubing was injury to the vaso-motor supply.

Post-mortem Examination of the Parts Involved in a Bassini Operation for Inguinal Hernia Six Weeks after its Performance.—Dr. George E. Brewer reported the case, as it was unusual to have opportunity to examine the united parts so short a time after the Bassini operation. The manner in which the several structures had adhered together was described.

The Treatment of Torticollis.—Dr. Weiss recommends the use of curare in this disorder. He employs a filtered solution of curare, of the strength of two grains to three drachms of sterilized water. This is given in doses of from fifteen to thirty minims.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 13, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT.

Intestinal Perforation.—DR. F. M. JEFFRIES presented three specimens of intestinal perforation. The first was from a man who had been taken to St. Vincent's Hospital on November 9th. When found by the ambulance surgeon he had refused to talk, and had been suffering from abdominal pain. The pupils had been dilated and the pulse weak and rapid. On admission his temperature was 103° F.; pulse, 136; respiration, 24. He had some colicky pain for a short time, and more or less constant vomiting of greenish mucus. Constipation was present. His temperature fell on the third day after admission to 98° F., but just before death it rose to 105.6° F. The abdomen was at first retracted, but on the second day it was distended, and percussion showed flatness on the sides. A diagnosis of intestinal perforation was made. At the autopsy a large quantity of yellowish fluid was found in the abdominal cavity, the intestines were matted together by lymph, and there was a perforation eight inches from the ileo-cæcal valve. There was a recent pleurisy over the left lung, and a hypostatic congestion of both lungs. The pericardial cavity contained about two ounces of dark reddish-brown liquid. The valves of the heart were normal: the muscle-wall was pale and thin. The liver showed moderate cirrhosis. The spleen was fairly normal. The capsule of the kidney was non-adherent, and presented a smooth, glistening surface; the epithelium was swollen.

The second case was a woman, fifty years of age, who had been brought to Bellevue Hospital suffering from alcoholism, and consequently very little of the previous history could be ascertained. It was learned, however, that about one week previous to admission she had fallen and struck the right side. The vomiting was continuous at first, and consisted of the contents of the stomach; later on, it contained biliary matter. There were great pain and tenderness over the entire abdomen with considerable enlargement in the right hypochondriac region. On admission the temperature was 104° F., the pulse thready and irregular, and there was evident peritonitis and shock. Cathartics and purgative enemata were given with little result. The autopsy showed fatty infiltration of the heart, interstitial nephritis, and suppurative peritonitis with perforation about seven feet from the ileum. There was also a large uterine tumor.

The third case was an Italian woman, who had been found dead in her room. The autopsy showed some œdema of the brain. The cavities of the heart were dilated, and the walls infiltrated with fat. On opening the abdomen a large quantity of extremely offensive yellowish fluid bathed the intestines. The latter contained yellowish fæces, and there were a number of ulcers, with perforations in two or three situations.

General Miliary Tuberculosis.—Dr. Jeffries also presented a case of general miliary tuberculosis. The patient was a negro, who at the time of admission had a high temperature. So far as could be ascertained he had enjoyed good health up to twelve weeks ago. The autopsy showed miliary tubercles.

Hydronephrosis.—DR. JAMES EWING presented two cases. The first specimen had been removed from a woman about forty years of age. As was often the case, the condition had been entirely overlooked during life. The usual symptom of a line of tympany running down over the course of the tumor, produced by the colon being pressed forward by the tumor, was absent in this case because there was a well-marked meso-colon which allowed of the large intestine being pushed to one side. The hydronephrosis was due to cancer of the uterus. It was estimated that a pressure of about one pound would have been sufficient to empty the pelvis of the kidney, showing that the pressure that had caused the hydronephrosis had been slight. There was the usual dilatation of the pelvis and flattening of the kidney, and the cavity was divided into several compartments by hypertrophy of the septa of the original organ. Microscopical examination of these septa showed a new growth, and at either end the remains of the kidney showed epithelioma. The tubules themselves were nearly normal, except that they were dilated. The tumor contained nearly normal urine. In the urine a single specimen of worm was found under the microscope. It resembled closely the filaria sanguinis, but the worm had not been definitely identified.

The second specimen had been removed from a subject in the anatomical department of the college. Death was supposed to have been due to cirrhosis of the liver, showing that this condition had been overlooked also during life. In this case the distended colon passed over the tumor. The sac measured 28 ctm. in one diameter and 42 ctm. in another. The contents were not urine, but a fluid which became almost solid on boiling it. It contained a large quantity of blood, and in a portion of the tumor were a number of blood-clots, showing that death had been due to hemorrhage into this large mass. There was an almost entire atrophy of the kidney substance. The ureter was pervious up to within one or two inches of the pelvis of the kidney. This sac also contained septa, but much thinner than in the first specimen. The tubules in the other kidney were much hypertrophied, showing that this kidney had been doing double duty for a number of years.

Cystic Tumor in the Kidney of a Bullock.—DR. GEORGE P. BIGGS presented a kidney from a bullock showing the very marked lobulation of these kidneys. In one end was a large multilocular cystic tumor containing a clear amber-colored fluid. The remaining portion of the kidney tissue appeared to be normal. Such cysts, the speaker said, were not very uncommon in sheep, and were usually regarded as congenital.

Mitral Stenosis Confounded with Uræmia.—Dr. Biggs then presented a heart removed from a woman, thirty-three years of age, who had lived only about two hours after admission to the New York Hospital. She had been sick for about two weeks. On admission there was acute œdema of the lungs, and the heart-sounds were feeble. The urine contained a large percentage of albumin and numerous casts, and was of low specific gravity. The clinical diagnosis had been uræmia complicating pregnancy, but Dr. Biggs said he had ventured on the diagnosis of mitral stenosis, and this had been confirmed by the autopsy. The uterus contained a well-developed fœtus of about eight months. The other organs showed an extreme degree of chronic venous congestion. The heart was distinctly hypertrophied, and both cavities were markedly dilated. The wall of the left ventricle was rather thinner than normal. The right ventricle was both dilated and hypertrophied, the wall in many places being ¾ ctm. thick. The valves of the right side were perfectly normal. The aortic cusps were slightly thickened and retracted. The mitral valve showed a marked degree of stenosis, not admitting the tip of the little finger. The left auricle was considerably dilated and hypertrophied. The speaker said that he had based his diagnosis of mitral stenosis on the history of acute œdema, the expectoration of blood-serum, and the recollection of another similar case seen some years previously. In this previous case there had been no cardiac murmurs, the woman had been pregnant and had given a history of attacks of sudden and alarming pulmonary œdema coming on only during pregnancy. Dr. Janeway had stated that the cardiac murmurs would appear if cardiac stimulants were administered, and this had proved to be the case. It became necessary in this instance to induce premature labor. She recovered. This con-

dition, Dr. Biggs said, of rapid and irregular heart action without murmurs often led a physician seeing the case then for the first time to mistake the real condition. He recalled a recent case of this kind in which one well-known physician had repeatedly examined the heart and had stated that there was positively no heart disease present, and yet death had occurred from this cause shortly afterward. Pregnancy decidedly aggravates these symptoms, and the question of inducing premature labor or abortion claims careful consideration.

Dr. Ewing remarked that the specimen from a bullock showed the difference between congenital and acquired tumors; the congenital tumors showed lobulation and division, while the acquired tumors had a more dense capsule about the cyst, and showed the remains of the original kidney tissue.

Karyokinesis.—Dr. J. S. Ely exhibited under the microscope a specimen of frog's blood showing karyokinesis. One white corpuscle was shown in which the chromozones had been collected together in the centre, and another in which the chromozones were just separating from each other. Dr. Ely said that karyokinesis had been first definitely studied in 1889 by Sprank, who had found it in blood from frogs, and from human beings. In human blood it should be found in about one on a thousand of the white corpuscles. Sprank had also observed it in leucæmia. It was believed that the small mononuclear leucocytes were the ones which underwent this change, the polynuclear leucocytes being now looked upon as having originated from the mononuclear leucocytes probably by a process of subdivision. If it could be shown that the so-called transition stages among the leucocytes were definitely derived from the small mononuclear leucocytes, and that they then gave rise to the polynuclear leucocytes by a process of direct cell division, the polynuclear leucocytes would have to be regarded as degenerate cells. The polynuclear leucocytes were much more commonly found in pus, and recent investigations of Janofsky went to show that the cells which migrate in suppurative inflammation were for the most part mononuclear leucocytes, and that in the formation of the polynuclear leucocyte, or the typical pus cell, the process is one of direct cell division, and not a process of karyokinesis.

Heat-stroke in the Navy.—During the past year fifty-five cases of heat-exhaustion among the engineer force of the United States Navy have been reported, the greatest number of cases appearing on the following vessels: Bennington, 11; Bancroft, 8; Columbia, 6; Amphitrite, 5; Raleigh, 5. In his annual report just issued, Dr. Tryon says that these figures are significant and merit attention by the department. The average temperature of the engine-rooms of modern ships, under ordinary cruising conditions may range from 106° F., with hatches large and open like the Charleston, to 152° in badly arranged and closed ships like the Amphitrite. In the fire-rooms the average temperature under the above conditions may range from 124° in ships with only one set of fires in each fire-room, like the Charleston, to 189°, when the fire-room is between two sets of fires, like the Cincinnati and Amphitrite. In the case of the Cincinnati, when only one set of fires is used in each fire-room, the average temperature is reduced from 189° to 159°. The result of these high temperatures, together with overwork and other trying conditions, is plainly shown by the number of disabilities in the Engineer Corps attributed to this cause. Since January 1, 1894, eleven chief engineers and three past-assistant engineers have been or are now on sick leave, and of this number six have been recommended for retirement and two have died.

Clinical Department.

THE DIAGNOSIS AND TREATMENT OF FRACTURES.[1]

By W. L. HUGHLETT, M.D.,

COCOA, FLA.

In the whole domain of medicine and surgery there is no class of cases that call for greater knowledge and skill on the part of the general practitioner than cases of fracture, none that so frequently get the members of our profession involved in suits for damages. While we are rarely called upon to perform operations of great magnitude, any of us are liable at any time to be called to attend the most serious fractures that can occur; we should therefore be prepared to render promptly such service as may secure for the patient useful limbs and for ourselves commendation rather than censure and lawsuits. It is to be regretted that there is no fixed standard, and that our leading men differ so materially on this subject. The best thing for us to do is to master thoroughly the anatomy and physiology of the human body, so that when bones are broken we may have at least knowledge enough to restore the fragments to a normal position, and skill enough to confine them favorably for nature's beautiful reparative processes. The diagnosis of fractures is not always easy. It takes no special skill to tell that a bone is broken if the fracture be in the shaft of a long bone, or of a rib, or a depressed fracture of the skull; but when fractures run into the joints, involve the epiphysis, are intra-capsular, occur at the base of the skull or in the vertebræ, diagnosis is sometimes very difficult. It is often difficult to say whether a fracture of the long bones is oblique, transverse, simple, or comminuted. I assisted in a case of amputation of the thigh (when a student), the patient being a large negro man who had been run over by a car wheel; this case was diagnosed by several competent surgeons as one of severe comminuted fracture. After the limb had been removed I made a dissection and found a simple transverse fracture of the middle one-third of the thigh. This man's leg might have been saved had a correct diagnosis been made. The symptoms of fracture, as a rule, if in a limb, are quickly noted. There will be loss of function, swelling about the injured part, deformity caused by muscular contraction, pain increased by attempts at motion, and generally crepitus on motion. We shall also have a history of severe blow, fall, or violent exercise. (A few years ago I treated a young man for fractured thigh caused by running a base in a game of ball; simple muscular force.)

The most serious error in diagnosis is to confound a fracture with a dislocation. This is most likely to occur at the shoulder, the elbow, and hip. If we know we have a fracture to deal with a few days may be allowed to elapse until swelling has subsided, but if there is doubt, in my opinion the best practice is to put the patient under the influence of an anæsthetic and settle the diagnosis. In this way a dislocation is readily reduced, or if we find we are dealing with a fracture we get more accurate knowledge. If we fear any heart or kidney complication we may often use morphia and atropia hypodermically, instead of chloroform or ether. In the case of children I always prefer, and nearly always use, chloroform. Anæsthetics carefully administered promptly relieve the nervous shock and pain and permit of thorough manipulation when required. Not only is this a great consideration, but if we are ready with our apparatus we can at once apply the dressings and the patient rouses to find the dreaded operation of bone-setting all over, much to his delight.

[1] Read before the East Coast Line Surgical Association, at their meeting at St. Augustine, Fla., September 4, 1895.

No man can be really expert or scientific in the diagnosis of fracture unless he be thoroughly acquainted with the anatomy of the parts, not only with the bony structures involved, but the muscles, nerves, and blood-vessels as well. I have seen paralysis result from the nerve being caught in the callus of a fractured humerus, and death has resulted from simple fractures from emboli or thrombus forming in the vessels. I know of one case where fracture of the femur by a pistol-ball caused aneurism of the femoral artery, a spicula of bone having pierced that vessel. Occasionally we see gangrene following fractures, the nerve and blood supply having been cut off.

It is necessary, then, that we not only be very careful in handling injured parts, but cautiously to consider all the accidents that may occur in the course of treatment. Unless we are dealing with a complete fracture, extreme care is required in handling the affected parts. For instance, a partly fractured clavicle had better be left alone than made complete, as callus is quickly thrown out at the point of attachment and union takes place with less deformity. An impacted fracture of the neck of the femur or humerus had also better be left alone—unless there is great deformity. A few years ago a boy was brought to me with a complete fracture of the ulna, in the middle third, and a green-stick fracture of the radius, so that his forearm was bow-shaped. I put him under chloroform and cautiously attempted to straighten the arm. In spite of caution and gentleness I snapped the radius, and so made a complete fracture of both bones ; I dressed the arm at once, and fortunately the boy made a good recovery. I do not see that this accident could have been avoided ; however, if the boy had not recovered with a good arm, I should no doubt have been charged with results. I would like, also, to impress upon you that a common fracture with children—fracture of the clavicle—may be easily overlooked. I have seen two cases that were entirely overlooked by me on first examination. In these cases there is sometimes no pain and no deformity. As in one of these cases, the child was found running around complaining of nothing except slight pain in the shoulder-joint. If asked to throw a stone, however, they will either not attempt it, or if they attempt to do so they will cry out with pain at the seat of fracture ; the second day diagnosis will be easier because some swelling will have taken place.

When called, then, to any case that is injured—though to all appearances slight—let us not be hasty in forming or giving out opinions, but consider every question involved not only for our own safety, but to satisfy clamorous friends. In doubt resort to anæsthesia, and never make a business of promising brilliant results, because experience teaches that while as a rule all fractures do well, and sometimes most unpromising cases are followed with remarkable results, yet in many simple cases we have accidents and bad results that cannot be foreseen.

There is another point that must not be overlooked : fractures that occur in railroad accidents are generally more serious than those from ordinary causes ; the force is violent, shock is great, and injury generally more extensive than external appearances indicate. Those of us who have had occasion to amputate for railroad fractures generally find the bones broken and split up far beyond the point of injury.

Now as to treatment. The reparative process which nature institutes to repair a broken bone is something wonderful. In the museum of the Medical College of Virginia is a femur that had been fractured in the middle third. It had never been set, or if set, not properly. The fragments had been separated about two inches and remained so. Nature took the case in her own skilful hands, threw out a bridge of bone between these separated fragments and created as firm and strong union as though the fragments had been set in perfect juxtaposition.

We also see in the lower animals fractured limbs repaired without apparatus. Let us then remember that nature will repair the damage if we give her a chance.

I do not deem it necessary here to dwell upon the varieties of fracture, or the nomenclature of the subject ; suffice it to say that in railroad surgery we shall have chiefly to deal with compound fractures, especially such as involve the joints. A few years ago a compound comminuted fracture almost invariably called for amputation ; now, thanks to asepsis, antiseptics, and greater skill, amputation is the exception, not the rule. I shall speak briefly of the materials used for splints and the treatment of the fractures most frequently encountered.

Of material. Of first importance is plaster of Paris (dental plaster preferred), then may follow shaped wooden splints, perforated tin or zinc, Levis's splint, Russian felt, wooden boards and strips, leather, cardboard, starch bandages, adhesive plaster, elastic bandages, etc. If we have access to any or all of these things we would be likely to choose a splint ready made, but unfortunately we are often called to out-of-the-way places ; then the ingenuity of the surgeon is taxed, and he is frequently compelled to make out of rough boards or some other handy material the needed splints. I have used pieces of cigar-boxes, orange-boxes, and other handy material, well padded with layers of absorbent cotton, with just as perfect result as could be desired. The plaster-of-Paris bandage, in my opinion, is the most valuable single material at our command. We will now consider some of the more frequent fractures and their treatment.

Fractures of the skull are serious in proportion to injury of its contents. Bryant says that "slight fracture of the skull with concussion is more dangerous than compound fracture with no injury to contents."

When the fragments are depressed they should be elevated at once ; if there are symptoms of congestion large doses of bromide may be given, patient kept in a dark room, and cooling applications applied to head. Fractures at the base of the skull are always serious—mortality about fifty per cent. They are nearly always accompanied by severe constitutional disturbance, bleeding from the nose and ears, frequently by a discharge of watery serum from the ears, now known to be cerebro-spinal fluid. Treatment must be symptomatic.

Fracture of the clavicle, Roberts says, is successfully treated without apparatus if the patient will go to bed and remain on the back ; this position is strongly advised in the case of young ladies, as deformity is found to be less than when any form of apparatus is used. I have generally used Sayres's apparatus with good results. In one case, at the suggestion of Dr. Worley, I used the figure-of-8 bandage across the shoulders with a good result. I recall one case of a girl who would not allow any bandage or apparatus ; she had a very good result—deformity hardly noticeable.

Fractured ribs are best treated with wide adhesive straps entirely encircling the chest ; this compels diaphragmatic breathing and relieves the pain incident to ordinary respiratory movements. Fracture of the scapula is likewise best treated with adhesive straps or wide bandage.

Fracture of the spinal column in any part is a serious lesion, as pressure from depressed or displaced bone is liable to cause paralysis, and confinement to bed causes bed-sores and exhaustion. When caused by diseased conditions extension and the plaster jacket may give some relief, but in direct injuries from accident exploratory incision, with elevation of fragments and removal of spiculæ of bone seems the rational course ; the subsequent treatment being directed to injury of the cord.

Fractures of the pelvis are always serious, and the possibility of injury to the contained organs must be

borne in mind. They can only be treated on the expectant plan.

Fracture of the humerus at or near the surgical neck is infrequent, though it sometimes occurs, and is likely to be confounded with subglenoid dislocation. When satisfied that we are dealing with a fracture, the arm should be fixed in an immovable apparatus, a wedge-shaped wad of absorbent cotton placed in the axilla, and arm bound firmly to body with a wide bandage, the forearm being supported with a sling. "Fractures of the shaft of the humerus are satisfactorily treated with moulded splints of gutta-percha, felt, or Levis's perforated tin, well padded ; the forearm to be carried in a sling."

It is in the shaft of this bone and the shaft of the femur where we most often have no union, or bad union with a large callus. I am of opinion that this can be explained on the ground of greater mobility of the parts and the constant tendency of attached muscles to separate the fragments. These conditions create more or less irritation continually about the point of injury, and in consequence we have an abnormal production of callus and imperfect bony union. The treatment quoted is on good authority, but I think creates in the mind of the young surgeon an idea that should not exist, that is, that the fracture is simple and treatment also simple. If we would secure good union in these long bones we must put the injured parts at perfect rest, and confine them so for at least six, and, better, eight weeks before they are disturbed in any way. It is better practice to keep on a perfectly fitting apparatus for one or two weeks longer than might be absolutely necessary, than to remove them and run the risk of recurring fracture. I permitted one patient with a fractured thigh to get on crutches in ten weeks, as there seemed to be firm union. Unfortunately his crutch slipped, causing him to get a severe fall, which again fractured the thigh in the same place, necessitating another lay up of ten or twelve weeks.

Fractures of the lower third of the humerus and the upper third of the radius and ulna, involving, as they frequently do, the elbow-joint, are serious accidents. We are generally confronted by a greatly swollen condition of things, and confused as to diagnosis. Hamilton's practice was to apply cold applications until the swelling subsided, then to put up the arm in the flexed position, and on or before the seventh day to begin gentle passive motion as a preventive of anchylosis. No doubt this treatment worked well, or it would not have been advised by so eminent an authority ; however, the minds of men are widening and the science of surgery advancing. An entire change in this treatment is now advised. Allis, of Philadelphia, and Thorn, of Toledo, now advocate the extended position, with perfect immobility of the joint, until motion can be made without causing pain. By demonstration Thorn claims this position to be anatomically correct, and by reasoning, as well as by experience, concludes as follows :

"If the joint structures are not encroached upon, certainly there can be no necessity for submitting the parts to the chances of torturing the patient. Rest for the injured parts to prevent inflammation, rest for the inflamed parts to hasten recovery. Do not treat what does not exist. If the joint is not injured, anchylosis cannot obtain ; if it is injured, rest is what it needs."

To my mind the greatest bugbear in the treatment of fractures is the fear of anchylosis, and the greatest torture to the patient usually comes from the unnecessary efforts made to prevent it. I say to my patients when there is freedom from pain begin to use the joint, not before. Then time and voluntary effort will complete the cure. From a personal letter I quote Dr. Thorn as follows : "To my mind, doctor, the most important contention is that against passive motion."

If after firm bony union has taken place, and gentle passive motion been tried, we find that we still have a seriously anchylosed joint, we may proceed, under anæsthesia, to break up adhesions and restore the function of the joint. This, however, in a large percentage of cases, will fail, and then our only other resort is to resect the joint. I assisted in one case where forcible effort was made, under anæsthesia, to break up adhesions in the elbow-joint, but the operation only did temporary good ; generally these operations would be followed by more or less inflammation, after the subsidence of which we found our joint again anchylosed. In fracture of the upper third of the ulna it should be remembered that dislocation of the head of the radius may take place in the course of repair ; it is therefore necessary to confine this fracture in a plaster dressing, a good plan being to place the arm in a flexed position and carry dressing from a point above the condyles to the middle third of the forearm. This dressing should prevent rotation, and as far as possible prevent contraction of the ulna, which is supposed to cause the dislocation of the comparatively loose attachment of the head of the radius in its normal position. Fractures of the lower forearm are frequent ; they should be promptly reduced and held in place by well padded splints ; care should be taken against undue pressure on the blood-vessels at the wrist. The wooden splints should be held in place by elastic bandages or straps. In case a plaster dressing is used it should be split up as soon as the plaster sets, for any considerable amount of swelling under an unyielding plaster cast may be the cause of serious injury. Fractures about the wrist-joint should be treated on the same general principles suggested for the elbow-joint—perfect rest and local measures to allay inflammation. Fractures of the metacarpal and phalangeal bones are satisfactorily treated by light board splints, well shaped and wadded to fit the hand.

We may now briefly consider fractures of the lower extremity. Fractures of the neck of the femur, whether intra- or extra- capsular, require considerable time for repair. Bonnet's trough splint, with moderate extension, seems of all the older methods to be the best. Professor Despres, in his "Treatise on Fractures," claims that no splint is superior. In my opinion the plaster cast enveloping the hips and carried down the injured thigh to the middle third is the apparatus *par excellence* for this accident. This at once immobilizes the joint, and with slight extension is all that can be desired. It must be remembered that this accident is most frequent in the aged, consequently repair is slow and seldom by firm bony union. Bryant says : "Gentle traction can be practised for two or three weeks, after which patients may be allowed a little exercise on crutches, as long confinement in bed may lead to bed-sores and exhaustion." It seems, however, to me a mistake to allow any motion in these fractures under six or eight weeks ; in nearly every case of ununited fracture that I have seen we find a history of early effort at motion, which, no doubt, had disturbed the reparative process. The fracture-bed, so highly recommended by some, is only within the reach of a few, hence I need only mention it. On any bed, where a fracture of the thigh is to be treated, it is well to put a wide, smooth board under the mattress to prevent sagging of the body. There are various methods of treatment for fractures of the shaft of the femur. After a study of many methods I am disposed to think that those worthy of special mention are the long external splint and Buck's extension apparatus. I have lately treated two cases of fracture in the middle third by a combination of these two methods with most satisfactory results. There is scarcely over half an inch shortening, and no deformity to speak of in either case. I prepare the bed and the patient as directed for Buck's extension, elevate the foot of the bed four to six inches, then apply the pulley and weight for extension. The limb is then set in as natural a position as possible, and a long exter-

nal padded board splint is applied. For a grown man I make this splint about four inches wide, and long enough to reach from the axilla to a little below the foot. The splint is held in place by three wide, many-tailed bandages, placed one around the chest, one around the thigh over seat of fracture, and the other around lower third of leg, made to confine the foot if there is tendency of the foot to turn inward, which I have found generally to be the case.

This apparatus is simple, easily applied, and has given me excellent results.

In four or five weeks, or after union has taken place, I remove the external splint and apply a plaster cast at the same time, removing nearly all the weights used for extension. I do not think it good practice to allow a man to walk on a thigh that has been fractured inside of twelve weeks; from the experience that I have had I am sure that firm bony union does not take place in much less time, and no doubt some of the shortening and deformity in this fracture is due to the weight put upon the hardly consolidated callus. I insist that nature have time to do her perfect work.

Fracture of the lower third of the femur, involving the condyles and the knee-joint, do best put up in some immovable apparatus, the limb in a slightly flexed position. When the fragments of the lower third of the femur are displaced by the contraction of the gastrocnemii muscles Bryant advises division of the tendo Achillis. Dr. Thorn's rule for passive motion at the elbow-joint applies as well to the knee-joint.

Fracture of the patella is of frequent occurrence, and the fact that there is such a variety of apparatus for its treatment shows that the best surgeons are not agreed. Drs. Senn and Fluhrer advocate wiring, Bryant and Roberts the posterior padded splint with elastic straps. Wiring promises bony union, and possibly a stronger joint, but it converts a simple into a compound fracture with the possibility of septic infection. Treatment by splints and bandages secures only ligamentous union, with some impairment of function, but no material danger to life. The treatment by hooks, screws, and other similar devices is not good surgery; they are painful and endanger the patient to septic infection. The average surgeon will do better with his posterior splint, elastic bands, and subsequently the plaster bandage, than experimenting with other, perhaps more scientific, methods. The operation of wiring, while perhaps the ideal method, calls for considerable skill, and certainly is not without danger. I assisted in a New York hospital in wiring a simple transversely fractured patella, but never saw the patient after the operation. It was whispered around that he went the way of all flesh.

Fractures of the tibia and fibula are common. Simple fractures of the fibula in the lower two-thirds may be satisfactorily treated by simply bandaging the leg, the tibia acting as a splint, and resting in the recumbent position. In fracture in the upper third of the fibula, near the head, the limb should be flexed and kept so; then may occur separation of the fragments requiring wiring.

Fractures of both bones of the leg do well either in splints, fracture-box, or plaster cast. The best apparatus that I have any account of is that advised by Professor Despres. This is a plaster splint which does not encase the limb, but is applied laterally.

Strips of prepared plaster bandage of required length, and two to three inches wide, are soaked a few minutes in warm water, an assistant holds the limb in proper position, the bones being set; we then take one of these strips, and beginning just below the knee on either the inner or outer side of the leg, it is carried down one side around (or under) the foot and up the other side, additional plaster is rubbed on this, then another layer of bandage, and so on until a good strong splint is moulded to the leg. The leg is held steady for twenty minutes, or until the plaster has hardened, which is then held in place by three elastic strips—one at the top, one about the fracture, and one at the ankle. This apparatus allows the patient to take any desired position in bed, prevents displacement of fragments, and allows of frequent examination and dressings in case of compound fracture without changing the apparatus. The elastic bands give way for swelling and contract as the limb shrinks, so that even pressure is maintained. This apparatus need not be changed during the whole course of repair of a simple fracture of the leg.

Fractures about the ankles, as with other joints, require immovable apparatus and perfect rest. I prefer the plaster cast. This should not be applied, however, until swelling has subsided, and even then it is well to split the cast to allow for any swelling that may occur.

Fractures of the metatarsal and phalangeal bones of the foot, if not compound, do well in an old easy-fitting shoe split through the top to allow for swelling, bound with an ordinary roller bandage. When compound I have used thin pieces of board padded to fit the bottom of foot held in place by adhesive strap and bandage.

I have thus briefly suggested a treatment for the fractures most commonly met with. After all, the successful treatment of a fracture depends largely upon the knowledge and ingenuity of the surgeon, for it is possible to have a bad result from the use of the most scientific apparatus available, and a good result without any. With reference to the treatment of compound fractures—as before indicated—great change has taken place. We no longer amputate every limb that happens to have severe compound fracture. However bad the fracture, if the blood and nerve-supply is not cut off there is always some chance to save the limb. In simple compound fracture, that is, where the opening through the skin is small, slight comminution of bone and slight hemorrhage, the wound should be closed with adhesive plaster or antiseptic collodion (iodoform or aristol collodion) and fracture treated as simple. When there has been severe comminution of bone, some hemorrhage, where dirt of any kind has entered the wound, it should be left open and treated antiseptically; finely powdered iodoform or boracic acid kept constantly applied. When pus forms it should be let out and parts irrigated with carbolized water.

If free arterial bleeding occur the vessels should be secured if possible, and closed by torsion or ligature, the wound enlarged if necessary for this purpose. Should the vessel lie very deep, as in the calf of the leg or upper forearm, it may be ligated above the seat of injury, as it has been demonstrated that the ligation of vessels does not much retard the repair of fractures. In case the plaster cast is used for compound fractures, a window should always be left over the seat of fracture to permit frequent examination and dressing. When from destruction of tissue—threatening gangrene—or extensive injury likely to render the limb useless, amputation may be performed, the sooner the better. In that unfortunate class of cases—ununited fractures—various methods of repair are in use. These consist of dowel pins of ivory and bone, screws, nails, silver wire, bone rings, etc. Dr. N. Senn advocates and uses bone rings. It occurs to me that strong silver wire thrown around the fragments would answer the same purpose as the bone rings, and could be much more readily removed after union had taken place.

It must be borne in mind that certain acquired or constitutional diseases play an important part in the repair of fractures. Syphilis, rheumatism, scrofula, tuberculosis, rachitis, lithiasis, etc., may collectively or separately prevent union even when the fragments are most favorably adjusted. We have all seen in scrofulous and strumous subjects diseased conditions of bone refuse to heal under any form of local treatment, until the patient was put on suitable constitutional treatment. We have seen rheumatic arthritis set up in a joint and so erode the heads of the bones that anchylosis of the worst form has been produced. We have seen gravel

produced in the bladder from excess of uric-acid compounds and long confinement on the back. Syphilis, of course, in any stage, but more especially in the tertiary one, would seriously complicate the treatment of any fracture.

I must conclude this paper, but before doing so I wish to call attention to the application of the plaster bandage. I have seen some very bungling work with plaster, but when carefully applied it is the ideal splint. Excellent plaster bandages are made ready for use by Johnson & Johnson, New York, but any surgeon with a little time on his hands can prepare his own. Strips of cheese-cloth or crinoline, two or three yards long and two to three inches wide, rubbed full of fine dental plaster and rolled up as an ordinary bandage, answer every purpose. In preparing a limb for a plaster cast some little care is necessary. The limb should be washed and dried thoroughly, any sore spots covered with a little subnitrate of bismuth, then vaseline or olive-oil rubbed on. The limb now being ready, should be smoothly bandaged with soft flannel over the entire part we expect to enclose. I usually use two layers of bandage. The plaster bandage is then soaked for a few minutes in warm water and is ready for winding around the limb. Over each layer of bandage I rub a little extra plaster, the same having been previously prepared to a creamy consistence in a handy vessel. The cast is now allowed to set. If we are likely to have swelling, I split the cast at once, otherwise it is left alone. In removing the cast for purposes of examination, or when from shrinking of the limb it has become loose and needs to be made smaller, I cut carefully through the plaster, then with scissors cut through the flannel bandage. We generally find the bandage has become attached to the plaster cast and has formed a nice padding for the splint.

A plaster cast, when properly made, is very strong. They are generally made twice as heavy as is necessary, adding unnecessary weight and inconvenience; but I believe that greater care in constructing will remedy these objections.

AN ANENCEPHALOUS MONSTER.

By RICHARD H. WOOD, M.D.,

CLIO, MICH.

With so many cases of monstrosities before us it may well be questioned whether it is necessary to refer to such common occurrences. But inasmuch as the one I have to report resembles so closely the cases related by Dr. Bowman, of Ontario, and Dr. Hinman, of Michigan, I offer it in the hope that it may aid those who are competent to properly classify these abnormalities and to bring out some knowledge of their etiology.

Mrs. G——, aged thirty, farmer's wife, was taken with labor pains about 5 P.M. I was called at 6 P.M. She claimed that her time was up a week before. Found abdomen fully distended, and palpation revealed fœtus lying transversely in uterus. Os rigid, like a hard rubber ring, with a few nodules along the margin, and dilated to the size of a half-dollar. Pains being slight I gave uterine sedative and went home. Summoned again at 11 P.M. to find that membranes had ruptured and an unusual amount of liquor amnii had escaped. With some difficulty the feet were reached and brought down through the partly dilated os, and in about two hours a dead fœtus was delivered. It consisted of a monstrosity of the anencephalous type. It had been dead perhaps a week. The shoulders were large and well developed. The integument of the upper extremities was sound. The lower extremities were small and the legs long, but the bones were not at all ossified, and the integument upon the lower extremities was broken and exfoliated in patches. The sex, barely discernible, was female. The nails on the fingers were plain, but those on the toes were hardly perceptible owing to lack of development. The eyes looked almost upwards, the nose was broad and flattened. The head was wanting in its posterior aspect, neither scalp, occipital, nor parietal bones being present. There was nothing like a cerebrum. A thin membrane, transparent, covered this posterior cavity, and on the integument, at its junction with this membrane, was a narrow fringe of long dark hair. The bones of the face were quite solid and could be felt through the membrane from behind. This monstrosity weighed about four and a half pounds. The placenta was only four inches in diameter, perfectly circular, and of unusual thickness. The cord was attacked at the centre. The mother had a specific taint, and had been suffering for weeks from a profuse purulent discharge.

POISONING BY OYSTERS.

By J. N. BELL, M.D.,

DETROIT, MICH.

The following case of oyster poisoning occurred recently in my practice. I was called hurriedly, on the morning of October 7th last, to attend the family of Mr. F——, three of the members of whom—father, mother, and daughter—were suffering from incessant vomiting and griping pains in the abdomen, the mother being in a state of collapse.

Upon inquiry as to what they had eaten for supper the evening before, I found that they had partaken of stewed oysters (canned).

A fourth member of the family, a little girl, aged three, who had not eaten any of the oysters, but had partaken quite freely of the broth, was not even nauseated.

Bismuth, subnitrate, hypodermic injections of morph. sulph., and brisk catharsis constituted the treatment. All recovered within twenty-four hours.

The point of interest in this case is that the toxic principle was undoubtedly contained in the substance of the oyster itself, and was not developed in the process of canning.

314 GRAND RIVER AVENUE.

SEVERE SPASMODIC MUSCULAR CONTRACTIONS DUE TO REFLEX IRRITATION FROM CICATRICIAL TISSUE.

By HENRY H SCHROEDER, M.D.,

NEW YORK.

While acting as resident physician for the Glenwood Hot Springs Company, Colorado, last summer, the following interesting case came to my notice. One of the local physicians in the neighboring town had operated for ingrowing toe-nail, and five or six days later noticed considerable suppuration and fetor about the wound, which, however, by the end of the second week after the operation, healed under antiseptic treatment. About fourteen days after healing occurred I was requested by the physician to meet him in consultation, as the patient had been having spasms daily for the past week. The patient was a girl, twenty years of age, and, when I saw her, was somewhat anæmic, although previous to operation she had been healthy and vigorous. At the moment of my arrival she was having a violent spasm of the muscles of the left leg (the operation was upon the toe of the right foot). While manipulating the leg the spasm suddenly shifted to the larynx, causing a distressing and alarming dyspnœa similar to that caused by a very aggravated attack of globus hystericus. In spite of large and repeated doses of chloral, bromides, and mor-

phine, this condition had come on every evening and lasted through the night, the spasms alternately affecting the glottis and legs. Further examination showed that the toe which had been the seat of operation was red, swollen, and extremely painful to the touch.

Discarding the view held, that the paroxysms were due to ptomaine poisoning, since the wound had healed fourteen days previously and there were no signs of pus, I advised the immediate application to the toe of a sedative ointment made up of opium, belladonna, and cocaine in generous proportions, with lanolin and vaseline as a base, and if this proved ineffectual, as I very much feared it would, the excision of the large amount of cicatricial tissue which was a result of the suppuration and excessive granulation after operation.

The attending physician told me two or three days later that the convulsive seizures had ceased shortly after the application of the ointment, and that the toe had lost all redness, swelling, and tenderness.

A few weeks later a chair happening to fall upon the toe it again become swollen and subjected to increased pressure from the cicatrix, which occasioned a return of the spasms. The trouble, however, quickly yielded to the local treatment.

230 West One Hundred and Thirty-fifth Street.

HEREDITY AS AN ETIOLOGICAL FACTOR IN EPILEPSY.

By A. H. HENDERSON, M.D.,

Monè, Shan States, Burma.

The following struck me as an interesting set of cases in proof of heredity rather than contagion as a factor in the spread of leprosy:

Case I.—A man, aged twenty-two, well developed, presented himself with a slight scaly appearance on parts of his arms and slightly hypertrophied spots of about half an inch in diameter on his upper lip. The first symptoms appeared on the outer part of his thigh nine years ago, where in one year two ulcers appeared, healing in three months, and leaving scars now visible. Now the skin in several places is roughened and inclined to be scaly.

Case II.—A girl, aged fifteen, sister of patient mentioned in Case I., with tubercles on both alæ nasi and lobes of both ears, together with an offensive ozena. The disease commenced eight years ago on the outer part of the thigh as a white scaly spot, which increased in size. The feet are now swollen, and there are ulcers on the plantar surfaces. This case led me to inquire into the family history.

Case III.—The father of above mentioned patients had presented the same symptoms for thirty years. He had ulcerations all over his body. One of the toes had gone, in fact his was a typical case of leprosy. The interesting part is that the wife, the mother of both children, is perfectly healthy.

The popular feeling here is strongly in favor of the view that leprosy is spread by contagion. I presume it may spread in both ways, though as far as my experience goes, heredity, rather than contagion, has to bear the blame.

The Medical Profession in Russia.—Russia has 15,740 qualified doctors, 310 of whom do not practise, giving one doctor to 8,000 persons throughout the empire. As by far the greater number of the doctors live in the cities, and the urban population of Russia is only fourteen per cent. of the whole, the peasants are poorly provided with medical assistance. One-fifth of the total number of doctors are in the army or navy, and five hundred and fifty-three are women.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING OF GENERAL MEDICAL COUNCIL—CLEFT PALATE—INJURY TO BRACHIAL PLEXUS—SOME EXHIBITS AT THE CLINICAL SOCIETY—THE SALVATION ARMY'S SHELTERS—EDINBURGH COLLEGE OF SURGEONS—THE HUXLEY MEMORIAL.

London, November 29, 1895.

The General Medical Council has been sitting during the week, but whether its work has been worth the cost is a question that perturbs many. On Tuesday the President delivered his address, which follows the lines of its predecessors. Then the question of increasing the direct representatives of the profession was the next most interesting topic. It came up in connection with the petition of the British Medical Association, and may be said to have made some progress, inasmuch as two more members voted for it than on the last occasion on which it was considered. The plan has never commended itself to the Council as a body, which finds its numbers quite large enough, and many feel too large. The plan, in fact, was but the scheme of a fraction of the profession, though a noisy one, and but for the careful conduct of the representatives would have been found ridiculous. Its shortcomings are inherent in the plan, one of the most inadequate for reforming the council.

Dr. Glover brought forward the inadequate requirements respecting midwifery cases, on which also the British Medical Association had a petition in accordance with the resolution passed at the last annual meeting. It appeared, however, that the petition had not been properly adopted and forwarded by the executive of the association and had to be withdrawn. So the scandal, as many deem it, of insufficient instruction in midwifery, still adheres to certain qualifying bodies.

The person who was struck off the register for his conduct in regard to Count Mattei's nostrum applied for a reconsideration of the ruling, but without success.

On Wednesday the case of the Apothecaries' Hall, in Ireland, came up, and was subsequently considered in a different aspect. I have already informed your readers of some of the peculiarities of this case. There is no doubt that a dead-set has been made at the Hall (through its conjunction with the Surgeons' College) with a view of extinguishing it. It is scarcely to be denied that this corporation could well be spared, as, too, could some others. The Hall ought not to have obtained the position of a qualifying body, but having obtained it and exercised it lawfully, is natnally unwilling to be disfranchised by a side wind.

The Hall faculty applied to the Council to appoint for it examiners in surgery, as was done for the London Hall, and opposition to this was, of course, offered, with much talk about the power to do so and its limits. At length it was agreed to obtain the opinion of the standing counsel on several points, postponing a decision to the end of the week, so I cannot report it to-day.

The disciplinary powers of the qualifying bodies were discussed in a rambling way, and eventually a resolution was carried instructing the Executive Committee to report to the Council at its next meeting.

The results of visitations and examinations were considered. As usual a number of returns and other official documents were produced and some other cases for the judicial powers of the Council investigated.

The sad case of a medical man who was alleged to have caused the death of a woman through negligence or want of skill when attending her in labor, occupied the courts on Monday and Tuesday. The defence was illness, for which he had taken chloral. A verdict of guilty was found, and the judge, taking into consider-

ation extenuating circumstances, pronounced a sentence of imprisonment, without hard labor, for three months. He stated that had intoxication led to the sad result, as was at first alleged, the sentence would probably have been a year's imprisonment at hard labor.

The best time to operate for cleft palate seems unsettled, some surgeons recommending early operation, others advising some delay. On Monday, Mr. Owen read to the Medical Society of London notes of five cases on which he had operated this year and of which four were completely successful, one of the patients being only eight months of age. Mr. Owen is decidedly in favor of early operation, but he recommended spring and summer as the most favorable seasons, as then the children may be taken into the open air, a point to which he attaches great importance.

Mr. Morgan demurred to this early interference and thought a delay until the child was two years of age would be better, and at that age no serious defect of speech would have arisen.

Mr. Clutton remarked that the age for operating depended less on the extent of the cleft than on the shape of the palate and thickness of the tissues. The flaps, he said, could be brought down without undue tension when the palate was arched, but when it was flattened the difficulty was much greater. He had observed improvement in the voice follow operation later in life. This would depend greatly on the length of the hard palate, which when short might not catch the laryngeal vibrations.

Mr. Davies-Colley said the flap operation which he devised so diminished tension that union of the hard palate could be relied on to follow, but union of the soft palate might fail for a time. He was much in favor of early operation, not only for the sake of the perfection of speech, but to prevent the facial deformity which occurred in long-standing cases.

Mr. A. Lane insisted on securing sufficient room and advised cutting through the united lip should it be necessary.

Mr. Walsham recommended that the edges of the flap should not be pared until the end of the operation, so as to have the surfaces fresh.

At the same meeting Dr. Beevor related a couple of cases in which it was thought the brachial plexus had been injured. There was paralysis of all the muscles of the arm and loss of sensation along the outer surface of arm and forearm. The small muscles of the hand, the flexors of the thumb and fingers were not paralyzed.

Among a series of interesting cases exhibited at the last meeting of the Clinical Society I may specify one shown by Dr. Buzzard (President), of early Charcot's disease, benign form, in a woman aged thirty-eight. No destructive changes have at present appeared. Twenty months ago the right foot swelled greatly, but without pain, the tarsal joint being affected and containing fluid; six months ago the whole left lower limb swelled without pain. At present the left is much enlarged and there is great laxity of the ligaments of this joint. But for the absence of pain such cases would probably often be classed as rheumatic arthritis, of which a case was shown by Dr. H. Campbell, the chief lesions being limited to the elbows, but there was grating in the wrists and in the temporo-maxillary articulations.

Mr. O. Paget showed a case of myositis ossificans in a child five years of age, who was minus the first phalanges, the metacarpals articulating direct with the second. The thumbs were normal. The pectorals were ossified at their insertion and the latissimus dorsi along its outer border. The sterno-mastoids were affected in the same way. There was a node on one of the ribs and another on the forehead. No history of gout or rheumatism.

Mr. Clutton showed a boy in whom the tibia was absent, and there were other malformations; also a photograph of a similar case.

A decision has at last been obtained on the Salvation Army's Shelter case. The magistrate has granted a prohibition order. For two years and a half this shelter has been more or less before the public as a centre for spreading infectious fevers. But for the energetic medical officer of health, Dr. Waldo, this danger would have continued unabated. More than one thousand persons were crowded into a space only enough for four hundred, and when a vagrant with small-pox entered the result was easy to foresee. It appears that this charitable part of the Salvationists' social scheme was more than self-supporting. It is strange but true that the promoters object to be put under the same control as common lodging-houses, but they must submit. Some two years ago the Local Government Board sent Dr. Airey to inspect the several shelters, but his report has not been made public. If the suppression be due to the fears of the late government, the present Cabinet may be expected to have no need for such reticence. There is no general election at hand, and the public health should be a strong platform in the government programme.

The Edinburgh College of Surgeons was founded nearly four hundred years ago, and, as pointed out in the *Scotsman*, is the oldest medical corporation in Scotland. I lately reported the quarter-centenary of Aberdeen University. Both these bodies started in the reign of Jamie IV. of Scotland, himself "ane singular guid chirurgeon," so that the princes now following the craft have a capital precedent for their actions.

On Wednesday there was a meeting of those interested in promoting a memorial to the late Professor Huxley. It was resolved to erect a statue in the Museum of Natural History, to provide a medal in connection with the Royal College of Science, and to devote the balance of subscriptions to the futherance of biology.

OUR PARIS LETTER.

(From our Special Correspondent.)

TREATMENT AND PROPHYLAXIS OF DISEASE BY HYPODERMIC INJECTIONS—THE GLYCERO-PHOSPHATES—SEROPATHIE AND VACCINATION — ANECDOTE OF RICORD AND INOCULATION, ETC.

PARIS, November 23, 1895.

IMMUNIZATION and seropathie are more than ever engrossing attention, not only in the laboratories and at the École de Médecine, but with the profession at large. To day in the treatment of disease, whether prophylactic or curative, the Pravaz syringe is rapidly taking the place of the Meritt. Whether this would be an advantage may be open to question; it is, however, quite certain that the abscesses and erythematous eruptions frequently observed after the free use of the hypodermic syringe, are of quite as much moment as the disordered stomachs and constitutional symptoms so often seen after the exhibition of drugs. When we arrive at the prevention of syphilis by this method, inoculation will have indeed reached perfection.

A favorite injection with the Paris profession just now is the glycero-phosphate of lime, soda, or iron, whose introduction is due to Professor Albert Robin. His experiments were made chiefly with the glycerophosphate of lime, which is used with some success in tuberculosis, anæmia, and neurasthenia, the ordinary dose being from twenty to thirty centigrammes injected every morning, and continued for at least several weeks without interruption; if the benefit is marked at the end of that time, it is well to stop the injections for one week and then begin again, and these periods of alternate rest and treatment have sometimes to be kept up for several months.

But let us look for a moment at the effects of vaccine serum, or *serum vaccinicum*, as it is termed by Professor Hlava and Dr. Houl, of Prag, who have been

endeavoring to solve a problem of vast importance to science as well as to preventive medicine, namely, replace the inoculation of animal virus by injections of serum taken from an animal made refractory to vaccinia.

A first serum is prepared in the following manner: two heifers are vaccinated and their lymph secured on the fourth day after inoculation; it is proved that they are immunized against vaccinia by a double revaccination without success. After bleeding them the serum of their blood is taken up. This serum is injected to three heifers without morbid reaction; vaccinated afterward, one of them remains healthy, the other two present pustules, but small, withered, and having a dry appearance.

Thirteen children are submitted to the same experiment; they support the dose injected (1 to 2½ centimetres cubes, from 15 to 35 drops for each kilo or two pounds of weight) very well. These children are subsequently revaccinated; six remain without pustules, on the others they are rare.

In the first experience the evolution of vaccinia was disturbed by gathering the lymph on the fourth day.

In a second series of experiments the disease was left to develop itself freely on the animal in order to take the serum only after it was cured. Five heifers receive this serum by injection; this inoculation being followed by an eruption of small dry pustules without special character. But on five children treated in this manner vaccinia was well developed. These facts show plainly that the serum taken at the end of the disease is less active than that taken earlier. A third series of experiments were then made with the complete blood of the animal mixed with citrate of soda, and taken on the fourth day after inoculation. This liquid immunized perfectly two heifers against vaccinia; a third animal did not resist it because the dose injected was insufficient. On the children it produced an elevation of temperature, 38.6° C. to 39.5° C.; or about 100.2° F. to 101° F., but prevented the breaking out of vaccinia.

These experiments are certainly interesting and merit the attention of all thinking men. They can, however, only as yet be considered a step in the right direction. They have not decided the crucial questions: Does vaccinal serum possess immunizing properties against small-pox, and Has the method by injections—as a method—any advantage over that usually employed?

While on the subject of inoculation, it may be interesting to recall how Ricord nearly lost his great reputation as an authority. The question arising whether the virus of a secondary syphilitic ulcer could produce the disease, was appealed to Ricord, who unhesitatingly decided in the negative—little suspecting that a trap was being laid for him by a rival professor and a distinguished editor who is still living. They proposed to inoculate a healthy monkey; to this Ricord agreed, and accordingly all met at the hospital a few days later, including the monkey, who was duly inoculated from a patient in the syphilitic wards having a secondary syphilitic ulcer. In a few weeks the monkey was thoroughly saturated with the poison and left to die, to the great mortification of Ricord, who was just then entering upon the apogee of his fame. The experiment was not repeated until some time later, with tertiary syphilitic virus, which, it is now well known, can also produce syphilitic symptoms after inoculation.

Failure of the Oregon Medical Law.—According to the *Medical Sentinel* the recently enacted law regulating the practice of medicine in Oregon seems likely to prove ineffective. It is stated that a Chinaman, who was practising without a license in Portland, was arrested and tried three times before he could be convicted, and then only had to pay a fine of $50. Another irregular practitioner was tried and acquitted.

PRIVATE MEDICAL COLLEGES AND PUBLIC HOSPITALS.

To the Editor of the Medical Record.

Sir: Confusion exists in the minds of many physicians and others as to the exact relation which the medical colleges bear to the public hospitals. The undergraduate medical colleges which recently induced the city's authorities to turn over all the public hospitals to them, and who absolutely control their medical boards, have, as a matter of fact, no right whatever to exercise such control. These colleges are private stock companies, chartered by the State, and conducted as any other stock company for the sole benefit of the stock-holders. They advertise, and hold out every inducement possible to get students to attend them—more students, larger dividends, more reputation, and more consultations from the students—which means more cash income to the stock-holders, who are the professors. In other words they are conducted as business enterprises, and are in no sense charitable institutions or public benefits, except as any other stock company honestly conducted is a public benefit.

They cannot lay claim even to a desire for better educated physicians, for they fought the State legislature, inch by inch, in its efforts to raise the standard of medical education, and require a preliminary examination of the applicant for matriculation, for fear students would be driven away and the income of the professors be reduced.

We mention these facts, not in a sense of criticism, nor do we arraign the colleges for adopting the same business methods of other corporations engaged in money-making; but they are mentioned to show that these medical colleges must take their places along with all other business firms.

The public hospitals are built and maintained by taxation of all the citizens, and all the citizens ought, therefore, to have equal rights to enjoy all the benefits to be had from them. Their wards should be open to receive any citizen for care and treatment who is qualified to receive it by reason of his ascertained inability to care for himself.

Appointments to positions on the medical boards of these hospitals should be equally open to competition by all the citizens of the city; none should be rendered ineligible for any reason except by their demonstrated lack of skill and experience to perform the professional duties of such positions. This is only common justice.

Instead, we have to-day a condition of things which is not only an insult to nearly four thousand physicians in this city, but that actually robs them of the right to even compete for a place on the medical board of a public hospital.

Three or four men, each a "boss" in one of these private medical corporations, got together and, taking advantage of the ignorance of the Mayor and some of the Charity Commissioners, and by promising influence to aid in retaining another, secured the passage of the outrageous resolution.

Hereafter no physician is eligible to be a member of the staff of a city hospital, which he is taxed to support, unless he has a "pull" with a "boss" of one of these private corporations and is willing to wear his collar.

By this resolution of the Commissioners a still greater injustice was done: the old medical boards of the public hospitals were turned out, and it is true that some of the men who had proper "pulls" were reappointed, but in a number of instances men of excellent professional standing, and a record of years of faithful service in the hospitals, were replaced by young and recent graduates, who were the relatives of the "bosses" or their immediate henchmen.

The Commissioners of the Department of Charities and Correction have no more right to disqualify a number of competent physicians from the right to perform the duties of attending professionally the in-

mates of the public hospitals because they have not the proper "pull" with certain medical bosses, than the Commissioners of the Dock Department have to show favoritism in letting contracts for building the city's piers and disqualifying certain contractors, because they have not the proper "pull" with a political "boss."

In one case the lowest bidder should build the pier, and in the other the man best qualified, after a civil service examination, should attend the sick.

And this is all done under the name of "reform." But where does its twin sister, "Fair Play," come in?

An Impartial Outsider.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 14, 1895.

	Cases.	Deaths.
Tuberculosis	78	102
Typhoid fever	18	6
Scarlet fever	76	6
Cerebro-spinal meningitis	1	1
Measles	242	15
Diphtheria	252	36
Croup	0	6

Micro-organisms on Coins.—The *Revue d'Hygiène* publishes an interesting account of some experiments made at the bacteriological laboratory of the Military Hospital of the Dey at Algiers. Dr. H. Vincent explains that money is specially liable to be contaminated by saliva, pus, pathological secretions, dust, and the morbid germs that may be found in dirty pockets or on dirty fingers. He does not think, however, that evidence of this danger can be easily obtained by placing dirty coins in culture broth. The investigations at the Dey Hospital were conducted in a different manner. A piece of cotton-wool about the size of a pea was dipped in water and sterilized. Pieces of wool thus prepared were seized with pincers that had been held in a flame and were gently passed over the coin to be examined. The pieces of wool were then placed in culture broths and kept in a temperature of 35° C. The product, which soon contained various micro-organisms, was sown anew in gelatine plaques so as to isolate the bacteria. In other cases it was inoculated in doses varying from one to five cubic centimetres, in the blood or under the skin of rabbits, guinea-pigs, and white rats. A lengthy description of the methods employed and the results obtained is given. The number of bacteria found on the surface of coins varied very considerably—on silver and gold from four hundred and sixty to thirty-five hundred, and on copper a still larger number. To destroy many of the non-pathogenic microbes some experiments were made at a temperature of 37° C. The injection of mixed cultures from coins only produced death or serious results in about one out of every ten inoculations. Death was sometimes rapid, with symptoms of acute septicæmia. In one case tuberculosis was communicated to a rabbit by a piece of wool which had been passed over a ten-centime copper coin. In another case there was slight tetanus. There can be no doubt that germs of disease are often to be found on the surface of coins—notably the microbe of suppuration, the staphylococcus pyogenes, and the streptococcus. Nevertheless, as the experiments were repeated they proved that there were fewer infectious germs than had been anticipated. Another series of experiments was then made which demonstrated that, though coins are often contaminated they possess in themselves antiseptic qualities which greatly reduce the risk. If pathogenic germs are placed on coins it is seen that they do not live long. The time varies according to the temperature and the nature of the metal. In a cold temperature the germs of typhoid fever and the Friedlander bacillus are killed in eighteen hours if placed on a sterilized copper or silver coin; and the pyocyanic bacillus and that of green diarrhœa in twenty-four hours. At a temperature of a pocket, about 36° C., the bacilli of typhoid fever, of blue pus, of diphtheria, and the streptococcus are destroyed in less than six hours. The bacilli of diphtheria are among the most tenacious, and in cold will live three days on silver and six days on bronze. Gold, of course, is less antiseptic, and the Eberth bacillus will live five days and that of diphtheria six days on a gold coin in a temperature of 20° C. At a damp temperature of 36° C. the destruction of the microbes is very rapid, and that is the temperature which often prevails in the pockets of clothes.

Ogdensburg (N. Y.) Medical Society.—At a regular meeting of the Ogdensburg Medical Society, held at the residence of Dr. G. Madill, the following resolutions were unanimously adopted:

Whereas, We, the members of the Ogdensburg Medical Society, have learned with deep regret that Drs. J. M. Mosher and Robert Cook, active members of this society and of the Medical Staff of the St. Lawrence State Hospital, are to sever their connection with our society to enter private practice in their special lines; we realize we are to lose the genial companionship, the able and active co-operation of two of our most estimable and efficient members; be it

Resolved, That we tender them a dinner, as an expression of our good-will and fellowship and as a tribute of our high appreciation of their scientific and professional attainments. And be it further resolved, that we believe that any community in which they may locate can place every confidence and reliance in their professional skill, honor, and integrity.

Resolved, That a copy of these Resolutions be spread on the minutes of this Society, and a copy be sent to each of the gentlemen. Also, that copies be sent to the medical press for publication.

B. F. Sherman, M.D.,
President.

A Visit to Professor Kitasato's Institute for Infectious Diseases.—Dr. J. M. Atkinson, colonial surgeon, Hong Kong, sends the following account of a visit to Kitasato's laboratory to *The Lancet:* On July 28th I visited this institution and was shown around by Professor Kitasato, Dr. Nakagawa, a Japanese gentleman who is a graduate in medicine of New York University, acting as interpreter. Professor Kitasato, although having an intimate knowledge of German, does not speak English. We first proceeded to the laboratory, and I was shown the following specimens: 1, Tubercle bacilli; 2, plasmodium malariæ; 3, pneumococcus (Fränkel's); 4, Löffler's bacillus; 5, tetanus bacillus; 6, bacillus anthracis; 7, plague bacillus; 8, lepra bacillus; 9, typhus fever (enteric fever) bacillus; 10, cholera bacillus; and 11, gonococcus. Professor Kitasato's method of obtaining the plasmodium malariæ is first to fix the specimen with a one per cent. solution of corrosive sublimate, afterward staining with a saturated solution of eosin in absolute alcohol, and then with Löffler's solution of methylene blue. With reference to diphtheria I had a long conversation with Professor Kitasato. He has succeeded in obtaining an antitoxin much stronger than any yet used. To show this, 9 c.c. of his serum are all that he injects to cure a case of diphtheria; with Roux's serum, on the other hand, it is necessary to use as much as 100 c.c. He can obtain this from the blood of a horse, but prefers that of a sheep. I was shown large pieces of diphtheritic mem-

brane which had been coughed up by patients who had been injected with this antitoxin. The "tetanus bacillus" was a beautiful specimen, and is shaped somewhat like a clove, the head being the spore, and is stained red with carbolized fuchsin, the body of the bacillus being stained blue. The sixth specimen showed the spore formation very well, the spores being, as in the previous case, stained with fuchsin and the bacilli with methylene blue. The plague bacilli are very distinctive, and are exactly similar to those which were obtained this year from the few plague cases which have occurred in Hong Kong. They are of an oval shape, presenting two deeply-stained poles with a clear non-stained interval between them. The simplest way to obtain the plague bacilli is to take some of the juice from one of the affected lymphatic glands, smear it on a cover-glass, and, after fixing, stain with eosin or methylene blue. Bacilli are found to be present in great numbers; they are almost identical in appearance with those of chicken cholera. The bacillus of enteric fever, which was quite new to me, presents a deeply stained body with a number of fine filamentous processes passing off from it; none of these are branched. The specimen was from a culture obtained from the fæces in a typhoid fever case. After this I was taken round the menagerie, where there was a large number of animals—guinea-pigs, dogs, rabbits, mice. monkeys, etc., for the purposes of inoculation, investigation, etc.; and finally I visited the wards. In one room there were two patients convalescent from diphtheria, who had been injected with Professor Kitasato's antitoxin; in another ward he showed me a case of leprosy in which the tubercles were disappearing under the influence of an antitoxin which he is now investigating. In another ward there was a child with traumatic tetanus; this case was also on a fair road to recovery, the seizures being much less since the injection of a tetanus antitoxin, and the temperature having fallen after each injection. There were also some twelve cases of phthisis. Just off the wards there was a Lyons steam disinfector. The laboratory was furnished with every requisite, and one could not but be convinced that here, in the middle of Tokio, some excellent scientific research is being carried on by Professor Kitasato and his assistants.

Easy Exposure of Occultism.—There is an organization in Boston known as the Society of Psychical Research. The other evening, at one of the meetings, a certain person, said to possess remarkable occult powers, volunteered to give an exhibition, which offer was gladly accepted by the society. The "professor" was a woman, slightly built, with pallid cheeks and dark raven hair. One of the members, while not particularly sceptical, thought he would try a little experiment on his own account, so before going to the meeting he provided himself with some pieces of phosphorescent paper, that in the dark lit up like a glow-worm. This he tore into small pieces, and, just before the lights were extinguished, contrived to place three or four bits of the paper on the "professor's" head. Then he sat down and waited. When the room was dark the "professor's" cranium emitted a pale light, visible to everyone in the room but the "professor" herself. In a few minutes the phenomena began, but, strange to relate, when a tambourine in one corner of the room began to sound, the illuminated was there also, and the moving about of the operator could be easily traced. The suppressed mirth told the "professor" something was wrong, and when the light was turned on and the paper discovered, the remarks made were far from spiritual. There were no more manifestations that night.

The Number of Epileptics in the State of New York Available for Craig Colony.—Quite recently the State Board of Charities, through their representative, Dr. Charles S. Hoyt, canvassed the State to determine the number of epileptics in county and city asylums and almshouses available for transfer to the newly organized Craig Colony for epileptics in Livingston County. Dr. Hoyt reported four hundred and twenty-seven patients in these institutions. Feeling that this number by no means represented the actual number of epileptics available for admission to the colony, Dr. Frederick Peterson, the president of the board of managers of Craig Colony, has instituted a special separate inquiry among all sorts of public and charitable institutions, such as almshouses, hospitals, homes, protectories, orphan asylums, and the like, and the figures presented by him in this more extended canvass are as follows:

Epileptics in County Poorhouses	194
" " City Almshouses	13
" " New York County Almshouse, Hospitals, Homes, etc.	246
" " Kings County Almshouse, etc.	39
" " various other public and charitable institutions in the State (exclusive of almshouses)	70
Total	562

In addition to these 562 epileptics a careful inquiry elicited the fact that there are nearly one thousand epileptics in insane asylums throughout the State, of whom, at the very lowest estimate, fifteen per cent. are available for residence under the moderate restrictions of Craig Colony, making an additional 150 patients. Moreover, nearly one hundred letters have been received by officers of the colony from epileptics not in almshouses, asylums, or other institutions, but nevertheless poverty-stricken and eking out some sort of miserable existence on the charity of friends. The number of those then immediately available for the beneficent advantages of Craig Colony may be recapitulated thus:

Number of epileptics available for Craig Colony in poorhouses, hospitals, and other public institutions in the State	562
Number available from insane asylums (a moderate estimate)	150
Number of dependent epileptics not in institutions, already applicants	100
Total	812

It need hardly be said that these figures really fall short of the actual number of epileptics in the State of New York who should ultimately receive the benefits of the State's newest and greatest charity, for physicians familiar with the services in out-door departments of hospitals and in the poor dispensaries of our cities, know that very large numbers of epileptics come under their observation every year, epileptics without occupation, dependent upon charity and occasional temporary employment, or supported in idleness and misery by hard-working but equally poor relatives; and it is safe to say that the number of these deserving unfortunates in New York City alone must aggregate between three and four hundred.

Suicide in Its Medical and Its Moral Aspects.—It has been noted that a tendency to suicide has recently been somewhat unusually prevalent. The regular, though happily never frequent, connection between solar heat and this form of crime has been repeatedly observed, and may, without undue straining of logical conditions, be accepted, at all events as far as it goes, as a working hypothesis founded on accurate observation. When we go further and seek to explain the hypothesis itself, however, we are still conscious of the insufficiency of our data. The theory by which Dr. Haig would associate mental depression with blood vascular tension due to uric acid is indeed helpful in its measure, as it is certainly ingenious. The measure of assistance toward a sufficient explanation is, nevertheless, in both cases, very meagre. It is evident that in the case of most persons a wide desert of despondency intervenes between the state of mind which corresponds to a hard pulse and overladen tissues and the last fatal folly of despair. Save in the case of insane or weak-minded persons, it is hardly possible to conceive that men can

be impelled to suicide by purely physical conditions, which are, after all, so common as hardly to be regarded as abnormal except by the scientifically educated mind. We would by no means overlook the necessity of treating these cases by appropriate means, but we are none the less assured that the reckless will which induces men to convert a weariness of life into a purpose of self-destruction does not depend upon mere atmosphere or mal-excretion. Where they are free to operate, the reserves of moral sense, thought, and resolution have either been previously exhausted or have not been drawn upon. A feeling of personal loss or a morbid fear of such has obliterated the sense of human relationship. The interest of dependent or associated neighbors and of relatives is forgotten. Self-love, not social duty, is the impelling force. We have not much hope that persons in this mood will be greatly influenced by changes of weather or by purely physical treatment. We would rely more upon the full and frank assertion of the duty and utility of all human beings to each other, and to the Providence essentially friendly to men which called them into being. Suicide is, after all, a moral failure, an evidence of the mastery of mistrust, an act of rebellion against the authority of patience. Obviously no drug, no social reform even, can effectually cure it, unless they be aided in the first place by a frank and full recognition of man's moral relation and responsibility.—*The Lancet.*

Prolonged Hiccough.—Dr. Ferguson reports a severe and prolonged case of hiccough in a man, aged thirty-three, which lasted for seventy-two hours without cessation, except during short periods while under chloroform anæsthesia (*The Lancet*). The case was treated unavailingly by chloral, camphor, ether, aromatic spirit of ammonia, tincture of opium, morphine hypodermically (gr. ½), tincture of belladonna, ice, and galvanism to the phrenics, and ice to the spine. The patient was in a critical condition, no nourishment had been taken for many hours, cyanosis was intense, while the hiccough was continuous and violent. As a last resource a hypodermic injection was administered containing morphine, gr. ½, and atropine, gr. $\frac{1}{60}$. The same quantity of morphine had been already injected without producing any further effect than a little drowsiness. In five minutes the patient was fast asleep and the hiccough had entirely ceased. In two hours symptoms of poisoning developed, the face and lips being cyanosed and the breathing stertorous, slow, and labored. Tickling the soles of the feet restored consciousness, so that he answered questions and swallowed some coffee. After another hour's sleep his breathing became so obstructed that he was again awakened, this time with far less difficulty than before. Next morning he complained of nothing except some stiffness of the neck and difficulty in swallowing, and in a few days he regained his normal condition. There was no return of the hiccough.

Grief from a Medical Stand-point.—The nervous system requires complete rest after blows caused by sorrow. Recent medical observations show that the physical results of depressing emotions are similar to those caused by bodily accidents, fatigue, chill, partial starvation, and loss of blood. Birds, moles, and dogs, which apparently died in consequence of capture, and from conditions that correspond in human beings to acute nostalgia and "broken heart," were examined after death as to the condition of their internal organs, and it was found that the nutrition of the tissues had been interfered with, and the substance proper of various vital organs had undergone the same kind of degeneration as that brought about by phosphorus or the germs of infectious disease. The poison of grief is more than a man. To urge work, study, travel, the vain search for amusements, is both useless and dangerous. For a time the whole organism is overthrown, and temporary seclusion is imperative for proper readjustment. Grief cannot be ignored, neither can it be cheered up. It must be accepted and allowed to wear itself away. Readjustment comes slowly. Sorrow, grief, and all great misfortunes should be regarded as conditions similar to acute infectious diseases, which they resemble in result; and, later, as convalescence from such diseases. Seclusion, rest, sleep, appropriate food, fresh air, sunshine, interests that tax neither mind nor body, these are requirements in this class of illness.—*Charlotte Medical Journal.*

Death in a Hospital Bath.—A strange death formed the subject of an inquest at Portsmouth recently. A man, aged thirty-two, was sent as an applicant for admission to the Royal Hospital at Landport. He was suffering from bronchitis in both lungs, and, having been examined by the house surgeon, was sent to get a bath and go to bed. The water was from 90° to 100° F. in temperature, and one of the nurses asked him before he was left if he was subject to fainting fits, to which he replied in the negative. He had been in the bath-room about ten minutes when a nurse, requiring something from the compartment, sent a lad to get it. The latter found the deceased under the water and at once ran for assistance. The man was, however, quite dead, and he had not the appearance of asphyxia from drowning. A necropsy revealed a ruptured aneurism. —*The Lancet.*

Fake Hospitals in Chicago.—The *British Medical Journal* is informed by its Chicago correspondent that a crusade has been started against the so-called "fake" hospitals which have come into existence of late years. To the end of effectually getting at the evil, the Council has had presented an ordinance, a draft of which is here submitted. Whether or not the restrictions are drawn close enough to affect the illegitimate massage establishment or not must be left to the thought of the reader:

Section 1. That it shall be unlawful for any person, firm, association, or corporation other than the regularly constituted authorities of the State of Illinois, or the county of Cook, or the city of Chicago, to open, conduct, manage, or maintain any hospital as hereinafter defined within the corporate limits of the city of Chicago without first obtaining a permit therefor, to be issued by the Commissioner of Health of the city of Chicago, upon the written application of such person, firm, association, or corporation, which application shall state the location, or proposed location, of such hospital, the purposes for which it is to be opened, conducted, or maintained, the accommodations or proposed accommodations for the inmates thereof, the nature and kind of treatment given or proposed to be given therein, and the name and address of the chief surgeon, physician, or intended chief physician or surgeon attendant thereat.

Section 2. It shall be the duty of the said Commissioner of Health, upon the presentation of such application, to make or cause to be made strict inquiry into the facts set out in such application, and if upon such inquiry he shall find that such hospital is or is intended to be constructed so as to afford proper accommodation for the care of the persons received or proposed to be received therein, and that the chief physician or surgeon, or intended chief physician or surgeon attendant thereat, gives or is under agreement to thereafter give such attendance thereat as does or will render him responsible professionally for the medical or surgical treatment given or to be given to any and all persons thereat, and that such chief physician or surgeon is regularly authorized to act as such under the laws of the State of Illinois, and upon the payment to said Commissioner of Health of a license, permit, inspection, or examination fee of . . . dollars, he shall issue a permit in the name of the City of Chicago to such applicant to open, conduct, manage, or maintain a hospital at the place and in the manner and for

the purpose in such application mentioned, which said permit shall cease and be operative the 31st day of December next following the issue thereof.

Section 3. It shall be the duty of such person, firm, association, or corporation permitted as aforesaid to open, conduct, or maintain a hospital within the corporate limits of the city of Chicago to make a report to the said Commissioner of Health on or before the 5th day of each calendar month, showing a complete record of such hospital during the preceding month, including the number of inmates received, discharged, and died during the month, causes of death, and such other information as may be necessary to an intelligent sanitary supervision of the establishment; such record to be furnished on blanks prepared and supplied by the Commissioner of Health, verified by the affidavits or affirmation of the chief physician or surgeon or superintendent attendant thereat.

Section 4. Every hospital permitted as aforesaid shall at all times be open to the inspection of the said Commissioner of Health, or his duly appointed assistants or inspectors.

Section 5. The Commissioner of Health of the city of Chicago is hereby authorized and empowered to inspect, or cause inspection to be made, whenever and as often as he may deem proper, of any hospital permitted as aforesaid within the corporate limits of the city of Chicago, and if, upon any such inspection, he shall find the same to be conducted, managed, or maintained in violation of the terms of the application for the permit under which the same was opened, conducted, managed, or maintained, or in violation of any of the health or sanitary ordinances, rules, or regulations of said city of Chicago, then and in that event he is hereby authorized and empowered to revoke any such license issued for the opening, conduct, management, or maintenance of the same.

Section 6. Any person or persons, or corporation other than the regularly constituted authorities of the State of Illinois, county of Cook, or city of Chicago, opening, conducting, managing, or maintaining a hospital as hereinafter defined within the corporate limits of the city of Chicago without first having obtained a permit therefor as provided in Section 2 of this ordinance, or after a revocation of such permit under the authority conferred in Section 5 of this ordinance, or in violation of any of the provisions of this ordinance, shall be and is hereby declared to be guilty of maintaining a nuisance, and upon conviction thereof shall be fined in a sum not less than . . . dollars nor more than . . . dollars.

Section 7. For the purposes of this ordinance a hospital is hereby defined to mean any place or establishment used for the reception or care of the sick, injured, or dependent, including women awaiting confinement, or used for the medical or surgical treatment of mental or physical disease or injury.

Section 8. This ordinance shall take effect and be in force from and after its passage and due publication.

International Institute of Sero-therapy.—The treatment of diphtheria and other diseases by antitoxic serums has taken hold in France to such extent that it has been proposed to create an International Institute of Sero-therapeutics for the purpose of guaranteeing to the profession the purity and strength of the serums required. It is said that some of the serums sent out from certain laboratories are greatly wanting in these qualities. The proposal is to place the Institute in Switzerland, in order that international jealousy may be avoided.—*Medical Press.*

The Plague in China.—The plague, during its recent outbreak in China, was the immediate cause of two thousand five hundred and fifty deaths, and of the emigration of one hundred thousand Chinese. The percentage of Europeans who recovered was eighty-two, while that of Orientals was as low as twelve.

Treatment of Acute Bronchitis of Infancy.—Dr. Perrier directs that in the very acute forms of bronchitis in children the chest should be rubbed with oil; warm drinks should be given, particularly hot milk. Sometimes, if there is much oppression, it is well to apply a thin and light but mild mustard plaster. If the stomach is loaded with partially digested food an emetic of powdered ipecac, 1 to 2 grains, and syrup of ipecac, 1 ounce, may be given, in the dose of a teaspoonful every ten minutes till the desired effect is produced, and if the fever is high 1 or 2 grains of the hydrochlorate of quinine may be given in a little coffee. The air of the room should be moderately warm and moist, but it is most important that the ventilation be good. As the disease progresses, if bronchial secretion becomes very profuse, the following prescription may be used:

℞. Oxide of antimony..... gr. ss.
Syrup of senega..... ʒ j.
Syrup of acacia..... ʒ ij.
M. Sig.: A teaspoonful every two hours.

Or this may be replaced by

℞. Terpine hydrate..... gr. ij.–iv.
Brandy..... ʒ ij.
Syrup of cinchona..... ʒ ss.
Syrup of orange..... ʒ ij.
M. Sig.: A teaspoonful every two hours.

Often an emetic will aid in relieving the lungs of mucus. During the day a little additional brandy or red wine may be given as a stimulant. In those cases in which frequent attacks of bronchitis follow one another it is useful to give the child warm baths, followed by cold sponging, and this, in turn, by active friction of the skin in drying the body. Malt extract should be given with each meal, and a teaspoonful of the following prescription ordered three times a day:

℞. Arsenate of sodium..... gr. j.
Distilled water..... ʒ vi.
M. Sig.: A teaspoonful after meals.

If, notwithstanding these measures, the child fails to improve, it must be taken to a dry climate.—*Therapeutic Gazette.*

Race and Disease—Investigations in reference to this interesting subject, by Dr. John S. Billings, include a special study of ten thousand Jewish families, in all fifty thousand persons, and near views of Germans, Irish, and the colored race, with the following results, that are probable conclusions for the United States. The colored race is shorter-lived than the white, with a very high infantile death-rate. It is especially liable to tuberculosis and pneumonia; less liable than the white race to malaria, yellow fever, and cancer. The Irish have rather a low death-rate among young children, but a very high one among adults, due in part to tuberculosis, pneumonia, and alcoholism. Germans appear to be particularly liable to disorders of the digestive organs and to cancer. Jews have a low death-rate and more than average longevity. They are less affected than other races by consumption, pneumonia, and alcoholism, but are especially liable to diabetes, locomotor ataxia, and certain other diseases of the nervous system.

The Pennsylvania Colony Farm for Epileptics—The project of establishing a colony for epileptics, where country living and farm work, judiciously apportioned, would constitute the principal therapeutic treatment, which has been under consideration for some time, has at length assumed a definite shape. The court has granted a charter for the "Pennsylvania Colony Farm for Epileptics," and the corporators have organized, November 13th, by the election of Dr. Wharton Sinkler, President. Among the directors are Drs. Charles K. Mills, James C. Wilson, and Wharton Sinkler. A charitable gentleman of Philadelphia has offered to give $50,000 for the erection of suitable buildings, provided that the farm be secured before January 1, 1896.—*Boston Medical and Surgical Journal.*

THE "DIAPHRAGM PHENOMENON" AND ITS IMPORTANCE IN CLINICAL MEDICINE.

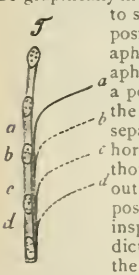
BY MORITZ LITTEN, M.D.,

PROFESSOR IN THE UNIVERSITY OF BERLIN.

THE object of this communication is to call the notice of my colleagues to a new motor phenomenon exhibited by the diaphragm, which has hitherto escaped attention. It being a physiological utterance of the normal organism, we are able plainly to observe its course during each individual respiration, neither previous measures nor artificial light being required. I first published a short description of this "diaphragm phenomenon" in 1892, and now, after three more years of work, I again bring forward the subject on account of its great practical and scientific importance, which has not so far met with sufficient recognition. All who once have had occasion, in my lectures, to witness this phenomenon, both students and practitioners, have fully realized the value of this new aid to diagnosis, and have since made use of it in all cases. Add to this the great convenience offered for examining a large number of individuals, for military and polyclinic purposes, for instance, or in life insurance.

By the term "diaphragm phenomenon" I understand the visible expression of the gradual detachment, during its inspiratory descent, of the diaphragm from the walls of the thorax, and its gradual apposition to the thoracic walls while it rises during expiration.

Remark: This line, visibly progressing downward during inspiration, and upward during expiration, may be graphically illustrated by this schematic drawing: *T*, to signify the thoracic wall, and *a*, *b*, *c*, *d*, positions successively occupied by the diaphragm during an inspiration. The diaphragm should be imagined consisting of a perpendicular portion closely adjoining the walls of the thorax—from which it is separated by a capillary space—and of a horizontal part intervening between the thoracic and abdominal cavities. At the outset of an inspiration the diaphragm's position is at *a*, *a*: now, in the course of inspiration the upper part of its perpendicular portion becomes detached from the wall, while the lower parts (at *b*, *c*, *d*) still cling to it. At the same time the horizontal portion presses downward. The position of the diaphragm at this juncture is represented by the dotted line *b*, *b*. During the following phase of the same inspiration the perpendicular portion at *b* is detached, *c* and *d* yet remaining adherent to the wall; the position *c*, *c* is thus assumed. Finally *c* becomes detached, leaving the diaphragm in the position of extreme inspiration, *d*, *d*. It is the progressive detachment at *a*, *b*, *c*, *d* of the diaphragm from the thoracic walls that finds visible expression in the so-called diaphragm phenomenon. Precisely the reverse takes place in the course of an expiration.



This physiological process, which is repeated during each respiration, is plainly marked on the thoracic wall, by the regular rising and falling of a peculiar shadowy line, caused by the motion of the diaphragm and denoting its momentary position. As a regular and physiological accompaniment to the act of respiration, this line may be observed on the chest of every individual, healthy or diseased, unless morbid processes be present that interfere with the mobility of the diaphragm. It passes down along the thorax at an acute angle with the ribs, in the shape of a straight horizontal shadow or a wavy undulation, starting on either side at about the sixth intercostal space, and descending several interspaces, sometimes as far as the costal margin, during a deep inspiration. During expiration it again rises to its original position. During forced respiration the excursions of the diaphragm comprise two or three intercostal spaces, 2⅜ to 2⅝ inches being the medium; in superficial breathing, on the other hand, no more than one interspace or one and a half are covered. The visible motion of the diaphragm may comprise the entire breadth of the sides of the thorax, being evident from the axillar line to the margin of the sternum when the patient is recumbent on his back, or from the hinder axillar line to the vertebral column when he is resting on his chest, or better still on knees and elbows. Sometimes this phenomenon is more plainly marked on the right side than on the left, but I have also observed the reverse.

Although a practised eye will be able to make it out, whatever the position of the body, yet it is most plainly visible when the patient is so placed that the part of the body concerned, *i.e.*, the costal region below the seventh rib, receives the most light (if possible in a tangential direction). For this purpose the patient is made to lie on his back, his head but slightly supported, opposite the window to which his face is turned, while at a distance of three or four feet the observer, with his back toward the window, scans his chest at an angle of forty-five degrees. Now, when the patient fetches a deep breath a broad shadow is seen to travel down and up, coincident with each inspiration and expiration; no one, after having one time plainly seen this, can fail to easily recognize it in future. I wish to emphatically state here, in the face of prejudice, that this is not a matter of fine clinical distinctions, but that I am speaking of a phenomenon which whoever cares to see cannot help seeing. The only conditions to be observed are: horizontal position of the patient, good light, and deep breathing.

From a scientific point of view it is highly interesting to be able, accurately and without any trouble, to watch the alternate movements of the diaphragm. But the subject has a practical bearing, too, in regard to medical instruction, both physiological—the concealed action of the diaphragm, hitherto visible only in vivisected animals, being now rendered apparent to the student in the live human being—and clinical; the beginner being enabled to himself verify the correctness of his percussing, instead of blindly acquiescing in the corrections of his teacher on the strength of the latter's authority.

The appreciation of another important clinical fact, the respiratory shifting of the abdominal organs, is greatly advanced by our phenomenon. Among these organs those situated immediately beneath the diaphragm partake of its motions and may in their turn rhythmically displace others. These movements can be seen and felt. They are owing, needless to say, to the muscular

action of the midriff. Where its mobility is diminished or absent, there the motion of these organs is correspondingly arrested. This knowledge has been turned to a diagnostic account long ago in regard to liver and spleen, and recently in regard to the kidneys. It is interesting to observe both movements, of the diaphragm and of the organs, simultaneously, the former by sight, the latter by sight or touch. Thus the stomach, or a coil of the intestine, or the liver, may be seen to move in time with the diaphragm; the same observation is made in bimanual palpation of the kidneys. If, with a pencil, you mark on the skin the limits of the visible excursion of the diaphragm, the upper line (about over the seventh rib) denotes the expiratory position; the lower line (ninth rib, about) the inspiratory. Both correspond to the inferior margin of the lungs, or in other words to the superior surface of the liver. The normal excursion of the diaphragm amounting to $2\frac{3}{8}$ to $2\frac{4}{8}$ inches on an average, you can tell at a glance whether the lungs expand in the normal way, and whether their margins occupy the right position.

A great saving of time is thus effected by this method of examination; the volume of the lungs is easily ascertained, and the vital capacity gauged more rapidly and better than by measuring the chest circumference and the amount of air aspirated. A smaller excursion than the average two and a half inches bears a pathognomonic significance, provided the patient drew as deep a breath as he could. Mostly in these cases emphysema is present, whereby the diaphragm's position is one or two intercostal spaces further down (in the mamillary line), or even as low as the costal margin, where it is never found under normal conditions. An impeded excursion of the diaphragm may be further, owing to general debility—it is not found depressed in that case, but at its normal altitude—or to circumstances allowing of costal respiration only. Thus it will be greatly diminished in the last months of pregnancy. In very fleshy individuals it is mostly not visible at all.

It is in unilateral trouble that my method achieves its greatest triumphs, the difference between the diaphragm's movements on either side striking the eye. If the phenomenon is totally absent on one side, whereas on the other it is normal in extent and situation, then there is either a considerable effusion of liquid or of air present in one pleural cavity (empyema, pleuritis exudativa, hydro-, hæmato-, pneumo-thorax), or else we have a case of pneumonia of the inferior lobe. In the latter affection, as well as in empyema and in pyo-pneumo-thorax, the action of the diaphragm, owing to the infiltration of its muscular substance, is entirely suspended on the diseased side; in the case of serous effusion, slight motions of the diaphragm are often visible abnormally far downward.

At any rate, one glance at the chest is enough to tell whether, and to what extent, the muscle is confined in its movements. In the case of extensive attachment of the diaphragm to the lungs, or to the spleen and the liver, and especially in cicatricial retraction of the thorax, the motion will be still visible on one side, though much retracted. Where there is an area of dulness in the lower part of the thorax not owing to the liver or the spleen, and where the phenomenon is visible notwithstanding, though to a lesser degree, above the dulness, there can be no doubt as to the subphrenic position of the trouble—a subphrenic abscess thus being revealed. Further evidence as to the nature of the dulness is obtained by a probatory puncture. If pus is then produced the diagnosis is assured.

In the presence of tumors within the thorax, the diaphragm, if visible at all, will be seen very low down. In several cases of mediastinal and pulmonary tumor we were able to distinctly perceive it, though its motion was much hampered; this was the case especially where the disease was situated in the inferior lobe. In the presence of large tumors of the spleen and of the liver we have in many cases seen the phenomenon most plainly; once only was it totally lacking, in a case of enormous melanotic degeneration of the liver. (The organ weighed 36 pounds.) It was never to be perceived in extensive ascites, diffuse peritonitis, or in ileus with considerable meteorisms of the intestine. In one case of acquired diaphragmatic hernia there was clear tympanitic percussion sound above the visible phenomenon, whereas in pneumo-thorax it is invisible, owing to the inspiratory in-drawing of the intercostal spaces being rendered impossible. In the same way, there will be no trace of the phenomenon in unilateral paralysis of the phrenic nerve.

My method is of great service in judging of the action of the lungs after pleuritic effusions and after injuries. The more pleuritic adhesions have formed and the firmer they are, the less clearly is it visible; by comparing it with the other side we get a pretty definite idea of the degree to which the lung's action is interfered with. On the other hand, in many doubtful cases of the after-effects of accidents, it has been possible in this way to ascertain with positive certainty that there was no impediment to respiration, *i.e.*, to the inflation and mobility of the lungs. I have thus repeatedly in forensic cases where the injured party claimed to be unable to breathe properly (for instance in consolidated fractures of the ribs), found occasion to expose a fraud on the ground of our phenomenon showing no alteration. It serves as a reliable guide, too, in forming an unbiassed judgment in regard to therapeutic effects, especially in pneumo-therapeutics, improvement in the action of the lungs being infallibly discerned. In many instances of emphysema and pleuritic effusion treated by means of a Steinhoff apparatus, we were thus enabled to gauge the measure of success achieved. The superior and inferior limits of the "phenomenon" should be marked with lunar caustic at the beginning of a treatment, then in emphysema you may, if successful, see the phenomenon extend beyond these lines in a couple of weeks.

Since I made the discovery, in 1891, that this phenomenon was a regular physiological occurrence common to all human beings, all the patients of my polyclinic (to the number of 5,000 to 6,000 a year) have been examined with a view to this, and it has been found in every case unless counteracted by some morbid process or other. I am sorry to see that my efforts to promulgate this knowledge[1] have not so far attracted that amount of attention which the matter undoubtedly deserves. I trust that all medical men who will take the small pains to really see this phenomenon, will appreciate it and give it a place alongside of the other methods of physical diagnosis.

Exercising the Chicago Police.—Dr. Hawley, of Chicago, has obtained the consent of Mayor Swift and the Chief of Police to the introduction of a system of athletic drill into the Police Department, for the purpose of developing agility, skill, and endurance among the policemen of the city, and increasing their strength. It is hoped, also, that the general health of the force will be increased, so that there will be a smaller aggregate loss from sick-leave.

To Suppress Press Notices of Suicide.—It is stated in the *Hospital* that the Medical Society of Berne has inaugurated a scheme, which it would be as well if other places would also adopt; this is the suppression of press notices of cases of suicide. It has been observed that suicides have so frequently been "suggested" by these notices that the measure seems a salutary one from this point of view.

A STUDY OF THE INFECTIOUSNESS OF THE DUST IN THE ADIRONDACK COTTAGE SANITARIUM.

By IRWIN H. HANCE, M.D.,

NEW YORK.

Associated with our increasing knowledge of germ life and the practical application of bacteriology toward solving the causes of disease and tracing back to its fountain-head the source of any infection, there exists among the laity and also some physicians an intense fear, sometimes amounting to mania, that they are continually exposing themselves to an invisible danger which is lurking about them in the food they eat, the water they drink, and the air they breathe. The most dreaded nightmare of them all is the fear of becoming infected with the germs of tuberculosis. No one can deny the presence of this danger in a great many places; but oftentimes in the places where popular opinion considers it greatest it is actually less to be dreaded than in other localities where with the external appearances of refinement and cleanliness there exist the most favorable conditions for the permanent lodgement of infectious material in the dust.

This fear of infection from tubercular germs has become so general and reached such a climax that the poor tubercular patient whose mental and physical suffering is already extreme must carry around with him an added burden of anxiety and care, since people look upon him as a dangerous character in the home or community. It is within the writer's experience that parents have refused to have their children return home lest some other member of the family might be infected; and men have found it difficult to hire flats in New York City or Brooklyn when they wished to make a home for a dying wife or child. In one instance a physician wrote to have his former patient kept in Saranac Lake until she died, as he thought that was the only way of avoiding possible infection for the other members of her family; in the end she was taken home to die in a hospital.

Such heartless actions are due to a great extent to the ignorance of people concerning the real dangers of infection, and their lack of knowledge as to how they can be avoided. In their blind ignorance they think to avoid an apparent danger, little dreaming how much more frequent and dangerous are the daily exposures to the same diseases in their social intercourse, travels and amusements.

For these reasons it has seemed a fitting time to make some experiments on this subject to determine how great the danger of infection is in a large community of consumptives where all sanitary measures are enforced as regards the care and disinfection of sputa.

Two facts have been positively affirmed by previous experiments: 1. Buildings for consumptives, prisons, private dwellings, and public conveyances do become infected with tubercular germs. 2. A tuberculous patient is absolutely free from the danger of infecting others by contact; it is the product of their excretions which is the dangerous factor. Destroy these and the house or home of the consumptive is no longer dangerous.

All investigators have established the first of these two statements, none more thoroughly than Cornet,[1] reference to whose work will be made later in this paper.

The second statement has also been repeatedly proven; but among the laity and also some physicians it is so dimly comprehended that time will not be lost in quoting some of the investigators and their experiments.

Two Italian investigators, Celli and Guarnieri, found the expired air of tubercular patients free from tubercle bacilli; and also that air blown by a bellows over and through sputum very rich in bacilli remained free from bacilli.

Fr. Müller,[1] Sormain and Brugnatelli,[2] Charrin and Karth,[3] Cadeac and Malet,[4] all found the expired air non-infectious.

For two months Tappeiner[5] had a woman with advanced phthisis cough through an opening into a wooden box in which were two guinea-pigs; at the end of that time they were killed and found sound.

Cornet[6] states that the expired air "never and under no conditions contains tubercle bacilli or their spores."

Since, then, personal contact with a tuberculer patient is free from danger, whence is the source of the infectious material? For all practical purposes it is contained in the sputum, which becomes dangerous and capable of infecting when dried and pulverized. In its moist state it is harmless; therefore, if tubercular patients are careless and dirty about their sputum they are dangerous, not alone to themselves, but to all who come in contact with them.

Knowing these facts, and taking pains to make them clear to the patients in the sanitarium, it may well be said, after five years of personal observation, that the rules concerning the care and disinfection of sputum have been since its inception and are to-day most carefully carried out there. Occasionally a very sick or careless patient does transgress the rules, but this occurs very seldom for such a large institution.

In order to test the efficacy of the system, a complete examination of the group of buildings was made, some of which have been occupied eleven years by consumptives. In every instance dust from the darkest and most likely to be infected spots was taken; for if infected, the management was most desirous of knowing it.

The experiments were done at Dr. Trudeau's request and under his supervision at the Saranac Laboratory for the Study of Tuberculosis. They were arranged in two groups, the details of which were as follows: First group of four buildings consisted of the main building (parlor, sitting-room, and public library); the infirmary, where all the acutely sick are sent; the "Red Cottage," which was the oldest on the grounds, and the "Penfold," the most recently built cottage. One square yard of dust from each of these buildings was collected and inoculated into ten guinea pigs. Second group consisted of thirteen cottages, from each of which half a square yard of dust was taken and inoculated into three guinea pigs; thus the second batch of pigs received proportionately a larger quantity of dust than the first.

The technique was as follows: Sterilized cotton swabs moistened with sterilized water were used to collect the dust from the walls, backs of pictures, and darkest corners of the rooms; 1 to 2 c.c. more of sterilized water was added to cleanse the cotton of the dust. The swabs were then squeezed in a piece of coarse sterilized gauze, and an equal share of the whole dust, suspended in water, inoculated into each guinea pig; all inoculations were made into the abdominal walls, extraperitoneal. Save for any infections in the dust, all other sources of contamination were excluded by thorough antiseptic precautions.

The animals were kept from one to three months and then killed. Any enlarged glands or suspicious areas were carefully examined for tubercle bacilli, and the diagnosis of tuberculosis only made when these

Out-building	1	0	0	0	0	1	¼
Thus of...	81	5	4	9	11.11	72	

In all 81 pigs were inoculated with from 2 to 3 c.c. of sterilized water with the dust in suspension; of these only 4 or 4.9 per cent. died of other infectious diseases on the third to sixth day and 5 of tuberculosis. These five constituted just one-half of the number of pigs inoculated with dust from the "Red Cottage," a small cottage holding two patients, always occupied by the sickest men, one of whom had been complained of by his room-mate for spitting around the cottage. The five pigs lived sixty days, were then killed, and although tuberculosis was present in the omentum, spleen, liver, and lungs, they were well nourished and strong, apparently showing a diminished virulency of the infecting germs.

The infection of this cottage demonstrates two things: first, how easily a patient by carelessness and disobedience of rules (probably due to his very weak, sickly condition) may render a cottage dangerous to himself as well as to others; second, that the technique of the experiment was faultless.

It brings out, however, in stronger contrast the successful results of the experiment as a whole, since sixteen buildings out of seventeen, inhabited by consumptives for so long a period as ten years, were absolutely free from infectious material. This is the more striking when we consider the great vitality and virulence of the tubercle bacilli, Stone [1] having proven by inoculation of rabbits that dried sputum after the lapse of three years was capable of inducing tuberculosis.

With this array of negative results a most conclusive proof is given that a body of consumptives need not infect the houses they occupy when their excretions are destroyed. To attain this end it requires that each new patient should be carefully instructed concerning the disposal of his sputum, and close supervision of them all be maintained.

Then each patient feels that he endangers himself as well as the others by not obeying the rules; if anyone becomes careless in the matter it is quickly reported to the medical authority by one or more members of the sanitarium, everyone appreciating fully the grave consequences of possibly infecting the cottages or public rooms.

The methods used are to burn all cuspidors daily, and the Japanese napkins as soon after using as possible; never to expectorate except into the large sanitary cuspidors when about the main buildings, or the small individual hand cuspidors. Paper napkins are used in the infirmary in hemorrhage cases or where patients are too feeble to get up on their elbows so as to spit into the cuspidor; these are used but once, then placed in a pasteboard receptacle and the whole thing burned several times a day. During the greater portion of the year fires are burning in every cottage, and the patients burn everything in the stove or fireplace.

In summer a barrel with some moist sawdust in the bottom is placed in an out-building, and the cuspidors and napkins are carried to this barrel, which is saturated with kerosene and burned three times a week. One-fourth of a square yard of dust from this building was inoculated into one guinea-pig, which remained healthy. A properly constructed crematory is much needed, but too costly at present to build. The cuspidors used are made by Seabury & Johnson, and of two sizes: one, the hand cuspidor, for individual use, and the other, a much larger size, for the piazzas and public rooms. The latter are placed in covered wooden boxes about four feet from the floor; these are easily taken down and cleansed. By this arrangement patients cannot spit at a cuspidor from a distance, and the mass of sputum is not blown over the edges of the cuspidor by the wind, as happened at first when uncovered cuspidors were placed upon the floors.

It is perhaps too much to suppose that all particles of infectious materials are thus destroyed; where seventy to eighty small hand cuspidors are in daily use there may be some slight soiling of a stand or the linen covers on which the cuspidors are placed; also in coughing some small masses of sputum may be violently expelled. These sources of contamination must be small, and are fraught with less danger by frequently washing the tin frames for the cuspidors, and the cottage plan of housing patients, thereby avoiding the evils of overcrowding.

Besides the destruction of the sputum, other factors equally important have served as auxiliary means of keeping the cottages free from infection, not alone with tubercle bacilli, but also other germs: these are the construction of the cottages, which are built so as to insure thorough ventilation; the immense volume of air space allotted to each patient—this is secured by large openings from the various bedrooms into the sitting-room, which communicates with the outside air by transoms opening above the piazza roofs; the smooth, hard-wood wainscoating, 7 to 8 feet high, around the whole cottage, permitting of thorough cleansing with soap and water; the absence of wall-papers, the upper walls and ceilings being heavily sized and then painted, rendering these also easily cleansed; the plain, simple furnishings—iron hospital beds, rugs, and hard-wood floors, and as few tapestries as possible; lastly, the large area of window surface, allowing the sun's rays and strong light free access to all parts of the cottage. Added clinical proof of the non-infectious character of the dust may be deduced from the fact, that not one of the twenty to twenty-five attendants has ever developed tuberculosis; and also that no patient who was admitted suffering from pulmonary disease without the bacilli being present ever subsequently developed them.

How do these results compare with those of other experimenters?

Heron [1] inoculated one hundred guinea-pigs with dust taken from various sources in the City of London Hospital for Diseases of the Chest. In the greater number of experiments "a piece of dust was introduced into the sub-peritoneal tissue;" in some a solution of dust in sterilized water was injected into the pigs. Twenty-six pigs, twenty-six per cent., died of "either intense inflammation spreading from site of inoculation

[1] A. K. Stone: American Journal of the Medical Sciences, March, 1891.

[1] G. A. Heron: The Relation of Dust in Hospitals to Tuberculous Infection. Lancet, No. 3,671, January 6, 1894.

or septicæmia." Of the remaining seventy-four, two pigs (both inoculated with dust in solution), or 2.7 per cent., died of tuberculosis. The dust in each case came from "the tower of the hospital which acts as up-cast shaft," and was dark and unventilated. It would seem as though the implantation of a piece of dust was too small to place too great reliance on negative results.

Cornet,[1] seven years ago, gave us the following table :

Places.	Number of Animals Inoculated.	Of These Died of		Died of Infectious Diseases.		Remained Sound.
		Tuberculosis.	Other Infectious Diseases.	All Told.	In Percentage to Inoculated Animals	
In seven hospitals	94	20	52	72	76.6	22
In three insane asylums	33	3	16	19	57 5	14
In two prisons	14	0	6	6	42	8
Inhalation rooms	4	2	0	2	50	2
Dwellings of private tubercular patients	170	34	91	125	73 5	25
Polyclinic, orphan asylum, etc	28	0	14	14	50	14
Surgical wards	8	0	1	1	12 5	7
Streets and hygienic institute	41	0	16	16	39	25
Streets alone					55	
Thus of	392	59	196	255	65.5	137

In the hospitals 47.6 per cent. of the pigs not dying of acute infection developed tuberculosis ; in private dwellings, 43.6 per cent. ; in insane asylums, 17.6 per cent.

M. Kirchner,[2] in examining the garrison lazaret of one of the army stations, experimented on forty-two pigs by inoculation with dust suspended in bouillon or implantation of dust-infected sponge in abdomen. Twenty-six, or 61.9 per cent., died from the operation and infection of wound. Sixteen, or 38.1 per cent., remained alive. One of the sixteen developed tuberculosis.

The writer secured the dust from a large city hospital out of the wards occupied by male and female tubercular patients. From male ward were inoculated three pigs with one-half square yard of dust. From female ward were inoculated three pigs with one-half square yard of dust. From female ward were again inoculated three pigs with little less than one-half square yard of dust. Of male ward pigs, one died ; of female (first lot) all three died ; of second lot one died of an intense cellular inflammation much resembling a malignant œdema. All these died on the first to third day after inoculation. The four living pigs were killed in sixty days, and one of those inoculated with dust from female ward had well advanced tuberculosis ; thus, twenty-five per cent. of the pigs remaining alive developed tuberculosis, while 55.5 per cent. died of acute infection, some of which might have developed tuberculosis. In these wards the beds were carbolized once a week ; the floors washed daily and scrubbed twice a week ; the walls rekalsomined every six weeks, and Seabury & Johnson's cuspidors used, which were changed twice a day. In the female wards, however, long pieces of cheese-cloth were given to the sickest and weakest patients, which were used as a roll to spit into, and would last a patient from four to eight hours. This, in all probability, was the source of infection.

A close perusal of these results shows that the careful disinfection of the sputum has been productive of good results, but not yet fully satisfactory, since in each experiment the dust has been infected with tubercle bacilli. Of far more importance, however, is the fact that the dust was infected to such a virulent degree with other germs ; to-day we know how much more serious are the cases of tuberculosis with mixed infection than are those of simple tuberculosis ; that the latter may quickly be changed into the former when patients must live in an atmosphere laden with infectious germs is scarcely to be wondered at, inasmuch as, according to the above experimenters, three hundred and sixteen out of five hundred and forty-three inoculated pigs (or 58.1 per cent.) were killed by some form of infectious disease, the germs of which were contained in the dust.

Mixed infection is a most important factor in relation to a tubercular patient's condition, whether this arise from without by inhaling the germs of a heavily infected atmosphere, or is the result of an inflammatory process in the lungs. To it may be attributed the sudden and rapid changes for the worse in patients, who were doing well under proper climatic surroundings, after a sojourn of two to four weeks in a large city.

May not the condition of "hospitalism" met with among the internes of the large hospital, and so frequently the precursor of tuberculosis, also be due to the same cause ?

A few words concerning the best means of disinfecting sputum. Fire is unquestionably the very best disinfectant, but patented cuspidors are expensive ; in place of these any cheap material, old pieces of linen, Japanese napkins, or even pieces of newspaper can be used. If such are made use of *they never should be used but once*, then, after being placed in some suitable receptacle, they, with the receptacle, should all be burned together. In a word, nothing into which a patient has expectorated should ever be handled again, and should not be allowed to dry. M. Kirchner[1] has shown, by inoculation-experiments, that sterilization for one-half hour is a thoroughly efficacious disinfectant.

Dry heat (100° C.), however, must be applied for several hours (Schill and Fisher).[2] The same experimenters give their conclusions concerning the disinfecting powers of various antiseptics as follows : Sublimate solutions cannot be considered suitable for disinfection of masses of tubercular sputum. Absolute alcohol gives indifferent results. Equal parts of a five per cent. carbolic acid solution and the amount of daily sputum will destroy with certainty the tubercle bacilli and spores in the sputum.

Delepine and Ransome[3] have shown, by inoculation-experiments, that solutions of chlorinated lime, 1 to 10 and 1 to 100 will satisfactorily disinfect the walls of infected rooms, or bed-linen and clothing that has been infected.

It is to be hoped that formaline will prove an efficient disinfectant owing to its easy applicability and its non-corrosive action upon metals. The most powerful and at the same time freely obtainable agents are the sun's rays and diffused day-light. They can be used by everybody, and have been proven to be the most efficient disinfectant known.

It has been the writer's aim to enlighten the public mind concerning the freedom from danger of contact with tubercular patients, where the necessary sanitary precautions are taken to destroy all sputum. This is shown by the positive proof that, with the exception of one cottage where cause for infection was discovered, all the cottages, the infirmary and public sitting-rooms of a community of eighty tubercular patients were found free from tubercular infected dust.

Since Koch's discovery of the tubercle bacillus and the subsequent proof that it alone is the cause of the wide-spread contagion of tuberculosis, the enforced improved hygienic laws and the dissemination of the knowledge of successful preventive measures have been

productive of good results as shown by the mortality tables of various countries, viz.: In New York State the mortality in 1889 was 120 per 1,000, whereas in 1894 it was only 108.46 per 1,000.

Much more can and will be accomplished within the next few years by education of the public and preventive legal measures; along with our efforts, however, to prevent those who are tuberculous from infecting their fellow-men let us at the same time look out for their well-being and try to save the lives of many of them. How better can we accomplish this than by patterning after the sanitarium where sun-light, fresh air, good food, and out-of-door life, with separate cottages for each group of four or five patients, allow them the best chance of recovery.

On the question of comfort, on the question of pure air, free from all germs of disease, on the question of economy, on the question of hygiene, and finally on the whole question of humanitarian principles, how much better off is the lingering consumptive in the open country or in the mountains than he who is cooped up within four walls of a city hospital with a measured cubic foot of air-space, spending his days and nights in an atmosphere artificially ventilated with air that is already contaminated.

130 West Seventy-third Street.

A CASE OF GENERAL ANALGESIA, WITH SYMPTOMS OF SCLEROSIS OF THE PYRAMIDAL TRACTS AND OF THE COLUMNS OF GOLL.

By PEARCE BAILEY, M.D.,

Assistant in Neurology, Vanderbilt Clinic; Attending Physician to the Almshouse, Workhouse, and Incurable Hospitals, New York City.

The following case, on account of the unusual association of its symptoms, and the absolute and general loss of all sensibility to pain, merits description, although there is no accompanying pathological report, and although any explanation of the symptom complex must be more or less conjectural.

The patient is a man sixty years of age, a carpenter by trade. There is no hereditary taint discoverable, with the exception of a facial tic in a parent. A venereal sore was contracted in early youth, not followed by secondaries. Alcohol and tobacco have been used to excess. The patient was always robust until twenty years ago, when symptoms referable to the nervous system first made themselves felt. These earliest symptoms, which were consequent upon a severe shock caused by falling from a boat into the river, consisted in slight headache, dizziness, impairment of memory, and nausea. The first serious symptom, however, came on twelve years ago, when his left leg became numb and paralyzed for two weeks. This condition soon improved, only to return again a little later. The subsequent improvement in his leg has been incomplete. Six years ago, the right leg became similarly affected, until now one leg is as bad as the other. He was able to continue light carpentering work until one or two years ago, when he noticed that his hands had become too uncertain in their movements to allow him to use the hammer. He would hit his fingers as often as the nail, but these misdirected blows caused him no pain. Thus, one or two years ago, his hands had become ataxic and had lost their sensibility to pain. At the same time he was obliged to use a cane for walking, owing to ataxia and rigidity of his legs.

There has been gradual loss of sexual power; bladder and rectal control unimpaired. Such is the history which the man furnishes. A slowly progressive involvement of muscular power, of muscular co-ordination and of sensibility to pain. No active pains, no trophic disturbances, no loss of bladder or rectum control. A more definite statement of the order of occurrence of the individual symptoms is not obtainable.

The examination of the patient shows us a man of medium frame, fairly well nourished. There is an extensive cicatrix on the back of the neck, the result of a carbuncle six years ago. There is a double inguinal hernia. The thoracic and abdominal organs appear normal, with the possible exception of a slight roughening of the first sound of the heart at the apex. The mental condition of the patient is unimpaired: he is not at all of an emotional or neurasthenic type. His intelligence is such as might be expected in an ordinary carpenter. He can read and keeps interested and informed on the affairs of the times. He has never given any evidences of mental disease.

The ocular muscles act normally, except slight drooping of the left eyelid. The pupils react to light and during accommodation. The left pupil undergoes a relative change in size from time to time. At times it is smaller, and again larger, than the right. The optic disks are somewhat pale, but no atrophy is present. There is no limitation of the visual fields. There is no impairment of smell. The sense of taste is accurate, although at the very tip of the tongue it may not be as acute as in a normal individual. The patient himself has never noticed any gustatory abnormalities. Occasionally there may be observed a slight twitching of the muscles supplied by the right seventh nerve. The motor abnormalities are those ordinarily met with in ataxic paraplegia, where there is a degeneration of the motor tract together with the posterior median columns, and perhaps the cerebellar tract.

The most serious interference with volitional movement is ataxia. It is marked in the hands, and so much so in the feet, that the patient requires two canes in order to walk. This inco-ordination in the legs exists to such a degree that, in executing intended movements, it assumes to a certain extent the character of an intention tremor. There is also a loss of the sense of position in the lower extremities. With closed eyes the patient can with difficulty indicate the position of his limbs.

Associated with these disturbances of motion, there is comparative weakness of all four extremities; while there is no true paralysis, the muscles quickly become fatigued. Under such circumstances, may now and then be observed fibrillary twitchings. None of the muscles are atrophied, and all react normally to faradism. The joints of the lower extremities are somewhat stiff, owing to slight contractures of the surrounding muscles. The gait has the combined characteristics of ataxia with slight spastic paraplegia. Romberg's symptom is well marked. Trophic disturbances are entirely absent, and there are neither secretory abnormalities nor changes in capillary circulation. The wrist, elbow, and knee jerks are active. No clonus. The abdominal and plantar reflexes do not respond to stimulation; the cremasteric react fairly well for a man of his age.

The chief claim to attention which is advanced by the patient consists in the changes in sensation. Tactile sensibility is slightly impaired. Very light touches with a camel's-hair brush are not felt, and the markings of the æsthesiometer are perhaps a little higher than normal. This change, however, is extremely slight; such as it is, it is universal.

Heat and cold are readily differentiated. There is no delay in the conduction of the sensation of touch. The patient can readily differentiate objects of different weights, and also can distinguish between different degrees of pressure. Localization of touch everywhere good. But there is complete loss of the sense of pain in the whole cutaneous surface, in the mucous membranes and conjunctivæ, in the nerve-trunks, muscles, and joints. In no part of the body, from the soles of the feet to the top of the head, can pricking, cutting, or burning elicit any evidences of pain.

Forcible crushing of the muscles and rough hyperextension of the joints produce no sensations other than those of contact and movement. While the patient's attention was attracted in another direction, a needle was thrust into the ulnar nerve at the elbow. Inquiry elicited that the patient felt a "pushing," but no pain. The mucous membranes share in this analgesia. Pricks on the tongue, lips, and inner surface of the cheeks cause no pain. Water, hot enough to be painful to the hands of an ordinary individual, is swallowed by the patient with composure.

Irritation of the posterior pharyngeal wall causes a feeling of nausea and slight reflex. Pressure on the conjunctivæ causes no pain, and there is a slight reflex on the right side only. Strong faradic currents are unable to produce any evidences of discomfort. The sleep phenomenon of Strümpell cannot be produced.

Thus, to briefly resume, the case exhibits symptoms of a slowly progressive spastic paralysis, combined with ataxia, of all four extremities, and an absolute and general analgesia.

The diagnostic possibilities embrace a wholly functional disease, an organic disease to which are superimposed functional sensory symptoms, or a wholly organic disease. Everything speaks against the symptom complex being of an entirely functional nature. Besides the close adherence, as far as the motor symptoms are concerned, to a recognized clinical type of spinal degeneration, the man has been for five years in the Almshouse and is slowly but steadily growing worse. There have occurred neither sudden improvements nor sudden accessions of new symptoms, and I think it can be safely asserted that the motor symptoms at least have an organic basis. Such was the opinion of most of the gentlemen who saw the case at the New York Neurological Society. The hypothesis that the analgesia is a functional addition to an organic disease is unsatisfactory. Hysterical analgesia of the entire cutaneous and mucous surfaces is rarely seen outside of coma; when it occurs as a permanent condition, as in cases reported by Strümpell,[1] Raymond,[2] and others, it is usually associated with changes in other forms of sensation, to which are invariably added other hysterical stigmata, such as anosmia, ageusia, limitation of the fields of vision, etc. General anæsthesiæ have also been reported during the course of psychoses. Krukenburg[3] had such a case (autopsy negative) with nearly complete sensory, cutaneous, and psychic anæsthesia. Berkeley[4] reports a similar condition in which hysteria could be excluded. Berkeley had another case of complete anæsthesia which he attributed to a specific neuritis with central changes in the medulla and cord.

Heyne[5] saw gradually develop, after typhoid fever, a cutaneous anæsthesia which began in the hands and feet, and which became general with the exception of the conjunctivæ, associated with loss of taste and smell, and without limitation of the visual field. This case, resulting in recovery, is rather suggestive of a multiple neuritis.

These cases mentioned, together with articles by Klaatsch,[6] Meynert,[7] Von Ziemssen,[8] and Prescot,[9] comprise the chief references which I have been able to find relative to the subject. The sensory changes in our case are totally dissimilar to those of the cases cited; consequently this analgesia cannot be classed with any recognized form of functional sensory change. The analgesia which has been observed in criminals, degenerates, and the insane, cannot explain the case under discussion, and all the symptoms speak against the presence of a neuritis.

The third possible hypothesis is that both sensory and motor symptoms depend on an organic cause. The motor symptoms unquestionably point to an interference of the conducting power of the motor tracts, of the columns of Goll, and perhaps of the direct cerebellar tract. They constitute a very complete and typical picture of the so-called "mixed sclerosis" or "ataxic paraplegia." If sensation in the head were not involved, the association of symptoms might possibly be explained by the assumption that Gower's tract, which is now generally believed to transmit painful sensations, was destroyed as well. But degenerations of sensory tracts do not result in complete and permanent anæsthesia; and, moreover, the path for sensations from the anterior part of the cranial surface is by the fifth nerve, which is in the pons varolii; although the descending root of the trigeminus reaches as low as the second cervical segment, its complete degeneration was found by Oppenheim,[1] in a case where there was no mention of sensory symptoms.

A case reported by Spaeth[2] resembles the present one more than any in literature. The autopsy revealed a syringo-myelia extending from the first cervical segment to the lumbar enlargement of the cord. There was anæsthesia of all four extremities and the trunk, combined with loss of the sense of position and ataxia. The patient could walk fairly well, and there was but slight loss of muscular power. But in that case sensation in the head and neck was normal. Since in my case sensibility to pain is involved in these parts also, central changes, if they exist, would necessarily be situated in the pons in such a way as to implicate the fifth nerve without seriously infringing upon the oculomotorius.

It would be unwarrantable to assert that a lesion could occur in the pons in such a way as to cause the symptoms of the case which has been described; while such a lesion might cause all, it probably would cause more.

Still another possible explanation would be a primary degeneration of those tracts of the spinal cord, which have to do with muscular co-ordination and movement, to which has been added a lesion of the pons, completely destroying the pain-sense conducting fibres.

Of the three hypotheses, no one is satisfactory. The diagnosis of cases, which have neither clinical counterparts nor pathological proof, must be at best, as stated in the opening line of this paper, conjectural.

All the motor symptoms point to structural changes in the cerebro-spinal axis; and to the assumption that the loss of sensibility to pain is in some way dependent on an organic cause, should be given serious consideration.

6 West Fiftieth Street.

Insufficient Hospital Accommodation in Paris.—It is reported that the strain on hospital accommodations in Paris is so great that of 69,899 applications for admission made at the Bureau Central in 1893, there were 38,689 refusals due to want of beds.

Weigh the Baby.—A valuable means of ascertaining the progress of a child, which is too often neglected, is regular weighing. A child, from birth to six months of age, should be weighed weekly, as by this means, almost to the exclusion of all others, we can tell how the child is developing. During the first week there is generally loss in weight, but by the end of the second week the child should have regained its birth weight, and if there is a gain of less than four ounces weekly, or a stationary weight, we know there is some fault with its nutrition, either in the quantity or quality of the milk which it receives, or its power of assimilation. —Towley.

SOME OBSERVATIONS ON HYDROPHOBIA AND HYSTERO-HYDROPHOBIA. ILLUSTRATED BY TWO CASES.

By F. W. A. FABRICIUS, M.D.,

NEW YORK.

EX-HOUSE PHYSICIAN, BELLEVUE HOSPITAL; ASSISTANT PHYSICIAN, NEW YORK CITY ASYLUMS, WARD'S ISLAND.

Hydrophobia, or rabies, sometimes called lyssa on the Continent, constitutes a disease which is rapidly fading from the medical horizon, due, in a measure, to the recent advances made in prophylactic bacteriology, and in some respects to certain improved regulations in our sanitary code governing the supervision of stray and vagrant animals.

Although the true nature of the exciting factor of this terrible nervous disease remains still a matter *sub judice*, the universal opinion leans toward the fact that it is a germ, whose isolation offers unusual difficulties, possibly belonging to the anaërobiotic variety, whose cultivation and germination can only be effectual after a more or less complete exclusion of oxygen. Essentially it reacts as a bacterium, varying like the anthrax bacillus in resistance to certain chemical reagents while under the influence of attenuation. The character of the poison seems to be of a distinctly proteid nature, inducing, when transmitted into the organism, a characteristic form of acute toxæmia recognized as ptomaine poisoning.

Owing to the infrequent occurrence of rabies in private practice, some members of the profession deny the existence of such a disease, merely classifying it among the symptomatic neurotic disturbances; the researches of the late Mr. Pasteur, however, prove beyond a doubt that it is an acute infectious and contagious disease, with a distinct period of incubation, directly traceable to an infection from subjects dying with the disease, running a definite course, and presenting symptoms of such grave psychical disturbance as occur in no other nervous affection. Of course, cases may turn up where the infection was incomplete and the resistance of the individual very high; it is only natural under these conditions that the general course of the disease is altered, but the etiological factors remain the same.

A good proportion of the so-called cases of hydrophobia result from the bites of dogs, not mad, but simply excited or epileptic; the prognosis in such individuals is generally favorable. But this does not constitute true rabies; here we have to deal with a pathophobia, an hysterical manifestation, whose symptoms at times so closely coincide with those of the ordinary type that the errors in diagnosis must of necessity be numerous; the cognizance of this statement renders the statistics of the Pasteur immunization treatment almost valueless.

The rabic ptomaine chemically bears a striking relation to the snake-poison in certain respects; they differ, however, in important particulars physiologically. The former enters the organism from without as the result of an infection, the latter is produced in the animal carrying it and stored away in the dental canals of the fangs. The striking similarity in action of these two powerful organic poisons will be illustrated in the near future by some interesting experiments as soon as they are completed.

Studying the following two cases side by side, but little difficulty will be encountered in establishing a diagnosis; taken individually, however, considerable doubt might be expressed as to the true nature of the disease.

Case I.—C. A——, twenty-eight years of age, a tinsmith by occupation, entered Bellevue Hospital October 31, 1893, with an every-day history of miasmatic poisoning of rather a mild type. He appeared to be in excellent physique and regular in his habits. The family history was negative. He enjoyed very good health up to three or four days before admission, when he noticed a slight chill followed by a dull, boring headache, considerable pain in the back and limbs, and an uncomfortable feeling of oppression over the precordial region. At night he was restless and uneasy, and considerably depressed. Several grains of quinine only added to his distress, till he was forced to apply for treatment.

On admission to the hospital patient was able to give a clear account of himself, but did so in an absent-minded manner. His countenance was pale, and expressed anxiety and apprehension. The pupils were widely dilated, responding both to light and accommodation. Tongue was coated and tremulous, pulse rapid, full and regular, temperature 99° F. per mouth. Increased patellar reflex and ankle clonus, fine tremor of hands. He was of irritable disposition and seemed quite agitated. Physical examination proved negative beyond a moderately enlarged spleen. The case was looked upon as an irregular type of malaria, and promptly treated with ten-grain doses of the bimuriate of quinine every three hours, with five grains of calomel in the form of tablet triturate at bedtime. A thorough microscopical examination of the blood failed to reveal the plasmodia or malarial pigment, and, as the symptoms augmented in severity, the further administration of quinine was suspended and the symptomatic plan of treatment adopted. During the night he was very restless, dozing off now and then only to wake up with violent starts and jerks. He passed seven ounces of pale clear urine containing a trace of albumin. The pulse toward morning had lost in tension, but gained in rapidity; respiration seemed normal, a trifle heavy. At noon slight cyanosis was noticed on ears, but its presence could not be accounted for after a thorough physical examination. Sensorium began to suffer, and toward evening mental obfuscation became quite marked. During a sponge bath a small red scar was detected on ulnar side of right hand, tender to the touch and surrounded by a small area of inflamed tissues. He complained of sharp, lancinating pains originating at this spot and shooting up the right arm toward the axilla.

The affected area was painted with iodine and the whole arm bandaged up with a wet carbolic dressing, to prevent further extension of the yet circumscribed lymphangitis. A little whiskey with water he swallowed with considerable difficulty, followed immediately by an explosive fit of coughing expelling the fluid through mouth and nose. To allay the increasing restlessness a hypodermic injection of morphine, gr. ¼, and atropine, gr. $\frac{1}{120}$, was administered, which produced little or no sedative effect. He never slept during the night, but only tossed about in an uneasy manner, mumbling incoherently. At times he would point toward the walls and then cover his eyes as if frightened; he thought he saw black figures moving about the room, which threatened to kill him. In order to check this growing mental excitation the hypodermic injection was repeated after the lapse of three and a half hours. At no time had the temperature risen above 99.8° F.; the pulse, however, indicated considerable nervous tension. During the night he vomited several times, which caused so much distress that patient refused all nourishment, which was then administered per rectum. Toward morning the nurse served a little milk in a cup, which he attempted to drink. But no sooner had the fluid touched his lips, when he shook from head to foot, his muscles contracted, respiration ceased abruptly, eyes fixed, widely opened and staring, face cyanotic deepening into purple, larynx elevated as during the act of deglutition, pulled up tightly against the lower jaw in a tetanic spasm. The expression of his countenance at this time appeared so ferocious and hideous that it baffles all description, resembling more a wild beast than a reasonable human being. After thirty-five seconds the muscles suddenly relaxed, the

head fell back on the pillow, and respiration was resumed with a violent puffing out of the retained air, while the perspiration just rolled off his body, completely wetting his bedclothes. Some coffee was then offered to him, but it had hardly touched his lips, when the frightful scene repeated itself in all its details. The distorted features with the bloodshot eyes, the severe laryngeal spasms, and the intense agony depicted on his countenance, together with the inflamed scar, suddenly suggested a diagnosis which had not even been suspected. His friend was instantly sent for, and he stated that about seven months ago patient had been attacked and bitten by a mad dog, which was killed and removed by the Health Department. He readily identified the scar on the hand. Here may be mentioned that the mere sight of fluid did not induce those laryngeal spasms; on the contrary the patient made frantic exertions to drink, the thirst being necessarily severe with such profuse perspiration; after the third attempt he began to realize his position and quietly objected. Later on he was painfully conscious of the effect foods, solid or liquid, produced; the mere thought of trying to swallow would then precipitate an attack.

In the intervals between the paroxysms the anxious, apprehensive look and the mute appeal for help constituted such a spectacle that it will never be forgotten. The spasms now resulted from the slightest irritation, and were always ushered in by a general tremor followed by a stiffening of the muscles without any tendency toward opisthotonos. During a sudden inspiratory effort the larynx jumped up in an instant, and remained fixed in this position from thirty to sixty-five seconds. Sometimes the upper part of the body was jerked upward and forward, the patient seemingly making violent efforts to breathe. Blood-stained foam gathered on his lips, his face almost purplish-black, when suddenly the patient collapsed, utterly exhausted, the foam rolling out of his mouth and the perspiration streaming off his body. The absorptive processes of his organism must have come to a standstill, for within the last twenty-four hours he had received subcutaneously five grains of morphine and one-half grain of hyoscine. Notwithstanding these powerful sedatives the attacks grew more frequent, but gradually lessened in duration and intensity. Chloroform, at first of some use, soon had to be discontinued, owing to the exhausted condition of the heart and the prolongation of the succeeding spasms. His efforts at resistance gradually grew weaker. At times he opened and shut his mouth and gnashed his teeth. Toward evening of the third day he had three slight convulsions, with loss of consciousness during from three to five minutes. The thermometer now registered 102.4° per rectum; pulse ranging from 140 to 210 per minute, very weak, almost imperceptible during a spasm. At no time did he try to bite the attendants, but continually ground his teeth, with foam covering his mouth. During the last six hours his countenance had changed terribly, so that his most intimate friend hardly recognized him. His face was very pale, eyes sunken, and his features completely relaxed. He had another convulsion, and died from respiratory paralysis three days after admission.

The second case presents phenomena which simulate closely the true type of rabies, but differ from this in essential particulars, which, when considered together, at once throws it into the class of hysterias conveniently called hystero-hydrophobia.

Case II.—F. L——, hostler, aged twenty-eight, was transferred to Bellevue Hospital with the diagnosis of hydrophobia. On examination, the patient, a powerful fellow, was found to be struggling severely with four attendants, who experienced great difficulty in controlling his violence. He was shouting and yelling incessantly, while the foam just rolled out his mouth, snapping and biting most viciously at the nearest persons. He jerked and jumped about on the stretcher with almost uncontrollable strength, exposing a deeply flushed face, which with its wild, rolling eyes, dilated pupils, and distorted features, certainly presented a terrifying spectacle. The surface temperature seemed to indicate a considerable expenditure of animal heat, the thermometer registering, however, only 101.5° per rectum. The pulse was full and bounding, of rather high tension and very rapid; respirations appeared correspondingly increased. The highest pitch of maniacal excitement was induced by the mere suggestion of water, which when dashed into his face would instantly precipitate a paroxysm of laryngismus ushered in by a loud scream, followed by a spasm of the glottis, during which the patient threw himself about violently, uttering loud shrieks. These spasms only seemed to last a few seconds, but frequently repeated themselves without the slightest irritation, broken at times by short ejaculations of: "I see them come, help me! They are biting me, hear them not!" etc.

A little milk offered to him in a cup he drank ravenously, with not the slightest difficulty; water, however, almost threw him into convulsions. At times he emitted a hoarse bark and made fierce attempts to bite the attendants. How long this stage of excitement would have continued is impossible to tell; according to reliable information, it had already lasted two hours prior to his admission. A hypodermic of one third grain of morphine and one-fiftieth grain of hyoscyamine was administered, resulting within forty minutes in a deep sleep, from which he awoke after several hours greatly exhausted.

Friends stated that he had been addicted to the regular use of alcohol for the past three months, and that about a week ago patient had been bitten by a dog, which, he supposed, suffered from hydrophobia. Since that time he had lived in constant fear and anxiety, walking about greatly depressed and melancholy, drinking considerably all along. About seven days after the bite, just recovering from a debauch, he suddenly lost all control over himself, said that he was going mad, that he had hydrophobia, etc., till his removal to the hospital became an absolute necessity. On examining the hand, a small lacerated wound was discovered, which had undergone repair in several places. The whole area with surrounding healthy tissue was excised and thoroughly sterilized with the thermocautery, the wound was then allowed to heal up by granulation.

The patient still expressed some anxiety, but calmed down completely by the use of bromides with capsicum and strychnine; he was discharged after an uneventful recovery six days after admission; when examined a year later he was in excellent health and no longer troubled by any fears.

The most important differential points to be considered may briefly be summarized as follows:

1. Direct infection by an animal suffering from or dying with hydrophobia. The rabic poison, contained primarily only in the buccal or nasal secretions, may lie dormant for three days, the animal being apparently well; a bite at this stage will call forth rabies of undiminished virulence. The disease is spread by fomites only by direct inoculation into wound.

2. Distinct period of incubation varying from three to six months.

3. Characteristic clinical history: 1st stage: Prodromal period, two to three days. 2d stage: Melancholia, one to two days. 3d stage: Mania, one to two days. 4th stage: Paralysis, asthenia, one to three days.

4. Termination almost invariably fatal on the fourth to fifth day.

5. Reproduction of the disease by implanting a fragment of the medulla from an animal perishing with rabies into the cerebral cavity of a sound animal, when the characteristic phenomena will show themselves with unerring certainty on the fourteenth day from the inoculation.

6. Violent laryngeo-pharyngeal crisis; spasms of the respiratory muscles, particularly the diaphragm; occurrence of convulsions and delirium; intense nervous prostration; inflammation of the cicatrix with a tendency toward lymphatic involvement; unusual tolerance toward powerful sedatives.

The rabic poison appears to possess a great affinity for the medulla oblongata, and to a less extent for the motor centres in the brain. The violence of the symptoms, the profound nervous disturbance centring on the respiratory nucleus, with the obscure pathologic lesions, so closely suggest tetanus that, were it not for the history of specific infection, the early delirium, and the predominating laryngeal spasms, an absolute diagnosis could not easily be maintained.

SYPHILIS *VS.* TUBERCULOSIS. REPORT OF A CASE.

By R. ABRAHAMS, M.D.,

NEW YORK,

DISTRICT PHYSICIAN TO MOUNT SINAI HOSPITAL; ASSISTANT IN THE SKIN DEPARTMENT OF THE MOUNT SINAI HOSPITAL DISPENSARY.

THE association of two infectious or contagious diseases in one individual at one and the same time, is a fact familiar to every practising physician. Instances of such combinations are plentiful, namely: diphtheria and scarlatina, measles and scarlet fever, measles and whooping-cough, typhoid and pneumonia, etc. On the other hand, a conflict or antagonism between certain infectious or contagious diseases, in the sense that in the soil wherein the roots of one infectious disease are spreading the seed of another infection cannot be planted, or if planted, cannot flourish with perfect impunity to the first, either condition, as yet, belongs to the realm of theory.

In the following case an antagonism between syphilis and tuberculosis seemed to be established:

John K——, a Pole, aged thirty-five, with no knowledge of a family history, but with a distinct recollection of repeated attacks of gonorrhœa, came to this country about five years ago. At that time he enjoyed excellent health. He was engaged as a miner somewhere in the Pennsylvania coal mines, but scarcely worked a year underground when he began to suffer from an annoying dry cough. Thinking that the trouble was caused by the coal dust he went to work on a farm. In a comparatively short time the cough ceased, and he returned to the mines. The cough soon reappeared, and finally he suffered a very profuse pulmonary hemorrhage. The blood frightened him, and he came to New York. When I saw him he was pale, emaciated; the skin was dry; hands and feet cold; appetite very capricious; bowels very irregular—diarrhœa alternating with constipation; intense cough with bloody mucous expectoration; breathing accelerated; some dyspnœa; pulse weak; there were exhausting night-sweats with mild rise of temperature in the evening. The sputa contained abundant bacilli. Physical examination disclosed flatness above and below the right clavicle; subcrepitant and mucous râles and bronchial breathing. Mucous râles were heard all over the chest. The patient was put on creosote. The mode of administering the drug was one I have found to work well, namely, starting with two drops, t.i.d., and increasing the daily dose by one drop, the increased dose to be taken before dinner. The best vehicle is milk, and the best time for taking the medicine, in my experience, is before meals. This patient ran up his dose to one drachm, t.i.d. The good effects of this excellent drug were quite appreciable, the night-sweats stopped, the appetite improved, the cough was less distressing, and the expectoration was less profuse, although the lesion in the lung apparently remained unaltered.

I lost sight of the patient now for about ten weeks, and when he returned he was found to have contracted syphilis. The initial lesion was situated on the glans penis, extending a short distance to the prepuce. The lymphatic glands in the inguinal region were indurated and enlarged, the lymphatic vessels along the dorsum of the penis felt like thin cords. The patient complained of nocturnal headache and rheumatic or lancinating pains in the bones. The general appearance of the patient at the time was not particularly bad, although he claimed that he was rapidly losing health and strength. The chancre, with its associate pains in the bones and headache, yielded nicely to mercurial plaster and iodide of sodium. Eight weeks subsequent to the appearance of the primary lesion I was called in a hurry to see the man at a lodging house. He looked wretched. I was informed that about 4 P.M. he was seized with a violent chill, which lasted nearly an hour. His temperature at 9 P.M. was 104.5° F.; there was a dry and coated tongue; respirations, 30 to the minute; pulse about 120, and weak. The cough was not unusually severe. I prescribed quinine and digitalis. The next morning the temperature was 101° F., the pulse and respiration much better.

In the afternoon the chill was repeated, the temperature rose again, the pulse and respiration followed the same type as that of the preceding evening. The following morning there was the same improvement in the patient's condition as in the preceding morning. On looking carefully over his body, I noticed for the first time a faint roseola on the chest and abdomen. The appearance of the eruption explained to my mind the chill and fever. This systemic disturbance continued for five days; every day the eruption became more and more pronounced and more and more diffused. At the end of this period, the temperature fell to the normal; the eruption then extended almost over the entire body.

The roseola was of the mixed variety, that which is commonly called maculo-papular syphilide. The papules were well defined, sharply outlined, firm, some large and some small. There was an extremely characteristic angina.

Up to this day the treatment consisted in stimulating and nourishing food; from this time on it was rigidly antisyphilitic.

The patient received fifty mercurial inunctions. Very often iodide of sodium was added to the mercury. The only other remedy he took was cod-liver oil. It is needless to state that all the secondary symptoms and the traces left of the primary lesion vanished under this treatment. But what was more wonderful was that, from the very start of the evolution of the secondary period, and all along through this energetic specific treatment, all the signs of consumption, one by one, disappeared. Night-sweats stopped; the evening fever abated; the cough and expectoration became insignificant; the appetite returned; the patient gained flesh and strength; and what is more, at the end of the fifty days' treatment, a physical examination revealed no trace, absolutely none, of existing phthisis; the percussion-note was normal instead of flat; the breathing was normal in place of bronchial; all râles were gone, the sputa failed to show bacilli, so that as far as I could see, the man was cured of his tuberculosis. I kept him for a couple of months under observation. Occasionally he required a dose of iodide, but I could not see any need for treating anything but syphilis. The patient to-day is in Poland.

Occasionally I hear from him that he enjoys the best of health.

The case has seemed to me of surpassing interest, and for that reason I have entered into the history with more minuteness than is usual with reports of such cases.

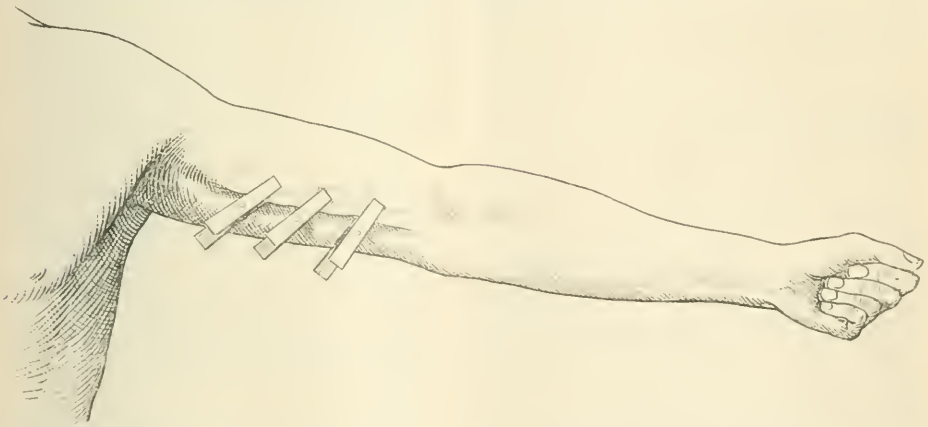
156 CLINTON STREET.

A RARE ANOMALY OF THE BRACHIAL ARTERY.

By EUGENE R. CORSON, B.S., M.D.,

SAVANNAH, GA.

A NEGRO, about fifty-five years of age, presented himself at my office for some slight ailment. His appearance of great age led me to examine him carefully. His hair was perfectly white, his face much wrinkled, the arcus senilis well marked, and the artery at the wrist evidently atheromatous. The temporal artery was sinuous and hard, and the pulsation very noticeable. The heart-beat was forcible, and the heart-sounds pronounced, but without any murmur. He complained of a strong pulsation in the left arm, which directed my attention to the brachial artery. To my surprise, I found it to be subcutaneous and outside the deep fascia. From its origin at the lower border of the teres major to the bend of the elbow, it could be picked up between the fingers and compressed, stopping all circulation in the forearm and hand. It was markedly atheromatous. I happened to have some spring-catch clothes-pins on my table, and with them I easily caught up the vessel and controlled the circulation. I made the accompanying rough sketch. The brachial on the



right side was normal. The arteries in the lower extremities seemed to be in their places, though atheromatous.

The man was intelligent and was more certain of his age than most of his race, and he assured me he was not over fifty-five years of age. He certainly looked as old as his arteries, and was evidently a marked case of premature senility. As I have shown in my paper on "The Vital Equation of the Colored Race," arteriosclerosis and atheroma are common with them; nowhere have I seen such striking pictures of senility in the comparatively young.

This anomaly of the brachial artery must be a very rare one, as I have not succeeded in finding any mention of it in the literature on the subject. As is well-known, the bifurcation of the brachial high up into the radial and ulnar is not uncommon, nor its swerving from the inner border of the biceps toward the inner condyle of the humerus to curve around a prominence of bone, and then finally to pass outward, through or beneath the pronator radii teres to the bend of the elbow.

In the large work of Bourgery, Paris, 1834, there is figured a radial and ulnar artery outside the deep fascia, with the brachial in its normal position. This does not seem so remarkable, however, as where the larger vessel has jumped the track. It has therefore seemed to me worthy of mention.

115 JONES STREET.

Surgical Suggestions.

Fractures.—In the case of a fracture near a joint there is generally a double injury. The joint is damaged more or less by the same force that fractures the bone. We have then not a simple fracture, but a fracture plus a sprain, and therefore in the ordinary methods of treating these cases the fracture is treated well enough, but the sprain is neglected. Rest alone does not cause ankylosis, but if the sprained joint be put up in plaster for some weeks, it will take as many weeks of massage to make it useful. The two injuries should be treated simultaneously.—MILLER.

A separation of the epiphysis of the femur can occur without giving rise to many definite signs or symptoms, and, on the other hand, may be serious enough to necessitate active surgical interference. It appears to be good surgery to remove a piece of the bone if the parts cannot be approximated, and there is no danger of arrest of development incurred thereby. There does not seem to be any callus of consequence thrown out when the fracture has been reduced and it is probable that immediate union takes place.—ELSNER.

The factors entering into the limitations of motion after intra- and extra-articular fractures are: First, bad positions of the bony fragments, within or without the joint, the direct result of injury; second, bony outgrowth, exostosis, the result of inflammatory processes following the injury, whether arising in the reparative callus or not; third, other inflammatory changes, mostly the formation of firm bands, both within or without the joint, including the filling up of fossa with fibrous deposits; fourth, the obliteration of the tendon surface of muscles moving the joints.—CARMALT.

Goitre.—Kocher has now nine hundred cases which have been operated upon in one hospital, and in none of them has cachexia strumipriva ever occurred, except in a single case where after extirpation of half of the goitre, the other half proved to be atrophied.

Burns.—1. Fresh, superficial burns, as well as deep ones, can heal under antiseptic treatment without the production of pus. 2. If pus is produced, the wound is disinfected, and the course remains the same as if non-infected. But if the pus is of long standing and the wound begins to granulate, then disinfection is not possible. 3. To disinfect widespread burns an anæsthetic will often be necessary, and to this end chloroform is best suited. 4. If the wound is non-purulent, the unnecessary use of an antiseptic hinders the healing process. 5. Antisepsis is the best analgesic. 6. Burns heal rapidly under the antiseptic treatment.

Burns of the second degree require eight days; of the third degree, from two to three weeks. 7. Burns of the second and third degree heal without trace remaining; of the fourth degree, cause a scar, which does not retract, while this will be smoother the less the amount of pus.

Cleaning Rusty Instruments.—Broder gives the following as an effective method of cleaning rusty instruments. Fill a suitable vessel with a saturated solution of chloride of tin in distilled water, immerse the rusty instruments and let them remain over night. Rub dry with chamois after rinsing in running water, and they will be of a bright silvery whiteness.—*Journal of the British Dental Association.*

Abortive Treatment of Gonorrhœa is not too late if the slight secretion is hardly colored and more mucoid than purulent; if the margin of the meatus is not swollen and but slightly tinted with an erythematous redness.—Diday.

Indications for Operative Interference in Gall-bladder.—1. In cases of repeated attacks of biliary colic, apparently due to gall-stones, which, not yielding to medical treatment, are wearing out the patient's strength. 2. In perforation from ulceration. 3. When there is suppuration in the neighborhood of the gall-bladder set up by gall-stones. 4. In empyema of the gall-bladder, which is usually accompanied by peritonitis. 5. In dropsy of the gall-bladder. 6. In obstructive jaundice, when there is reason to think that the common duct is occluded by gall-stones.—Robson.

Deaths Under Chloroform.—Two deaths from chloroform anæsthesia have recently occurred in Berlin, in both of which there were heart lesion, which might have been recognized during life.

Changes in the Blood in Syphilis.—In 1889 Semmola advanced the following propositions: 1. Constitutional progressive syphilis not treated with mercury causes a diminution of hæmoglobin and of red corpuscles. 2. If a syphilitic person in whom this diminution is observed is treated with mercury from the first day of treatment, there is an increase of hæmoglobin and of red corpuscles. 3. If, however, the mercurial treatment is continued longer than necessary, so that the mercury loses its specific power, its toxic action will produce a diminution of hæmoglobin and red corpuscles. 4. If mercury is given a healthy subject, there appears to be a rapid diminution of hæmoglobin and red corpuscles. Justus comes to the following conclusions: 1. In untreated syphilis the hæmoglobin is more or less diminished, and this diminution varies with the severity of the disease and its tendency to spontaneous recovery. 2. A sudden diminution of hæmoglobin follows inunction or injection of a large dose of mercury. (This is directly contradictory to Semmola's statement.) 3. The diminution caused by mercury varies according to the severity of the disease and to the condition of the nutrition; with injections of mercury the fall of hæmoglobin can be repeated after several injections. 4. The cure of the syphilitic lesion begins when the fall of hæmoglobin ceases, and is followed by a rise. 5. The sudden fall of hæmoglobin due to mercurial treatment is a specific peculiarity of the blood of syphilitic persons only, and does not take place in healthy individuals, or in other diseases. 6. This specific reaction of the blood is established at the time when swelling of the gland occurs; it disappears at the time when the existing syphilitic lesions attain the height of their development. Justus concludes that a specific change occurs in the blood of syphilitic persons, and this points to a specific means of treatment applicable only to the blood of syphilitic individuals. This specific condition of the blood, established by the action of mercury, precedes the affection of other organs, and the disappearance of this specific reaction, or the involution of the specific blood change, occurs before retrograde changes appear in other organs. If syphilis is not treated the evolution of the fall of hæmoglobin, and also the slow increase of the same afterward, are seen; if the disease is treated the fall of hæmoglobin is greater and more sudden, and the rise is also quicker. The cure by mercury is in all cases not absolute, but only varies according to the duration of time. The application of the above statements to the diagnosis is as follows: In doubtful cases, and in cases of late syphilis with a fresh train of symptoms, a diminution of hæmoglobin, after inunction or injection of mercury, is characteristic of syphilis.—*British Medical Journal.*

Aortic Aneurism.—After a thorough *résumé* of this subject the author concludes that aneurisms of the thoracic aorta may be most safely attacked, after medical treatment has failed, by the introduction of a small quantity of inelastic wire. Abdominal aneurisms may first be explored through a celiotomy wound, so as to determine their exact nature and relations, after which the question of treatment will depend on their situation. It may be impossible to use other means than that pointed out for the thoracic variety, or the other methods of temporary or permanent ligation may be resorted to, according to the conditions revealed by the exploration.—Bristow.

Anæsthetics.—Gurlt continues his statistics upon the use of anæsthetics in the German clinics, and reports on a collection of five years, with 1 death to 2,909 cases for chloroform, and 1 death to 6,004 cases for ether. But there is also to be charged to the ether a certain number of deaths from pneumonia, which is especially likely to be fatal after laparotomy.

Appendicitis.—Relapsing or recurrent appendicitis is marked by periods of inflammation similar to the primary attack, and recurring at longer or shorter intervals. It exposes the individual who suffers from it to peritonitis by perforation or without it, and in the intervals he is never free from danger. The etiology of the disease is not clear. The recurrent attacks seem at times to be favored by mechanical causes—foreign bodies, adhesions—but the immediate cause of the inflammatory process is unknown. The only curative treatment is excision of the appendix.—Challiol.

Cancer.—In a case where the bone has become involved, secondary to cancer of the breast, Aikmann obtained decided relief of pain by the administration of salicylate of sodium, in doses of ten grains, three times a day. Large doses of opium had been given in vain.

Erysipelas.—

℞ Potass. iodidi,
Tinct. ferri chloridi,
Syr. aurantii ..... āā ℥j.
Aq. puræ ..... ℥iij.
M. Sig.: One teaspoonful in water four times a day.

To Prevent Rust.—One per cent. of common baking soda put into the water in which instruments are boiled, in order to sterilize them, will, to a great extent, if not totally, prevent rusting.

Cause of Varicocele.—There are three principal causes: First.—Anything that impairs the general vigor of the part, as: 1, Lack of proper support from relaxed scrotum; 2, masturbation; 3, abuse of venery, ungratified desires, etc.; 4, chronic orchitis, or repeated attacks of acute orchitis. Second.—Anything that produces pressure, as: 1, Abdominal tumors; 2, enlarged inguinal glands; 3, hernia; 4, trusses, or belts worn around the waist; 5, accumulation of fat in the omentum and mesentery. Third.—Anything that produces prolonged muscular effort, as: 1, Prolonged riding on horseback; 2, prolonged rowing; 3, prolonged exercise in running or waltzing; 4, excessive and violent muscular effort; whooping-cough, sometimes.—Rand.

Varicocele.—Varicocele occurs on the left side in a proportion or ratio of 20 to 1. There are four good reasons for its frequency: 1. The left testicle hangs lower in the scrotum, and thus the veins support a heavier column of blood. 2. The spermatic veins of the left side are pressed by the sigmoid flexure of the colon when distended. 3. The spermatic veins of the left side join the renal vein at a right angle to the current of blood, thus impeding the rapid return of blood from the left testicle and veins. 4. The left spermatic vein is by some authorities stated to be poorly supplied with valves.—RAND.

Multiple Warts of Face.—

Sulphuris sublim.	ʒ v.
Glycerini.	ʒ jss.
Ac. acet.	ʒ ijss.

S. Apply locally to each wart. The warts dry up and then drop off. The treatment may be continued for several days.

—KAPOSI.

Slipping of Obstetric Forceps.—If the forceps slips when properly applied it means that the case is not adapted for delivery with forceps; *i.e.*, the forceps is contraindicated, and its further use will result only in doing harm. Fenestrated forceps blades slip just as badly as do solid blades, if the head is too large: any forceps will slip if it does not fit the head. If the forceps slips while strong traction is being made, the child's skull will surely be fractured. If the child must be born head first, because version is impossible, and if forceps cannot deliver, the cephalotribe is the best instrument for obtaining a hold on the head firm enough to accomplish delivery. Oscillation will cause advance when straight traction fails.—TUCKER.

Anal Fissure.—Several cases of anal fissure were treated with pure ichthyol applied with a brush twice daily, and also after each defecation. The cure was rapid in every instance. The same treatment is recommended in the case of fissures of the vulva and vagina. —WILLIGEN.

Abortion.—Threatened abortion should be treated by absolute rest, with opium or *viburnum prunifolium*. Where hemorrhage occurs without dilatation of the os and cervix the antiseptic tampon is indicated. When hemorrhage is present and a finger can be inserted the uterus should be emptied by the finger, accompanied by antiseptic irrigation. If the hemorrhage is considerable and only partial dilatation is present, the finger is the safest instrument to complete dilatation. In many cases, if the patient be kept clean, the membranes and placenta will be expelled without interference and without injury. In all cases ergot should be used in daily doses during the first week. The use of the sharp curette is not encouraged. Vaginal douches after abortion should be given for positive indications only.

—JACUB.

Chloroform Collapse.—Stretch the sphincter ani with thumbs or speculum. (Suggested by Dr. Daily, *New York Medical Times*, February, 1893, for morphine narcosis.)—DUKE.

Anal Fissure.—Palliative:

℞. Ext. bellad.	gr. ¼ to ½.
Cocaine hydrochl.	gr. ¼ to ½.
Ol. theob.	gr. x.

For a suppository to be used half an hour before an enema is given.

—ADLER.

℞. Ext. conii	ʒ ij.
Ol. ricini	ʒ iij.
Ung. lanolin	ad ʒ ij.

Apply to parts before and after passage.

—CRIPPS.

Rectal Hemorrhage in Women.—Elevate extremities and pelvis for twelve to twenty-four hours. Remove hemorrhoids with the wire écraseur after paralyzing the sphincter.—BROWN (of Stoneham, Mass.).

Hemorrhoids.—Sitz-bath and washing with water at 120° to 130° F. Insert into anus cotton tampon wet with two per cent. cocaine before and after stool. Dilate with Trélat's two-bladed speculum. Extirpate only as a last resort.—RECLUS.

Rectal Abscess.—Early free incision under anæsthesia, irrigate with 1–5,000 mercuric solution, introduce finger and break down bridges, loculi, etc., inject peroxide of hydrogen, divulse sphincter with dilator.—MATHEWS (*Mathews's Medical Quarterly*).

Strychnine nitrate, gr. $\frac{1}{40}$, as a muscular tonic in labor.—RUSSELL.

Ether Administration.—Use a Clover inhaler, but get a larger air-bag than is usually supplied. It is easiest to get good anæsthesia by rotating the reservoir until the indicator reaches the figure 2 until patient is under, afterward keeping it midway between 1 and 0. The quantity of ether is less, but the resulting anæsthesia is complete.—FREEMAN (*Bristol Medico-Chirurgical Journal*, September, 1895).

The Porte-Caustique should be kept most scrupulously clean—the nitrate of silver stick washed each time after using.

Electro-magnet applied over the arm detects, by a sticking pain, the situation of a needle embedded nearly a centimetre in the subcutaneous fatty tissue.—ULRICH (*Hospitals-Tidende*, ii., 35).

Nose-bleed.—Apply on the end of a sound wrapped with cotton a three per cent. solution of trichloracetic acid. A twenty per cent. cocaine solution can be added to prevent pain.—COZZALINO (*Journal de Méd. de Paris*).

Migraine.—Each night for a long time fifteen grains of salicylate of soda in coffee.—MÖBIUS (*Ther. Monats.*, ii., 1895).

Suppurative Adenitis of the Groin.—1. The operative field is shaved and rendered surgically clean in the usual manner. 2. A few drops of a four per cent. solution of cocaine are injected beneath the skin where the puncture is to be made. 3. A straight sharp-pointed bistoury is then thrust well into the most prominent part of the tumor until pus flows. 4. All of the pus is forced out through this opening by firm but gentle pressure, as this procedure is, as a rule, very painful. 5. The abscess cavity is irrigated with pure peroxide of hydrogen until it returns particularly clear. 6. It is then irrigated with 1 to 5,000 bichloride of mercury solution, all of which is carefully squeezed out. 7. The now thoroughly cleansed abscess cavity is completely filled, but not painfully distended, with ten per cent. iodoform ointment by means of an ordinary conical glass syringe, previously warmed in hot water. 8. A cold wet bichloride dressing is applied with a fairly firm spica bandage, the cold congealing the ointment at the wound, and thus preventing its escape into the dressing.—FONTAU.

Mixture for Local Anæsthesia.—The following mixture is given for local anæsthesia, applied as a spray:

℞. Chloroform	10 parts.
Ether	15 parts.
Menthol	1 part.

The anæsthesia resulting from the application lasts about five minutes.—LE GERANT.

In Good Old Days.—Dr. Lauder Brunton used to relate that when he was the secretary of the ——— Medical Society he discovered by the old records that one evening had been given in that society to the discussion of the subject: "Did Adam Have a Navel or Not?" and another to the question of "Eve's Physiology while in Paradise." Our medical societies today are less speculative and more practical.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 28, 1895.

THE PAST AND THE FUTURE OF THE MEDICAL RECORD.

IN closing another of the many volumes of the MEDICAL RECORD we take the usual opportunities for noting the part which the journal has taken in chronicling the history of medicine throughout the world during the period terminated by the present issue. Although this comprises but half the year, the occasion may warrant a general reference to the work of 1895 with the completion of the two volumes published during that time.

Notwithstanding no great discoveries have been made there has been substantial progress along the new lines of thought and study made possible by previous original investigations. In every department there has been a healthful and conservative effort to conscientiously verify preconceived opinions, on the one hand, or to modify them, on the other. Without desiring to disparage the great advances constantly being made in surgery, we are more than pleased to acknowledge that medicine proper is rapidly gaining in the race for those more distinctive and more substantial triumphs so long monopolized by her twin sister. The study of bacteriology in connection with the hitherto unknown causes of many medical diseases and the promising future of sero-therapy will tend to keep alive anticipations that can scarcely be too extravagant for any possible realization.

In attempting to review in detail the reasons for such general statements we feel that we would be going over ground already covered by all such as have attentively and studiously read the MEDICAL RECORD. To refer, even in a casual way, to the number of articles published, the variety of subjects treated, the multitudinous and widespread sources from which they have emanated, and their practical and timely characters, would occupy unnecessary space, and be a useless reiteration of well-demonstrated facts. The credit side of the account in such matters is given in our Index. Therein is shown not only what has been published in these columns during the past six months, but what has been done by all the notable workers in this country and elsewhere. We may safely venture to say that there is hardly a topic of any practical character in any of the departments of medicine or surgery which has not been noticed either in full as special contributed material or in abstract from similar articles in other journals, domestic and foreign.

In keeping with this desire to chronicle the broad and impartial history of progressive medicine in every line, we have aimed to give each branch its due attention in the hope that no man, whatever his special work may be, can fail to find in the MEDICAL RECORD something that may interest and instruct him, and make it worth his while to read and profit by a professedly cosmopolitan journal.

The success of the MEDICAL RECORD as shown by a subscription list far larger than any in this country, and equal to that of the leading foreign journals; its influence as an exponent of advanced medical opinion; its careful verification of facts before presentation; its impartial judgment on all matters affecting the true and honorable relations of physicians as a body; its disposition to give the humblest and most obscure contributor an audience in the interests of truth and fair play, and its freedom from any commercial benefits other than those that centre upon the business prosperity of a thoroughly independent journal, have abundantly proved that such a periodical managed for the profession and by the profession has abundantly vindicated its right to exist and to continue.

We trust also that it may not appear unbecoming in us to refer to the readers of the MEDICAL RECORD, scattered as they are over every country throughout the civilized world, and to say that we are proud of our friends and of their practical appreciation of our efforts. They compose an audience worthy of our highest endeavor, not only workers themselves, but keenly alive to the work of others. It is the common experience of writers for its columns that more earnest correspondence is invited concerning articles written and ideas advanced than is possible through any other legitimate medium. The writer from Oregon thus reaches the reader in Arabia, and the questioner from New York may receive answers simultaneously from Patagonia, Japan, or Siberia.

It will also interest the many friends of the MEDICAL RECORD to know that its circulation has increased so greatly that it is no longer possible to print it from type. To maintain its high standard as a medical newspaper its forms have to be kept open each week until the last moment and then printed in the most expeditious manner.

To meet the requirements thus made necessary we shall, beginning with the new year, set the type for the MEDICAL RECORD by machine and electrotype the pages as fast as they are made up. These electrotype plates will then be transferred to modern perfecting presses and the whole large edition run off between six o'clock on Thursday evening and daybreak of Friday. As soon as the last form begins to come off the press it is rapidly tranferred to the bindery in lots of one thousand for folding and wiring.

It should be known and appreciated that while the issue of a weekly medical journal of anywhere from 5,000 to 10,000 copies is comparatively a simple matter, only a printer and binder can thoroughly understand the difficulties which have to be overcome in getting out practically in about twenty hours an edition so large as that of the MEDICAL RECORD. With the great changes we have referred to, however, the MEDICAL RECORD will be able still to maintain its position

ahead of all competitors in the promptness of its issue; furthermore, they insure the printing of the paper every week from absolutely new and perfect type plates.

The MEDICAL RECORD will thus be, we believe, the only medical journal in the world printed from electrotype plates and on modern newspaper perfecting presses. It marks an epoch in the literature of medicine of which the profession in American may well be proud, for to their liberal support and appreciation of the efforts of the editor and publishers it is due. Nor can we omit our grateful acknowledgments to the local medical journals, many of them most ably edited and worthy of the generous support of their constituency, for the uniformly kind and hearty endorsement they have accorded the MEDICAL RECORD.

With an editorial staff comprising a number of learned and able men, with large experience and long training, and medically educated reporters of exceptional merit, with special correspondents established in most of the leading centres of medicine in the world, with an unstinting expenditure in every direction when possible results may seem to justify, it is hoped still further to merit the approval of the profession.

HOW EXPERT TESTIMONY COULD BE MADE VALUABLE.

THE recent case of Hannigan, who was adjudged insane on a trial for murder, committed to an asylum, and subsequently declared perfectly sane by the asylum superintendent, emphasizes the absurdity of the present system of expert testimony. We do not pretend to offer any opinion as to the real guilt of the slayer, whether the act of shooting in cold blood was, under the strong provocation of the case, justifiable or not, but simply to refer to the apparently inappropriate character of the plea for the defence. We simply note the fact that the plea, based on the opinion of experts, evidently had no foundation in fact. It is beyond question that such was due entirely to the confusion created in the minds of the jury by the degree and character of the swearing of those scientific gentlemen who were engaged to do the best for their respective sides. It is easy to see how questions concerning strictly scientific probabilities can be so ingeniously framed as to bring out telling facts in support of any medical or legal theory, and yet not in the slightest degree affect the real honesty of the answers, nor ostensibly impugn the proper motives of the witnesses. It thus frequently happens that trials based mainly on the theories of experts become a travesty of justice, and by technically overruling conservatively qualifying circumstances defeat, the real end in view, obtaining "the truth, the *whole* truth, and nothing *but* the truth." Hence there appears more ground than we are first willing to admit, for the oft-repeated assertions that experts can be made to swear to anything to contradict each other, and to prove opposite probabilities. Even the so-called intelligent jury, hemmed within the boundaries of legally admitted testimony and barred by the rulings of what is judicially considered "irrelevant, incompetent, and unnatural;" are as likely to go wrong as right in arriving at a just verdict.

Under such circumstances there is no need of argument to prove that it is absolutely impossible to obtain strictly impartial testimony. On former occasions we have frequently suggested a remedy for such acknowledged defects in our medico-legal systems in the creation of a commission of experts that should be strictly impartial, should take testimony for both sides, should properly reconcile apparently conflicting opinions, and should directly advise with the court on all the essential points involved in a given case. We take this occasion to reiterate our views on this subject, needing no better text for their earnest advocacy than the one which has just presented itself.

EARLY RISING AND INSANITY.

THE great poets of the world have always sung in praise of sleep:

"—— sore labor's bath,
Balm of hurt minds."

They have always consistently opposed the habit of early rising, except in so far as they have depicted (writing by the light of the lamp) the glories of the morning and the suggestive promises of a beautiful sunrise. The Scriptures are also on the side of prolonging slumber:

"Yet a little sleep, a little slumber, a little folding of the hands to sleep," says Solomon.

But the habits of modern civilization and the traditions of family life have been steadily set against these poetical and scriptural ideals. In whatever else men differ, or in whatever other way they err, it is agreed that the habit of early rising is seemly, advantageous, and necessary.

The statement, therefore, by a prominent alienist and superintendent of a large insane asylum, that early rising promotes insanity, comes with a terrible shock upon the serenity of established beliefs and long-cherished customs. Dr. Selden H. Talcott, of Middletown, N. Y., however, supplements this statement of his by arguments of no mean weight. He calls attention to the relative frequency with which farmers, their wives, daughters, and sons become insane. The cause of this has heretofore been thought to be their isolated lives, their hard work, and perhaps the excessive use of pie and potatoes; yet these have never seemed quite adequate explanations, when one considers the fact that the farmer has constantly fresh air, abundant exercise, no undue excitement or mental strain, and relatively little alcoholism and syphilis. So that Dr. Talcott's view is, at least, a helpful one, in the way of explaining the psychopathic tendencies of the ordinary agriculturist. He states that the excessively early hours of rising, which are customary among the farmers, and which hours are imposed upon their sons and daughters and wives, prevent a sufficient amount of rest. Growing children, he thinks, in particular, suffer from 'the artificial cut off' which is applied so rigidly to their lives.

The suggestion of Dr. Talcott is valuable from another point of view, because the particular cause of in-

sanity to which he refers is one that can be so easily and comfortably combated. It is not like the enforced abstinence from alcohol, and tea and tobacco, high thinking, and all the other ordinary comforts or luxuries of civilization. The diminution of insanity by staying in bed later mornings is a task to which all will address themselves with pleasure, and we believe that every farmer's boy will have a sense of particular kindness toward the physician who has discovered this new method for preventing possible mental disorders. We might readjust the well-known lines of Sir William Jones, for the benefit of the farmer, somewhat as follows :

> " Eight hours to sleep, to soothing pleasures seven,
> Nine to the farm allot, and all to heaven."

THE TREATMENT OF CHRONIC PROGRESSIVE RHEUMATISM.

This condition, commonly known as rheumatic gout, arthritis deformans, and rheumatoid arthritis, is far more distressing to the patient than it is interesting to the physician. As a potent cause of many kinds of suffering, however, it is raised of necessity to a position of dignity, and one worthy of careful study. A little paper by Cantagrel, in *Médecine Moderne*, October 16, 1895, emphasizes the importance of certain well-known facts and brings into view others less generally recognized. Rheumatic gout or chronic progressive rheumatism is a disease of general nutrition and thus differs widely from acute articular rheumatism, now believed to be an infectious process. It occurs at all ages, in all climates, though its most marked influence appears between forty and sixty. Women suffer more often than men. Heredity, direct or indirect, is a powerful factor in its production. It is found in families where there has been gout, phthisis, or Bright's disease, and is called into activity by damp and cold, by exposure and hardships, by overwork and strain. The first necessity is perfect hygiene : warm clothing, flannel next the skin, woollen sheets, and possibly a change of residence and also of climate. Diet must be arranged to suit special requirements. Above all, the patient must not be forgotten in the study of the disease. Massage and rubbings with alcohol are of service.

Of remedies, cod-liver oil is the best, together with iron, arsenic, and the iodo-tannic wine of Nourry. For pain, antipyrin, salol, salophen, and colchicum are of chief reliance. Charcot gave large doses of alkalies combined with quinine—thirty or forty grammes daily of bicarbonate of soda for weeks at a time. Between the intervals of acute painful attacks general nutrition should be improved by means of iodides and arsenic. This is the only real treatment, this improvement and modification of nutrition, and it should be begun early and continued late for a very long time, indefinitely. The iodo-tannic wine of Nourry possesses special advantages. Tannin acts as a powerful tonic and enables the stomach to assimilate readily the dose of iodine. Arsenic does not always give such good results, for it sometimes increases the pain. To obviate this difficulty M. G. de Mussy has devised a plan of arsenical baths, to be used upon the subsidence of acute symptoms. One to eight grammes of arseniate of soda and one hundred or one hundred and fifty grammes of bicarbonate of soda are dissolved for each bath. At the same time tonics are administered—quinine, iodide of potassium, or vin de Nourry. Baths seem to be of benefit because of their heat; hot mud baths are equally serviceable. The writer Cantagrel considers that this very hopeless disease is not without hope : iodide inwardly, arsenical baths outwardly. Pain may be made to disappear at the end of two or three weeks. Deformity and stiffness, under the influence of the internal iodide and the external arsenic, together with the prudent use of massage and rhythmical movements, cannot be expected to show much improvement earlier than three or four months. It must be remembered that rheumatic gout (chronic progressive rheumatism) is a condition that is partly degenerative and partly inflammatory. It is possible to arrest it and prevent acute attacks.

News of the Week.

No Medical Commissioner of Charity.—Mayor Strong has declined to appoint a medical commissioner of charity, a political laymen having been given the position. His Honor very significantly says : " I am *still* a reformer."

A Change of Heart.—Our esteemed contemporary, the *Medical News*, for some time of Philadelphia, is to remove its editorial offices to this city on the first of the year, thereby showing its appreciation of the great fact that there is but one medical centre in this country, and that the metropolis. Under date of July 27, 1895, à propos of the temporary removal of another Philadelphia journal to this town, the *Medical News* remarked : " We learn with regret that our most esteemed contemporary, the *Medical and Surgical Reporter*, in order to be nearer the printing-office of its new publisher, has moved its editorial offices to New York. We are sorry that business reasons should *force it to exchange the Medical atmosphere of its life-long home for one of such uncongenial surroundings.* It is indeed true that the footings of our clearing-house transactions do not equal those of our self-complaisant *sister city*." We are surprised that our esteemed contemporary's views have so changed in five short months that it will even come away from the printing-office of its publishers in order to breathe the congenial atmosphere of this centre of medical thought and activity.

The Harlem Medical Association Dinner was held at the Harlem Casino, December 21st. Dr. Samuel E. Gibbs presided in " Quaint Club " style and deftly joined to the speeches the following members : Drs. Malcolm McLean, Charles A. Clinton, Thomas H. Manley, Edward Fridenberg, M. C. O'Brien, E. Clark Tracey, Emil Mayer, A. H. Leary, John Shrady, F. M. Nye, Richard Van Santvoord, W. M. Leszynsky, and Ferdinand C. Valentine.

Prevention and Cure.—An ounce of soap is worth a pound of pus.

A Case of Quadruplets.—Dr. Frank A. Stahl reports in the *Journal of the American Medical Association* of December 14th, the history of a case of quadruplets. He gives with it a very striking picture of the babies, side by side, James, Patrick, Bridget, and Catherine. They are all nice-looking babies, but, unfortunately, they were born dead. The children were all born between three and six o'clock, and the labor was natural. The mother is thirty-three years of age, had had six children, all born alive but one; she had had no previous multiple births. Dr. Stahl says that a case of quadruplets occurs but once in three hundred and fifty thousand to four hundred thousand births.

Airol is a drug which is said to be an improvement upon dermatol, bismuth, iodoform, etc. It is a compound of bismuth, gallic acid, and iodine; a green powder, tasteless, odorless, and insoluble.

United States Marine Hospital Examinations.—There will be held at Washington, D. C., on February 10, 1896, a competitive examination of candidates for appointment to the position of Assistant Surgeon in the United States Marine Hospital Service. Candidates are required to be not less than twenty-one years of age, and no appointment is made of any candidate over thirty years of age. They must be graduates of a reputable medical college, and furnish testimonials as to character. Successful candidates, having made the required grade, are appointed in order of merit as vacancies arise during the succeeding year. There is at present one vacancy. The salary of an Assistant Surgeon is $1,600 per annum, together with furnished quarters, light, and fuel.

Fuller information may be obtained by addressing the Surgeon-General of the Marine Hospital Service, Washington, D. C.

A Diplomatic Doctor to Increase the Ranks.—The Nicaraguan Legation in Washington, D.C., has been closed. The Nicaraguan Government revoked the credentials of Dr. Horatio Guzeman as its diplomatic representative to the United States, and he at once closed the legation.

The Wilhelm Meyer Memorial.—The death of Professor Hans Wilhelm Meyer, of Copenhagen, has been followed by a movement of a somewhat unusual character. It has become a matter of history that Dr. Meyer was the first to actually recognize the condition known as adenoid hypertrophy at the vault of the pharynx, to warn against its dangers, and to propose the means for its prompt and effective cure. The result of Dr. Meyer's teaching has been to bring urgently needed relief to many thousands of children in every civilized country in the world, and it is safe to say that there is no man of our time to whom the present generation owes a deeper debt of gratitude. It is proposed to erect a memorial statue to Dr. Meyer in Copenhagen, from small nominal subscriptions to be collected from the patients and physicians who have been benefited by Dr. Meyer's work. An international committee, consisting of one representative from each of the principal countries of Europe and from the United States, has been organized abroad, the representative in each case being the president of the national laryngological or otological association of his respective country, an he is authorized to effect such local organization as may seem expedient. The representative of the United States is the president of the American Laryngological Association, under whose direction the establishment of a national committee is being rapidly perfected.

The College and Clinical Record will be hereafter known under the name of *Dunglison's College and Clinical Record*; a Monthly Journal of Practical Medicine.

Nitrites in Infective Diseases.—Dr. Petrone, an Italian physician, finds that rabbits live twice as long after having been inoculated with rabies, if they receive hypodermic injections of nitrite of sodium. He has used the same substance in syphilis and other infectious diseases, and thinks that it has a power against infections.

Obituary.

SAMUEL FLEET SPEIR, M.D.,

BROOKLYN, N. Y.

Dr. Samuel Fleet Speir, of Brooklyn, died at his sanitarium, 162 Montague Street, in his fifty-seventh year. His illness had lasted nearly a year, beginning with cancer and ending with blood-poisoning, inflammation, and hemorrhage of the stomach. He had been confined to his bed only two weeks. Dr. Speir was the son of Robert Speir, a leading merchant in this city fifty years ago. His mother was Hannah Fleet Speir, a lineal descendant of Captain Thomas Fleet, of Northport, L. I., who was a son of Sir Thomas Fleetwood, of the British navy, and dropped the second syllable from his name when he came to America and settled at Northport, in 1650. Dr. Speir was born in the old Fleet mansion, at Fulton and Gold Streets, on April 9, 1838. In 1857 he entered the medical department of the University of New York, and was graduated three years later with high honors, carrying off the Mott gold medal and the Van Buren prize, and also the Wood prize from Bellevue Hospital. After his graduation he passed eighteen months in professional travel in Europe, and on his return, under the direction of the Sanitary Commission, he went to the front with three assistants and rendered valuable service in the Army of the Potomac.

Among the best known works from his pen are "Use of the Microscope in Differential Diagnosis of Morbid Growth," and "New Method of Arresting Hemorrhage by the Use of Artery Constrictor." His essay on the last-named subject won him a prize from the Medical Society of the State of New York. He was a member of the American Medical Association, the New York State Medical Society, the New York Pathological Society, the Kings County Medical Society, a fellow of the New York Academy of Medicine, and a member of the New York Journal Association. He served by invitation as a member of the International Medical Congress in Philadelphia in 1876. He was the surgeon of the Brooklyn Eye and Ear Infirmary as far back as 1864, and had been identified with the work of the Brooklyn Hospital for the last twenty-five years. He was Demonstrator of Anatomy at the Long Island College Hospital, and was the founder of the Dispensary of the Helping Hand. Dr. Speir was an enthusiastic sportsman and a great lover of dogs and horses. He was the founder of the Robins Island Gun Club, which was organized in 1881. He was married to Frances S., a daughter of Peter A. Hegeman of this city, in 1869. She and one daughter survive him.

Progress of Medical Science.

Surgical Scarlet Fever.—Dr. McGraw reminds us that surgical operations render children exceedingly susceptible to scarlet fever. In a résumé of the subject in Warren's recent work on "Surgical Pathology and Therapeutics," numerous high authorities are cited to substantiate this assertion. Sir James Paget, Horsley, Thomas Smith, and others describe cases of this character. Smith, indeed, in forty-three cases of lithotomy in children, had the operation followed in no less than ten by an outbreak of scarlet fever. Warren concludes that "a certain number, and probably a majority of cases of so-called surgical scarlet fever are cases of genuine scarlatina." In Guy's Hospital, in 1879, four cases were observed in succession under the care of different surgeons, and in consequence thereof operations on children were temporarily postponed. In that hospital, during a series of years, nearly thirty cases of scarlatina were observed in children after operations, and Goodheart, after careful investigation, has no doubt of the correctness of the diagnosis. Hillier remarks that in the hospital for sick children, of the children who contract scarlatina, a very large proportion have been the subjects of a surgical operation within a week before the rash appears. Although the evidence in support of these views is overwhelming, there have nevertheless been many doubters as to the specific character of the disease in these cases. Hoffa, a German authority, quoted by Warren, has attempted an analysis of the cases reported, and divides them into four types :

1 Cases followed by a vaso-motor disturbance and characterized by a transient erythema of urticaria. 2. Toxic erythema, due to absorption from recent wounds. These are transient in character and vanish within twenty-four hours. The absorption of antiseptics, such as corrosive sublimate, may cause some of these eruptions. 3. Eruptions due to profound septic intoxications. These are various in kind and irregular in character. They may last for several days. 4. Cases of genuine scarlatina.

Dr. McGraw reports a case which might readily be considered one of surgical scarlet fever. A boy, fifteen years of age, was seized on February 15th with symptoms of appendicitis and was operated upon on the 19th. The operation was successful, and no septic symptoms appeared throughout. On the 23d scarlatina made its appearance, from which he died on March 1st. The autopsy showed that death did not occur from septic poisoning or from any abdominal complication. The value of this history is in the demonstrated fact that this case of surgical scarlet fever, in the person of a lad who was said to have had scarlatina before, did not originate in septicæmia or pyæmia. There was not one of the three physicians who were present at the autopsy who was not surprised at the entire freedom of inflammatory material exhibited by the abdominal cavity. Putting aside those cases of septic eruptions in which the evanescent and partial character of the rash and the absence of other symptoms make the diagnosis easy, the author doubts whether the so-called surgical scarlet fevers ever differ in nature from those termed idiopathic. He is fully in accord with Sir James Paget, who insists upon the specific contagion in these cases, notwithstanding the fact that the somewhat disorderly appearance of the symptoms in surgical cases has led to the belief that they are not genuine scarlatina. A grave responsibility rests upon the surgeon in these cases. A mistake in diagnosis, or a belief in the non-contagious character of the disease, will tend to spread it broadcast in the family and in the community.—*Archives of Pediatrics.*

Diet in the Etiology and Treatment of Diseases of the Skin.—An interesting discussion on this subject took place at a recent meeting in England (*The British Medical Journal*). Dr. Allan Jamieson directed attention, first, to the articles of food known to influence skin diseases; secondly, to the maladies of the skin which could be produced or modified by diet; and thirdly, to dietetics as a means of treatment in dermatology. Some articles of food produced their effect at once, as in the example of shell-fish, and these acted probably by toxic conditions of the blood, though there was the remarkable and unexplained factor of idiosyncrasy which came into play. But far more frequently the action of foods was slow and prolonged, and their precise mode of action was even more difficult of explanation. Referring to certain articles of diet, Dr. Jamieson thought that alcohol seemed to produce a too ready penetrability of the skin, as witnessed by the liability to sweating and the clammy fingers of topers. Alcohol was not liable to produce skin diseases, but it certainly aggravated some disorders. Second in importance only to alcohol comes tea, and it has been shown that tea when taken too hot, too strong, and in excess causes cold hands and feet and a shrinkage of the integument, in addition to gastro-intestinal disturbance. Dr. White, of Boston, has shown that strawberries and other fruits containing acid in abundance are liable to produce eczema. Persistent omission of green vegetables from the dietary causes relaxation of the cutaneous vessels, and in extreme cases scurvy. It had long been known that persons presenting a pallor of the surface and other evidences of mal-nutrition and deficient food are predisposed to eczema. As regards the diseases of the skin influenced by diet, certain of them could be at once eliminated, such as parasitic diseases, scleroderma and most hereditary disorders, herpes zoster, and some others. But there remained a large number which are undoubtedly so influenced. Eczema could be produced and modified by unsuitable diet, drinking large quantities of cold water, and other articles. Dr. Jamieson mentioned hurrying over breakfast as a predisposing cause of the disease in school children. Psoriasis was aggravated by alcohol, and he had seen this disease invade the surface more rapidly under the administration of this article. The influence of diet on lichen planus had not been fully investigated, but this disease often arose in overfed, obese women. Boils were undoubtedly sometimes due indirectly to diet, although the disease was essentially a local one. A sudden change from a poor to a luxurious diet, or *vice versâ*, was capable of producing the malady. Acne is very often associated with a spare diet, such as that which school-girls were encouraged to take. Lupus is often associated with a distaste for fat. The cause of the increase of cancer during the last half century, as shown by Heath's statistics, was ascribed by Yeo to the increased consumption of butcher's meat, but he thought it ought rather to be ascribed to the undoubted increase in the consumption of tea. He thought that the abuse of this article during the period of growth was the cause of the increase of cancer. The subject of diet in treatment was a very large one. Very different diets were called for in the various diseases, always allowing for idiosyncrasy. Alcohol and the regulation of animal food-stuffs were the most important. The latter, which contained iron, were very important for the treatment of the anæmia which often accompanied acne and other skin affections.

Dr. Walter G. Smith said that we have no certain knowledge of the real action of diet on conditions of the skin. It is difficult enough to trace the action of drugs, and still more difficult in the case of foods. The influence of diet in skin diseases was, he believed, much less important than is generally thought, and after all it might be best to adopt the rule that what most people eat agrees with them most, and what a healthy person finds appetizing agrees with him best. There are, however, three ways in which food may per-

haps influence skin conditions: 1. By lowering the general nutrition—*e.g.*, in scorbutic and purpuric conditions, and those due to a parasite which finds in lowered vitality a more suitable condition for growth and multiplication. 2. Reflex condition—*e.g.*, from stomach to skin, as in over-eating or taking unsuitable food. These conditions were brought about either by a vasomotor or a purely nervous mechanism. Urticaria and nearly all such skin conditions are known by their transitory character. They may be dealt with by a visit to Carlsbad, but may equally well be treated at home by purgatives, a good cook, and regulating the quantity and kind of the diet. 3. Toxic conditions of the blood—*e.g.*, the effects of tinned or unwholesome foods, and the hyperæmia of the skin produced by full doses of alcohol. It must not be forgotten that the skin is the avenue for the elimination of certain substances—*e.g.*, copaiba and other oleo-resins, and highly seasoned foods, which are liable to produce erythematous rashes. Turning next to the different diseases of the skin, Dr. W. G. Smith thought they might be grouped into three classes: 1. Cutaneous diseases acknowledged to be influenced by diet, such as the erythemata, acne rosacea, and perhaps acne vulgaris. 2. Diseases which might possibly be influenced by diet, such as psoriasis and some cases of eczema, though he had never been able to satisfy himself that eczema was ever affected by diet. 3. Cutaneous diseases, which are certainly not produced or modified by food—*e.g.*, herpes and lichen ruber. The effect of diet on leprosy had never been satisfactorily proved, nor, in his experience, had boils ever arisen or been modified by dietetic conditions. The fact that people now consumed one hundred and thirty-six pounds of butcher's meat per head per annum, as compared with forty-six pounds formerly, had been advanced as a cause for the increase of certain diseases; but he would point out that men probably consumed three-fourths more meat (and alcohol too) than women, and he would like to ask whether these diseases were three-fourths more common in the former. As regards salt meat, which was held to be so bad for skin diseases, he had given it to his skin patients without harm. Alcohol, undoubtedly, might sometimes increase the itching and congestion of the skin; but in reference to its supposed effect in producing skin diseases he would point out that the Parsees in India were not exempt from such maladies. If the skin disorder were secondary to diabetes, gastric or other derangements, these, of course, must be treated; but as long as practitioners differed so widely and so oppositely it was impossible to believe that diet had any important effect on the skin condition itself. By way of summary Dr. W. G. Smith stated his belief —(1) that very few skin diseases were directly produced by food (though diet may aggravate some already in existence); (2) that the diseases so arising are always erythematous and transitory; (3) that diet has no influence on the cure of skin diseases, even of acne; and (4) that the only practical rules necessary are to exercise moderation and temperance in all things, and especially in alcohol, to regulate the bowels, and to cure the anæmia if present.

Dr. Radcliffe Crocker agreed with Dr. W. G. Smith in thinking that the influence of diet had been exaggerated. He thought that salt meat and some other unwholesome articles acted chiefly by producing gastro-intestinal catarrh. The cooking and mode of preparation were even more important than the article. As regards the effect of alcohol, it differed widely in the different forms of alcohol; thus beer and port wine might do harm when well-diluted spirit would do good. Boils sometimes occurred in states of lowered vitality, sometimes in very healthy persons.

Treatment of Advanced Cases of Phthisis.—Dr. Otis summarizes the therapeutic agents which are best calculated to alleviate the lingering sufferings of the last stage of phthisis. He calls attention to the frequent presence of sepsis, and holds that all treatment in these cases must be symptomatic. The diminished lung capacity necessitates an airy room, in which sunlight is required as a tonic antiseptic. Feeding is a difficult question; in bad cases there must be frequent administration of easily or partially digested food. Pepsin, charcoal and bismuth tablets may be of much service. Malt and creosote, with cod-liver oil in the absence of fever, should be given, and alcohol is to be used freely. Fever should not be treated unless causing unpleasant symptoms; inunction of guaiacol reduces the temperature very effectually, but is severely depressant. Rest in bed, with light nourishment and a glass of cognac half an hour or so before the expected rise, has a favorable effect on the temperature. Antipyretics (of which phenacetin and sodium salicylate appear the best) should be employed if at all to prevent the rise of temperature rather than to lower it after it has risen. Sweating is best controlled by agaracin in doses of $\frac{1}{12}$ grain and upward; it is free from the after-effects of atropine. The distressing cough is due partly to the presence of material in cavities, partly to the irritability of the mucous membranes of the upper air-passages. That from the latter cause can be much alleviated, as Dettweiler has pointed out, by establishing a habit of self-restraint in the patient. Medicinally, codeia in one per cent. solution is the best agent. The morning paroxysm of coughing is necessary for expectoration of the products accumulated during the night; it can be shortened and at the same time made easy and effectual by administering a glass of some warm alkaline drink with a little brandy or rum in it. Cough from catarrh of the upper air-passages is often relieved by local applications. Vomiting may result from digestive disturbances or laryngeal irritation, and will require different treatment in each case. The various pains from which the patients suffer are best relieved by painting equal parts of glycerine and guaiacol over the affected area. Pleuritic pain at the base of the chest should be treated by strapping, as suggested by Roberts. Diarrhœa, when septic, indicates salicylic acid or naphthol; when due to tuberculous ulceration, opium and bismuth, with an astringent; this form requires careful dieting with peptonoids or peptonized milk. Hæmoptysis calls for the same treatment as in early cases; Darenberg recommends the application of ice to the testicles or vulva for five minutes twice a day. Insomnia may be relieved by light nourishment or a little stimulant at bedtime; if these fail, trional or chloralamid are the most satisfactory hypnotics. Œdema of the lower extremities can only be alleviated by position, gentle friction with alcohol and water, and wrapping the limbs in cotton wool. The mouth and lips should be cleaned with an alkaline wash. The anæmia calls for iron whenever it can be borne. For the cardiac debility strychnine is invaluable.—*The British Medical Journal.*

Recent Observations on Carcinoma of the Stomach.—Dr. Klemm summarizes his opinion on the subject as follows: 1. The treatment of these tumors differs in no respect from that of cancer elsewhere. It is purely surgical. 2. Operation is to be recommended when possible, before the tumor is palpable. 3. Examination should only be made under deep narcosis, and an exploratory incision made if required. 4. Those cases only should be recommended for resection of the pylorus where the tumor is freely movable, and there is no metastatic involvement. 5. If these conditions are not present, the formation of a fistula between the stomach and jejunum is indicated. 6. This operation should not be delayed until the patient is nearly dead of hunger, and the knife then used as a last resource, for the mortality is then much greater. Langenbuch has subjected three patients to total extirpation of the stomach for extensive carcinoma. Of these one only,

a woman of fifty-eight, survived. In this case the portion removed represented seven-eighths of the stomach. The pylorus was stitched to the remains of the cardiac orifice, making a cavity about the size of a hen's egg. Fearing lest the sutures might give way, the new stomach was fixed in the abdominal wound by passing behind it a piece of iodoform gauze; the rest of the abdominal wound was closed. The operation lasted one hour and a half. Milk was given in the evening, and meat on the third day. Convalescence was rapid, and cure was accomplished in three weeks. Levy describes an operation which he has devised for removing the œsophageal extremity of the stomach in cases of malignant disease. So far, the operation has been performed on cadavers and dogs only. The brief outlines of the operation are: 1. Incision through the abdominal wall, beginning in the middle line at the ensiform cartilage and extending to a finger's breadth below the navel, which is passed on its left side, and from this extremity of the wound a second incision is carried at a right angle through the right rectus muscle. 2. Isolation of the cardia by cutting through the adjacent portion of the lesser omentum and applying double ligatures to the arteria and vena coronaria ventriculi sinistra. 3. Isolation of the lower part of the œsophagus after dividing the serous covering around the cardia with scissors. 4. Excision of the cardia and union of the cut surfaces. The œsophagus is divided, a portion at a time, and united to the stomach wound as it is cut. Without this precaution the divided end of the œsophagus disappears in the foramen œsophageum, and suture is then scarcely possible. Rosenheim confirms the conclusions as to the presence of lactic acid not being a pathognomonic sign of cancer. He found it only in fifty-five per cent. of all cases. Lactic acid, therefore, is an inconstant phenomenon, this acid existing for a time, after which it subsides, to reappear later on. Lactic-acid fermentation disappears more particularly as soon as the motor functions of the stomach are markedly improved, which is the case especially after performing gastro enterostomy.—*The Hospital.*

The Dangers of Murphy's Button.—A compilation recently published, of several cases where the intestine was united by the Murphy button, gives interesting data as to the practical effect of this appliance. In one case, where death occurred with symptoms of obstruction, the opening of the button was plugged with hardened fæces. In another, the button was removed by a second operation from the *proximal* side of the anastomosis. Again, death occurred from intestinal gangrene at the site of the button, possibly from the manner in which it was applied (too close approximation of the edges) or its extreme size and weight. In another case the button was found on the proximal side of the end-to-end resection at the autopsy. In two cases of gastro-enterostomy the button was found after death in the stomach—one patient living ten days, the other two to three months. It is evident from the above that the danger of retention of the button is a real one, notwithstanding the successful cases reported. Its principal claim is that it can be applied rapidly, which is true. This will restrict its use to those cases where the most rapid operation possible is indicated, where speed is required at all hazard, and other risks must be ignored on account of the limited time at the disposal of the operator on account of the condition of the patient. The button itself is an appliance which should be properly made, and the technique of its application thoroughly understood. There can be little question that the use of the larger Murphy button is, in the hands of most operators, safer than anastomoses by suture in cases where the condition of the patient renders haste necessary. But, on the other hand, it is for just this class of cases that the anastomoses by absorbable plates—the bone plates of Senn, or the vegetable plates advocated by Dawbarn—have been devised. Anastomosis by these plates takes very little more time than by the Murphy button, and has the advantages of providing a free opening, and of being free from the danger of remaining on the proximal side of the anastomosis as a foreign body in the stomach or intestine. Again, the danger of producing pressure gangrene of the opposed edges is greater in a mechanical appliance of the size and weight of the button, and its unyielding metallic catch will allow no relaxation of its grip, if once too firmly made. Over the lateral or end-to-end anastomosis by suture alone, the plates have the advantage of greater ease and rapidity of application, a fact which renders their use the method chosen in the majority of cases which fall into the hands of the average surgeon. To recapitulate, then, although we must admit that when the patient is capable of sustaining a long operation and the surgeon possesses exceptional skill in dealing with these cases, anastomosis by suture is the ideal method; for the majority of cases, in the hands of the average surgeon, Senn's plates are to be preferred. The use of the Murphy button has been shown to possess inherent disadvantages which should restrict its use to those cases in which it is necessary to hasten in order that the patient may survive the shock of the operation.—*The Boston Medical and Surgical Journal.*

Analgesic Action of Bicarbonate of Soda in Digestive Disorders—Dr. Linossier claims that a diagnosis of hyper-acid dyspepsia, made by the fact that bicarbonate of soda relieves the distress after eating, is entirely erroneous. He asserts that this agent may afford relief in other conditions than hyper-acidity, and gives the following as his opinions: 1. If a gastric crisis following a few hours after meal is relieved by large doses of bicarbonate of soda, it does not follow that the distress is due to hyper-acidity. 2. The analgesic action of this drug may be used in most cases of gastric crisis occurring regularly some hours after meals, even when the train of symptoms or gastric analysis eliminates the possibility of excess of hydrochloric acid.

The drug is best given just before the usual meal time, in doses of from 0.50 to 2 grains, and may be repeated if the sedative action is only short-lived. The same rules are to be followed in the treatment of cases due to hyper-acidity, save that the dose is less, though there need be no hesitancy in increasing it if the calmative effect is not produced. It will be found advantageous in most cases to dissolve the salt in very warm water, the excitomotor action of the water accentuating the effects of the salt. The author insists on the fact that the cases amenable to soda are those recurring periodically toward the end of digestion. The latest cases are, in general, the ones most easily cured. Those occurring immediately after meals, or that are continuous, are not relieved, as a rule. Among the digestive disorders produced some time after meals may be mentioned the insomnia of dyspeptics. In many cases radical relief is obtained by the ingestion of 4 to 8 grains of the bicarbonate four or five hours after the last meal, as Glenard has already remarked. In some patients, unfortunately, the salt rapidly loses its effect and, though the doses are quickly increased, it is only efficacious for a few days. In others, again, it can be used indefinitely with good results.—*Medical Review.*

Genito-urinary Complications Due to Influenza.—Dr. Lamarque has recently studied this class of complications. According to him, the poison acts very often on the kidneys. (*The New York Medical Journal.*) In the simplest cases there is a somewhat intense inflammation of the glomeruli, with slight albuminuria, which lasts for several days and then disappears without leaving any traces, and without modifying the progress of the disease. In other cases, fortunately much rarer, it produces serious nephritis, which from the start exposes the patients to symptoms of renal insufficiency, and death from uræmia may be very rapid.

However, the nephritis of influenza is recovered from in the majority of cases; but it may also pass into the subacute or chronic state. M. Lamarque says that there may be two forms of nephritis in influenza, the hemorrhagic and the albuminous. In the first form hæmaturia is the first symptom; in the second form acute Bright's disease, with albuminuria and a more or less extensive œdema, is observed. Fiessinger, says the writer, was the first to describe grippal nephritis, and in his work on grippal infection he admits the existence of transitory inflammation of the glomeruli with albuminuria, of acute hemorrhagic nephritis without œdema, and of acute Bright's disease. The renal complications of influenza have been studied also by Leyden, Diard, Turoche, and others. Comby and Le Gendre have published observations showing that grippal hæmaturia may be due to simple fluxion. The bladder may be the seat of congestive symptoms, according to Fiessinger, which manifest themselves by a frequent desire to urinate and by trouble during micturition. There is sometimes hæmaturia, and it may supervene independently of any application of blisters. According to Comby, cystitis may be persistent, but usually it disappears at the same time with the influenza. Fenwick has observed atony of the bladder rather frequently, especially in subjects whose bladders have been very much distended during the height of the disease. This author also insists on the relative frequency of catarrh of the prostatic portion of the urethra, with neuralgic radiations. These symptoms are also observed among women.

Gottschalk has seen uterine hemorrhage supervene on the first or on the second day in influenza, accompanied by lumbar and sacral pains and by dysuria. The uterus was tumefied, softened, and very sensitive. This author also admits the existence of an infectious metritis. The hemorrhages last for five to eight days. Influenza predisposes the patients to puerperal infection, and suppurative symptoms may also set in during pregnancy. Abortion and premature delivery have also been observed during the later epidemics of influenza, and this is attributed to the cough and to hyperthermia. These two factors, says the writer, may have an influence in certain cases, but it is certain that the congestive troubles directly produced by the influenza play a very important part. As, on the other hand, congestion cannot explain the symptoms of suppuration and of septicæmia, we must attribute them to infection. The hemorrhages depend on acute endometritis, and they may occur in women who have undergone ablation of the Fallopian tubes and of the ovaries. With regard to puerperal infection, it depends on the streptococcus. Lesions of the testicle are not very rare, and they may or may not be coincident with urethritis.

The Meaning of Casts in the Urine Without Albumin.—According to Dr. Bremer, of St. Louis, a person who constantly or periodically passes urine containing casts, even without albumin, or perhaps with albumin in chemically demonstrable quantity, is not in good health. Such a person has a damaged constitution; his kidneys are, to say the least, vulnerable, and he is prone to contract and to succumb to other diseases. The irritative process which gives rise to the formation of casts may not amount to an actual state of inflammation, and there may not be the recognized signs of fully developed kidney-disease, and yet the subjective symptoms may be very pronounced. These symptoms are often unaccountable to the attending physician because sufficient importance is not attached to the presence of casts in the urine of such persons. In a number of cases periodic, intermittent albuminuria is the feature, and the albumin is in evidence only when a nerve-storm of unusual severity has set in. Such patients may be considered to have vulnerable kidneys. For a long time such patients may not present any albuminuria, the casts only being demonstrable; or even these may disappear, and the urine be absolutely normal; yet there is a dormant pathological condition which may be aggravated into activity. The diagnosis of vulnerable kidney may be doubted by other physicians. Aside from examinations which are based on chemical analysis exclusively, there are several reasons why the search for casts may be negative: First, microscopical incompetency; second, the kidney trouble may have become latent and the casts may be really absent; third, insufficient instrumental equipment—the centrifuge should always be used; fourth, the examiner, even if he find casts, may not attach any importance to them if unaccompanied by albuminuria. Among other reasons why the presence of casts in the urine is alleged to be compatible with perfect health is the finding of them in the urine of athletes after great muscular exertion. The athletes presenting this condition were certainly damaged men. The symptoms produced by this vulnerable kidney range over the neuroses, particularly neurasthenia, inexplicable gastro-intestinal manifestations and grip symptoms, megrim, and other forms of periodic headache.—*Medical Review.*

Experiments on the Gall-ducts and the Liver.—Dr. Nasse, of Berlin, has studied the effect of extirpation of the gall-bladder. Guinea-pigs and rabbits were unaffected. He was unable to corroborate Oddi's results, namely, that dogs after removal of the gall-bladder suffered great hunger, diarrhœa, and emaciation; that later there also developed a dilatation of the gall-ducts. None of Nasse's dogs showed these symptoms or condition. He also ligated single branches of the hepatic duct. This caused an hypertrophy of those hepatic areas where the biliary currents were unobstructed. In the ligated portions small areas of necrosis were found, also proliferation of the gall-ducts and an increase of connective tissue. Rapid atrophy of hepatic cells and shrinking of the affected lobe occurred. This change was complete in four months. The lobe then consisted of fibrous connective tissue and gall-ducts. In cases where the obstruction of the ducts was temporary, the development of ducts and connective tissue was checked, when the ducts became again patent. Even liver-cells regenerated after extreme degeneration.—*Boston Medical and Surgical Journal.*

Diagnosis and Treatment of Perforation of Gastric Ulcer.—Barling remarks that the incidence of perforation of gastric ulcers does not in the least degree correspond to their locality. A large majority of the ulcers occupy the posterior surface and lesser curvature, a few the region of the pylorus, and a still fewer number involve the anterior surface of the stomach; whereas, ulcers on the anterior surface perforate with great frequency, those on the posterior surface rarely in proportion to their actual number, while those on the lesser curvature perforate comparatively often (*University Medical Magazine*). The explanation of this varying tendency is found, first, in the fact that ulcers on the posterior surface and, to a lesser extent, those on the lesser curvature, as they advance tend to become adherent to adjacent parts, while those on the anterior surface, because of greater mobility, rarely form adhesions; and, secondly, because the symptoms of ulcers on the anterior wall of the stomach being less marked than those of ulcers situated elsewhere, the subjects of these are less often aware of their presence, and are more apt to be careless regarding the quality and quantity of diet, whereby the ulcer is subject to undue stretching and traumatism which may result in perforation. In considering the diagnosis, the previous history usually points to the stomach as the seat of lesion. Perforation usually takes place when the stomach is full or partly so, when the patient is in a more or less vertical position, and frequently after some particular act or exertion—stooping, sneezing, or lifting of some heavy weight. The moment of perforation is

usually marked by sudden acute abdominal pain, producing at times faintness, or even collapse or death. Occasionally there may be slight vomiting. The abdominal walls retract and the muscles become rigid; respiration is usually thoracic, quick, and shallow; the temperature subnormal; the pulse quick and feeble. The symptoms now ensuing depend upon the position of the ulcer, the degree of distention of the stomach, and the position the patient occupies. The extravasating material may spread widely into the peritoneal cavity, causing intense and rapidly spreading peritonitis, and death usually in from twelve to seventy-two hours; or it may remain for a time localized between the stomach and liver, eventually escaping from there into the generally peritoneal cavity, causing at first shock, which passes off; and when septic peritonitis ensues from further leakage death occurs, usually in four or five days from the time of the seizure; or, finally, the extravasating material may remain localized under the diaphragm, and produce a subphrenic abscess. In such a case, after the shock passes away, there ensues a period during which the symptoms are so slight as to almost make one doubt the accuracy of the diagnosis. Then follow the general symptoms of pus-formation and the local signs indicating a gas-containing cavity below the diaphragm. Following these may come symptoms of septic invasion of the thorax—pleurisy, empyema, pneumonia, or lung abscesses. As fully ninety-five per cent. of all cases left to medical care die, the only treatment that offers any hope of recovery is operation. Of thirty-seven cases operated upon, thirteen recovered, but he does not suppose that one-third of all the cases have been saved, as many unsuccessful ones have probably not been reported. Meet collapse by maintaining horizontal position, external warmth, enemata of warm fluids and stimulants, and morphine hypodermically; nothing by the mouth. If operation be declined, must depend upon recumbency, absolute rectal feeding, and morphine. If operation be determined upon, there must be a sufficient delay to allow of recovery from shock. The wound in the stomach is to be closed by Lembert sutures without excision of the ulcer, and is to be followed by irrigation of the abdominal cavity. If a subphrenic abscess forms, it is to be evacuated by an incision into it as directly as possible.

Diagnosis of the Pneumonic Form of Acute Pulmonary Tuberculosis.—Drs. A. Fränkel and G. Troje state this to be a rare form of the disease. It may begin with a chill, as croupous pneumonia, or be more insidious, or with a series of lesser chills. The fever soon becomes atypical, more or less remittent or intermittent, which latter sign is a certain diagnostic point to distinguish it from croupous pneumonia. Some patients present labial herpes. The pulse is always moderate, and respiration less disturbed than one would expect from the lesions. Instead of dyspnœa and cyanosis, there is an increasing paleness of the skin and mucous membranes. On auscultation, signs of considerable infiltration of even a whole lobe, thus simulating a croupous pneumonia. Besides pronounced bronchial respiration, extensive crepitation is observed. The most posterior portions of the lung, and generally the lowest lobe, are the favorite sites of predilection. During the course of the disease the dulness may clear up without signifying an actual resolution, for râles are still present. A complete or partial resolution may at times occur. The expectoration is characteristic of pneumonia, in the majority of cases; tenacious, clear, and translucent; in a few cases it is rust-colored, while in others it presented a grass-green coloration which Traube states to be characteristic; hæmoptysis may also be present. Tubercle bacilli are found in the majority. Albuminuria is very rare. Ehrlich's diazo-reaction is both of diagnostic and prognostic importance; it was very pronounced in all the fatal cases, but was absent in those that recovered. Delirium was observed now and then, even in non-alcoholics. Where the affections begin acutely and the expectoration is lacking, or pneumonic and no bacilli can be demonstrated, diagnosis is impossible. If it last for some time, then the following points will be of value: Lack of a typical or final crisis, frequent absence of dyspnœa and cyanosis, together with the early pallidity, the green color of the expectoration, and the presence of tubercle bacilli. The diazoreaction in the urine from the commencement; rapid loss of strength and emaciation. The prognosis is very unfavorable.—*New York Medical Times.*

The Blood Alterations of Ether Anæsthesia.—According to Dr. J. Chalmers Da Costa: 1. Etherization produces a marked diminution in the hæmoglobin of the blood. 2. The red corpuscles and the hæmoglobin are especially affected in blood previously diseased, in such conditions, for instance, as anæmia. 3. Irregular reports are due to faulty observation, to the presence of altered hæmoglobin in the blood, to the faulty aberration as to color of a Fleischl instrument, or to taking the blood before anæsthesia is completed. 4. The white corpuscles show irregular changes which are not characteristic, and exhibit variations not more pronounced than would be found in the same number of samples of normal blood on different examinations. 5. Age does not apparently influence the results. 6. Ether pneumonia may be possibly due, in some instances at least, to the action of intense cold on the lungs, produced by the action of ether vapor. 7. Œdema of the lungs may arise from contraction of the pulmonary capillaries, thus producing a loss of *vis a tergo* and damming up of blood in the veins. Furthermore, the same condition may produce sudden paralysis of the heart. 8. The often-quoted observation as to the effect upon the hæmoglobin of shock and hemorrhage requires enlarged repetition upon human beings before the statements can be accepted that hemorrhage causes a great fall in the amount of hæmoglobin, but that shock does not affect it. 9. The chilling of the blood-stream may be responsible for the nephritis that occasionally follows etherization. 10. Prolonged anæsthesia profoundedly deteriorates the blood and strongly militates against recovery; hence rapidity of operation is most desirable.—*Medical News.*

Treatment of Vaginismus.—Dr. Madden states that he has based his treatment of vaginismus on certain reasons, and has found it most successful in these cases, viz., first, the employment of constitutional nerve sedatives and tonics to allay the general neurotic condition; and, secondly, the application of local nerve-stretching to the affected parts. On the latter point he briefly recapitulates the steps of the local procedure which he has proved the efficacy of, and which he would, therefore, venture to recommend to other practitioners. First, then, the patient, properly prepared for an antiseptic vaginal operation, and the rectum and bladder evacuated, is to be etherized and placed in the ordinary left lateral semi-prone position; secondly, a large-sized bivalve vaginal speculum is to be introduced, and the blades then fully expanded; thirdly, a tampon of antiseptic cotton or wood wool, saturated in boroglyceride, is to be passed in through the speculum, so as to fill its calibre from the vulva to the roof of the vaginal vault; fourthly, the speculum, still widely expanded, is to be forcibly withdrawn, so as to overcome the contractility of the parts, and at the same time thoroughly stretch, or even slightly rupture, the affected nerve-fibres. In so doing, some little abrasion of the vaginal walls may possibly be occasioned; but any hemorrhage therefrom will be sufficiently controlled by the tampon, on which counter-pressure should be made during removal of speculum, so as to retain the included plug in the vagina, where it may be left for at least twenty-four hours, and then, at the same intervals, replaced by

other antiseptic tampons, which should be employed for the next week to maintain the patency of the passage. Immediately after removal of these tampons the vagina should on each occasion be thoroughly flushed out with some antiseptic injection. Finally, if at the end of a week any evidence of vaginismus or spasmodic contraction should still remain, then the same procedure may be again repeated, after which it will probably be found that the passage has regained its normal sensibility and capacity. In some exceptional instances that curative result may not be thus obtainable, and in such cases it may possibly become necessary to resort to the removal of any specially hyperæsthetic tissues in the vulva vaginal area, or else to some of the recent modifications of Sims's or Emmett's operations for vaginismus. These procedures will, however, be comparatively seldom required by gynecologists, who may adopt the simpler and, according to the author's experience, generally effectual plan of treatment he has described.—*Provincial Medical Journal.*

The Operative Treatment of Spinal Caries.—Dr. Calot holds that in the present state of science it is unjustifiable to operate in cases of paralysis due to Pott's disease of the spine, as most of these cases will recover, if treated by prolonged rest. Of twenty cases treated by the author during the last four years by rest and immobilization, nineteen are either quite cured or on their way to complete cure, one only having died in consequence of the rupture of a large psoas abscess into the bladder. Operative treatment is contra-indicated in Pott's disease by the seat and the extent of the lesions, by the nature of the tuberculous process, and by all the risk attending surgical interference. It has been stated that in fifty per cent. of the recorded cases thus treated, death has been due directly to the operation, and there is reason to believe that the mortality really amounts to between sixty and eighty per cent. The author concludes that the operative treatment, which is so fatal or useless in a large majority of cases, does not afford in the few successful cases better results than those obtained by strictly orthopedic treatment.—*University Medical Magazine.*

Tuberculosis in Syphilitics.—According to Dr. Jacquimet, it is quite frequent to see pulmonary troubles complicate those of syphilis. These complications have been long recognized, as Ambroise Paré speaks of them, but their nature has been questioned. Some thought that there was a lesion due really to the syphilis, others regard it purely and simply as phthisis. It has been shown that the pulmonary lesions occurring in syphilitics should be attributed to two different causes: one of a true syphilitic nature, which, therefore, should receive the antisyphilitic treatment, the other enters the body with tuberculous manifestations. Jacquimet has made a study of the evolution of pulmonary tuberculosis in syphilitics. If the syphilis exists in individuals already attacked by pulmonary tuberculosis, it aggravates the latter and increases it. If, on the contrary, tuberculosis develops in a syphilitic, it proceeds in two different ways: it develops very rapidly if the syphilis is in its secondary period, and, on the contrary, it proceeds slowly and torpidly if it arises in the tertiary stage. Syphilis plays a double part in regard to the tuberculous bacillus. In weakening the system it permits the development of the bacillus, and, on the other hand, by the lesions of the pulmonary apparatus, it permits inoculation of the tubercle bacillus. As to the pleurisies of the secondary period of syphilis, which have been recently described, Jacquimet agrees with Landouzy, that they are of a bacillary nature. The diagnosis between pulmonary syphilis and pulmonary tuberculosis in syphilitics can only be made by bacteriological examination of the expectoration. The author agrees with Landouzy, in believing that in the infectious group there is none worse, none so formidable, as the combination of syphilis and tuberculosis.—*Union Médicale.*

Forced Feeding for Nine Years.—Dr. Gadelius records the case of a tailor, aged thirty-two, an assiduous workman, slow, taciturn, but amenable to reason. Insanity of persecution developed; the prominent symptoms being anxiety and insomnia, with neglect of his person and refusal to take food. When spoken to he invariably answered, in an undertone, "Fine weather, to-day," and, later on, "I do not know." Forced feeding was carried on uninterruptedly from April 24, 1883, to February 12, 1892, the body-weight increasing during this period from 101 to 160 pounds. From April, 1883, to May, 1886, he remained in a condition of complete stupor and anæsthesia. The author considers the prodromic delirium as a paranoiac psychosis in a degenerate subject, and regards the case as a psychosis of exhaustion, being practically a condition of syncope from beginning to end. On awakening from the stupor, the patient had lost most of his former knowledge of things and places, but soon recovered it.—*Hygeia.*

Painful Digestion in the Hysterical.—Among the interesting papers in the July issue of the *Liverpool Medico-Chirurgical Journal*, is one by Dr. T. R. Glynn, on painful digestion in hysterical subjects. The symptoms are somewhat like those of gastric ulcer. Pain, especially after food and relieved by vomiting, and the occasional ejection of blood, are confusing points of resemblance. Nervous dyspepsia is very frequently met with in chloro-anæmia. Chlorotic young women suffer from painful sensations and hyperæsthesia in various parts: headache, tenderness in the head; backache, tenderness along the spine; pain or tenderness in the breasts and ovaries; teeth are extracted for toothache; there is pain after food and other stomach troubles; more or less tenderness on pressure over the epigastrium, and perhaps cutaneous hyperæsthesia, its area following the distribution of the tender spots characteristic of hysteria. The great majority of chlorotic girls are hysterical, presenting the stigmata of hysteria. The hyperæsthesia and neuralgias in chloro-anæmia are not directly due to anæmia, but to the hysterical condition dependent upon it. Nervous dyspepsia occurs in persons who are simply hysterical and not chlorotic, and is met with in subjects who have neither chlorosis nor hysteria. The chlorotic girls who are not also hysterical are free from nervous dyspepsia and from pain. A case, B. H——, was sent to the hospital for gastric ulcer. For a month there had been pain in the epigastrium, back, and beneath each breast. The pain was aching and wearing, intense after eating, coming on immediately after deglutition, and often keeping her awake at night. She vomited three or four times daily, with occasionally a little blood in the ejected matter, and often much bile. M. T——, also sent in as a case of gastric ulcer, complained of vomiting, and hæmatemesis. During convalescence from an acute illness, headaches began, and pains in the back, under the left breast, and in the left ovary. Milk diet improved her somewhat for a time. There was right hemianalgesia, restriction of visual fields, various tender spots, exaggerated knee-jerks, and absence of plantar reflexes. L——, very hysterical, neurotic family history, migraine ever since she could remember; was sent in as a probable case of catarrh of the stomach. She had entirely lost her appetite and vomited continually. No food had any taste. There was hemianalgesia, restricted visual fields, various tender spots, tremor, and loss of the olfactory, and of the gustatory sense. This loss was an exaggeration of a condition common in the hysterical, and often found in a marked degree in hysterical anorexia. The pain in nervous dyspepsia is often very violent. In one case under observation, the amount of shock was sufficient to suggest the possibility of intestinal perforation. Yet the hysterical analgesia was so marked that the inser-

tion of a hypodermic needle to introduce morphia was unnoticed. It is difficult to get patients to localize pain. It is referred to the end of the sternum, to the epigastrium, in the back, under the left breast, or it is said to stab through, or go around the body. Where pain is experienced on swallowing, the referred pain is felt over the ensiform cartilage, *i.e.*, over a small area supplied by the sensory root of the sixth or seventh dorsal nerves. The superficial pains follow the distribution described by Dr. Head, in *Brain*, Part LXI., in a paper on "Disturbances of Sensation with Special Reference to the Pain of Visceral Disease." They are referred to the surface of the body, back, and front, supplied by the sixth, seventh, eighth, and ninth sensory roots, the maximum seats of pain being distributed somewhat differently in different cases, over the epigastrium, and lower dorsal region. The theory that the mucous membrane of the stomach, in this form of painful dyspepsia, is in a hyperæsthetic condition, owing to an abnormal state of central gray matter, explains many of the characters of the affection. The swallowing of simple liquids gives pain. This symptom points to extreme sensibility, that is much more common in nervous dyspepsia than in gastric ulcer. The pain in the gastric neurosis is often severe at night. So also is that of gastric ulcer, reaching its maximum intensity between eleven and one. But the pain of nervous dyspepsia is frequently severe on waking, before breakfast. In gastric ulcer, hyperæsthetic cutaneous areas are more limited than in nervous dyspepsia. Flatulence is more common in nervous dyspepsia than in gastric ulcer. Pain in gastric ulcer depends largely upon the general condition of the patient, and it may be present at one time during the disease, and absent at another. Hysterical persons may also have gastric ulcer, and the chlorotic are predisposed to it. Hysteria, chlorosis, and gastric ulcer are close allies. In nervous dyspepsia, treatment directed to the general condition brings about better results than efforts directed to the local or stomach troubles. Absolute rest in bed is necessary, with cold sponging and massage, and a diet restricted to liquids for a day or two, but quickly made substantial, varied, and generous. Iron may be needed for anæmia and some sedative for pain. No benefit is derived from alkalies, acids, tonics, antispasmodics, antiseptics, etc. Drugging with nitric acid and pepsin, bismuth and carbonate of soda, sulpho carbolates and salol, leaves the patient in much the same condition for months, or years. Then, too, it is wise to remember always that with gastric ulcer there may be also a strong neurotic element that is made worse by an interminable course of milk and lime-water.

Rickets and Convulsions.—Out of 1,600 rickety children observed by J. Comby in a Paris dispensary, only one-tenth had convulsions, while Henoch attributes two-thirds of the cases of goitre spasm to rickets. Although rickets is so common in Paris, goitre spasm is very rare, and the author believes there is a relation of cause and effect between rickets and laryngeal spasm. Still less is this so with dentition (even when delayed and perverted by rickets). Among 70,000 children seen during eleven years, Comby never saw convulsions of purely dental origin, and never had occasion to lance the gums. Craniotabes, sometimes assumed as a cause of gastric spasm, if looked for is found with "extraordinary frequency," and in cases where there has never been any convulsion or glottic spasm. The bond that unites the two morbid states (rickets and convulsions) is dyspepsia (dilatation of the stomach, diarrhœa, constipation, etc.), with auto-intoxication, from which arise all these nervous disorders, and in a great part even rickets itself.—*Gaillard's Medical Journal.*

The Hysterical Breast.—Dr. Gilles de la Tourette considers this condition of much importance, not only because it is a well-defined manifestation of hysteria, but also from the fact that it has given rise to errors of diagnosis and needless removal of the organ. It consists in a temporary enlargement of the breast, with considerable hyperæsthesia of the skin covering the organ. This hyperæsthesia, liable to vary, becomes much more marked during menstruation; there is then also more swelling, and considerable pain is complained of. On palpation at such a time it is possible to perceive one or perhaps two tumor-like masses in the substance of the breast, about the size of a hen's egg, but which are not painful, the hyperæsthesia being cutaneous. The affection is often of long duration, more especially in those cases where there is faulty therapeusis, as often happens. It seems to depend on a hysterogenous band of hyperæsthesia at the level of the breast, which induces an œdema of the connective tissue of the gland. In this way are produced the local swellings, and even patches of white, pink, or violet under the skin.—*Journal de Médecine.*

The Causes of Death in Pneumonia.—Dr. Bollinger maintains that croupous pneumonia is a typical local infectious disease, pursuing in the majority of cases a very regular course. It is not dangerous on account of the duration or the intensity of the fever. The impairment of the function of the lung is likewise insufficient to explain death. The œdema so frequently found in the parts of the lung spared by the disease is not the result of a passively increasing collateral hyperæmia, but of cardiac failure. The collapse symptoms in croupous pneumonia and the fatal weakening of the heart are dependent on oligæmia, which leads to impaired nutrition of the cardiac muscle, already weakened by the fever and the extra demands upon it. Anæmia of the brain may cause disturbances of innervation of the heart, and this may be an additional factor. The exudate into the lung tissue may be likened to a venesection produced by the pneumococcus, which in a few days deprives the blood of a large quantity of important constituents. The reason why death takes place so early, and usually in the same stage of the disease, from the sixth to the eighth day (corresponding to the transition from red to gray hepatization), is probably because the exudate has to attain a certain acme before life is imperilled. If these facts are applied to therapeusis, it follows that, in addition to the usual treatment of pneumonia, every effort should be made to combat the oligæmia. Large quantities of fluids should be supplied to the system through every available channel, even in the form of saline infusions. This should be done at an early period, before collapse symptoms have manifested themselves.—*Münchener medicinishe Wochenschrift.*

Moist or Dry Asepsis?—At a recent discussion Sanger raised this question in a long paper, in which he described 147 cases of cœliotomy, all treated with Tavel's soda solution. His results were perfectly satisfactory, not one succumbing to sepsis out of the six deaths. Three of the sections showed no adhesions. He advocated this as the best antiseptic for keeping the peritoneal epithelium intact. Zweifel acknowledged himself as a devotee of the dry method. With carefully applied dry antisepsis he had not a single death to record from ileitis. It is true that he had two cases that showed symptoms of the chronic form of ileus, which subsequently was relieved by operation. He was convinced that the moist antisepsis had worse results to record. Freund was of opinion that improved surgical treatment or antiseptic treatment would not increase the liability to ileus after laparotomy. Within the last five years he had four cases of ileus, none of which, he was confident, were caused by the operation. Three of them were undoubtedly due to a catarrhal process which produced stenosis of the flexura sigmoidea, subsequently inducing ileus. Schauta said that he could record 1,300 cœliotomies. In the first half of these he had used moist asepsis with four deaths; with the second half, dry antiseptics with no deaths. He was of

opinion that moist or dry antiseptics had no effect *per se* on the production of ileus, but he thought better methods of operation with perfect asepsis had a considerable influence in its reduction. Tauffer recorded 348 laparotomies with dry septic treatment, and 443 with moist treatment. In the former series he had two deaths; in the latter ten deaths to record.—*Medical Press.*

Diet in Bright's Disease.—The question of what diet is the most suitable in the various forms of Bright's disease has been, and is still, a much-debated point. It is particularly a question where theoretical views are likely to influence practice. If Bright's disease is looked upon as a primary inflammatory affection of the kidneys, articles of diet possessing diuretic properties will probably be avoided. If uræmia is considered to be due to failure on the part of the kidneys to excrete nitrogeneous extractives, there will be a tendency to diminish as much as possible the quantity of proteid matter in the food. It is more especially in chronic Bright's disease that the question is important. Dr. Hirschfeld discusses anew the various diets suitable in this disease. He considers that the albuminuria is the first point that calls for attention, and that all articles of diet which cause an unequivocal increase in the daily loss of albumin are to be avoided—for instance, alcohol and smoked meats. Eggs are not harmful in moderation. He points out that although the actual loss of albumin in the urine may not amount to more than a few grammes per diem, yet this loss cannot be made up for by increasing the amount of proteid in the food. Not only is an increase of proteid in the food followed by an increase in the albuminuria, but, in addition, there are increased amounts of nitrogeneous extractives to be excreted, and thus more strain is thrown on the damaged kidneys. Although, of course, the increased loss of albumin is much less than the increase of proteid in the food, yet it is extremely doubtful whether any proteid is retained in the body as such. In health it is known that increased proteid food leads to increased proteid metabolism, and that, if proteid metabolism is to be checked, it is done most efficiently by increasing the fatty and carbo-hydrate foods. For these reasons the albuminuria is not to be combated by increased proteid diet. Many authorities on renal disease lay but little stress on the daily loss of albumin, and think that, if the general condition of the patient is improved by a more liberal diet, this should be persevered in notwithstanding the increased albuminuria. Hirschfeld states that a rich proteid diet is likely to lead to the retention of nitrogeneous extractives, since the increased excretion of these extractives following such a diet occurs later in patients with diseased kidneys than under normal conditions. Hence such a diet might predispose to uræmia. Hale White, however, states definitely ("Med.-Chir. Trans.," vol. lxxvi.) that in his experience an ordinary full diet does not increase the liability to uræmia, and he quotes one striking case in which a patient developed severe uræmia on a farinaceous diet, and when these symptoms became less a full diet was given without any return of uræmic symptoms. Hirschfeld would give about 6 ounces of meat and 13 ounces of bread daily, with a liberal allowance of vegetables and fruit, 1½ ounce of sugar, and 5 ounces of fat, as a typical diet for a patient with chronic Bright's disease. As regards the value of milk in this disease, he points out that it may be used in one of three ways. First (as Karell suggested), in small quantities—*i.e.*, two to three pints daily, and as the sole food. In this way the work of the kidneys is reduced to a minimum. At the same time it is almost a starvation diet, and is mainly useful in acute Bright's and in cases where there is great failure of appetite. Secondly, milk may be given in large quantities, say from four to eight pints daily. This is a form of treatment much advocated by Germain Sée and others. These observers state that albuminuria often disappears under this *régime*, and does not return when a more liberal diet is allowed. Finally, milk may be given in moderate quantities in addition to, rather than in lieu of, the mixed diet recommended above.—*The Practitioner.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 4, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Nominations.—*Vice-President*, Drs. Egbert H. Grandin, Virgil P. Gibney, R. W. Taylor; *Trustee*, Dr. Joseph E. Janvrin; *Committee on Library*, vacancy of four years, Drs. H. L. Collyer, C. G. Coakley, A. Rose, F. W. Wiggin; vacancy of five years, Drs. Dillon Brown, B. F. Curtis; *Committee on Admission*, one to be elected, Drs. R. A. Murray, John Girdner; *Five Delegates to the State Medical Society*, Drs. W. S. Gottheil, Joseph Collins, R. H. Sayre, Ralph L. Parsons, C. H. Richardson.

A Study of the Infectiousness of the Dust in the Adirondack Sanitarium.—DR. IRWIN H. HANCE read the paper (see p. 903).

Discussion.—DR. E. G. JANEWAY thought that while Dr. Hance had taken very little of our time to give us these facts, they were, nevertheless, very important and had involved a great deal of work. At a recent visit to the Sanitarium he had been impressed with its absolute cleanliness, the clear air about the cottages, their excellent ventilation, and the small number of inmates for the amount of air-space. In fact, he would much prefer to live in one of these cottages than at many hotels frequented by invalids. He felt that the chances of a patient sent there would be better than at most hotels. He often advised delicate people not to resort to hotels frequented by invalids, unless the proprietor was known to be extra careful regarding cleanliness, etc. We must not send our pulmonary invalids to places where they are liable to receive worse infection. Dr. Janeway said he knew from personal questioning of phthisical patients that there were many physicians in this city who did not warn their patients of the possibility of infecting others through the sputa and other excreta. If the precautions taken at the Adirondack Sanitarium were applied in this city we would have less tuberculosis. Yesterday, while riding in a street-car in Philadelphia, he observed a sign: "Passengers are positively prohibited from spitting in this car." This was a good warning, although it might not always be heeded.

DR. HERMAN M. BIGGS hoped the paper read would prove of great service to physicians and the Board of Health in combating tuberculosis in New York. It was exceedingly gratifying to learn that such precautions could be taken in a hospital for tuberculosis, which would effectually prevent danger of infection. The experiments narrated would seem to indicate that fact in the clearest way.

A few years ago, when the Board of Health contemplated classifying tuberculosis among the infectious diseases, a great outcry was made by the people and physicians that it would make these invalids a source of horror to their friends and cause them to be shunned as if they were lepers. The fact appeared to have been overlooked that, with proper precautions, they could be rendered absolutely innoxious to their associates. But where these precautions were not taken there was positive evidence of the greatest danger of spreading the infection. In one of our city hospitals as many as eleven nurses and orderlies, previously

healthy, had been dismissed within a little more than two years, because suffering from tuberculosis. It was due to the fact that the hospital was overcrowded, had poor ventilation, and other conditions favorable for the transmission of the disease. Moreover, patients admitted with other diseases and remaining in such hospitals a few months often contracted tuberculosis.

The Health Department had found it the exception for physicians to instruct their patients with tuberculosis as to the danger of their sputa and the necessity for its safe disposal. This was nothing less than criminal negligence or indifference. One of the largest and best hospitals in the city lately handed the clothing and handerchiefs of a man dying in its wards of tuberculosis over to the wife without first disinfecting them, and this woman herself knew that it was wrong and boiled the clothes immediately. The people, it seemed, were being educated in advance of a part of the profession, for they followed precautions which they learned through the newspapers and without having been instructed by the family physician.

Dr. Biggs said it had been a hope of his for years that eventually a home for the treatment of the poor with tuberculosis would be established in the country. The paper showed that such a method of caring for these cases would be safe and practical.

Dr. H. P. Loomis said that ten years ago phthisis was not thought of as an infectious disease, and he believed it was about five years ago that the pathologists of the Board of Health were asked whether tuberculosis should be regarded as a source of infection. To-day the laity understood perfectly that it was. They were talking about the dust in their rooms, and he believed that more of them recognized this source of danger than we supposed. It was a satisfaction to know that there was a place where we could go and get absolutely harmless air, even if it did necessitate a sojourn at a consumptive sanitarium. He had paid many visits to Saranac Lake, and remembered well that in the beginning the project of establishing such a sanitarium met with much opposition, one objection which was suggested being that to bring together so many patients with a lingering disease would have a depressing effect; also that after a time the furniture would become contaminated and prove dangerous. Dr. Trudeaux did not believe this, and the paper read by Dr. Hance showed that under the plan adopted, of separate buildings, cleanliness, and destruction of the sputum, the danger of infection was very slight.

Dr. Loomis thought there was no doubt but what the separate house plan, with cleanliness and proper disposal of the sputum, was best in the management of consumption. With one exception there was no general hospital in the city which would retain within its wards cases of tuberculosis, and he believed the Commissioners of Charities were about to exclude them from Bellevue. The position of the tuberculous patient was sad indeed, as he drifted about between the Scylla of an agonizing family without means and the Charybdis of a charity hospital with closed doors. In view of the safety secured against infection in the Adirondack Sanitarium, Dr. Loomis thought the hospitals in this city could have separate buildings or wards in which tuberculous patients could be treated without danger to other wards. He believed St. Luke's, in its new site, would provide for this want, and the example ought to be copied by other institutions.

Dr. Freudenthal said that at Montefiore Home the sputa was carefully destroyed and the ventilation was better than at Bellevue, yet cases of infection with tuberculosis did occur in nurses and inmates. This might be accounted for in part by the fact that absolute cleanliness of patients and clothing was hardly possible.

Tuberculous Heirlooms in Country Homes. — Dr. Andrew H. Smith hoped this paper and its warning would reach country practitioners and people, for a great many houses in the rural districts, along with their ancient tapestry and furniture, were hot-beds for the culture of tubercle bacilli. Unlike houses in the city, the contents were not subject to change, but were sometimes used by several generations. The result was, that not infrequently one after another in the house died of tuberculosis, and it was wrongly attributed to heredity instead of infection. They should be taught to leave their windows open and to renovate the furniture. Regarding sleeping-cars, Dr. Smith said the sheets were cleansed, but the blankets were used probably year after year without disinfection, and he never felt like permitting a patient going toward Saranac Lake to take a night train.

Infection in Hotels.—Dr. A. Jacobi said he knew from personal observation of the negligence of a number of our hotels with regard to infectious diseases. He knew more particularly of cases where diphtheria had occurred at intervals in the same suite of rooms in hotels, due, no doubt, to want of disinfection, cleanliness, and change of tapestry, etc. Tuberculosis could be spread in the same way. He thought there was more danger in the better class of flats, where the stairs were carpeted but seldom cleaned, than in the lower tenements, where no carpets existed.

Dr. Charles A. Leale said the sleeping-cars going north were not the only ones whose blankets might profitably be cleaner, as he had observed on a trip to Jacksonville. In Florida, too, he saw draperies and carpets in hotels so contaminated as almost to produce emesis in the healthy.

Dr. J. W. Brannan thought that since Dr. Hance had shown that it was possible to conduct a sanitarium on a clean principle, it ought to be exacted of all institutions in this country to show a like clean bill of health.

Dr. A. Rose said that in places in Europe visited by him three things were missing which we had here, namely, carpets, dark bedrooms, and a basement. It would be interesting to know how much less tuberculosis we would have if these three things did not exist.

Advancing.—The President said that five years ago, when he was Health Commissioner, he had a stereotyped letter sent out to twenty-four prominent physicians of the city, asking them whether they thought we were sufficiently advanced to justify the Board of Health in classifying tuberculosis among the infectious or contagious diseases. Five replies were received. Two hesitatingly said yes; one was of doubtful tenor; one was long, earnest, logical, and fully awake to the situation; the fifth said no. The President thought that the discussion to-night showed that steps had been taken which would bring forth fruit.

Dr. Hance, in some closing remarks, said that probably not one patient in fifty coming to the Sanitarium knew what disposition to make of his sputa until instructed. In the village they would not use the sanitarium cuspidor for a time, but they had so greatly changed that about two years ago the local Board of Health had made its use obligatory. That examination of dust under the microscope was a poor test of its infectious character was shown by the fact that out of many specimens examined from one cottage he found only one tubercle bacillus, whereas inoculation of guinea-pigs with this dust had caused tuberculosis in fifty per cent. In reply to an interrogatory by Dr. Brannan he said the Sanitarium was a charity, charging a fixed price of five dollars a week, while the actual expense averaged about seven dollars. Only such cases were received as gave some promise of recovery. Fresh air was an important part of the treatment, the patients being out of doors six or eight hours daily during the winter, and longer during the summer. He also stated that he did not know what was the cause of death in guinea-pigs injected with the dust and in which tuberculosis was excluded. Death usually took place in forty-eight hours, the prominent post-mortem changes being œdema, cellulitis, and peritonitis.

Therapeutic Hints.

Ulcers of the Cornea.—The use of the thermo-cautery combined with the mydriatic-meiotic alternation has, in my hands, produced the most gratifying results in the treatment of corneal ulcers. The following axiom will be found very useful: Use as much eserine as possible, avoiding the causation of an iritis, and as little atropine as possible, sufficient only to maintain a mobile pupil. Lack of space prevents a detailed description. Be the pupil large or small, it must invariably first be artificially dilated. Eserine should never be employed alone in this class of cases, as iritis will be the inevitable result. Atropine, used by itself for any length of time in ulcer, increases tension; nutrition is thereby impaired, reparation retarded, and frequently, in severer forms, the eye in consequence perishes. Judicious alternation keeps the iris in motion, and maintains normal intra-ocular pressure; as a result healing is expedited and facilitated.—H. Davison-Schwarzschild.

Creosote.—From it two very gratifying results are found: 1. It possesses undoubted power to relieve the fetor of the expectoration in foul-smelling cases of bronchiectasis and phthisical cavities. 2. In small doses (1 to 2 minims thrice daily) it promotes the appetite and tends to stimulate the powers of digestion. Beyond this it is not found that it modifies in any appreciable manner the ordinary course of phthisis.—Crook.

Calomel.—One grain of thoroughly triturated calomel is equivalent to five to ten grains of the untriturated drug. If given for its purgative effect or for its action on the liver, one-tenth of a grain triturated is administered every hour or half-hour until free evacuation occurs; or one grain is taken, then, if necessary, ounce doses of *liquor magnesii citratis* can be given until free action of the bowels is obtained. The drug is not a direct diuretic *per se*, but it may act indirectly to a slight extent simply by its general stimulating action upon the emunctories of the entire body, thus favoring secretion, excretion, and the elimination of intestinal ptomaines and systemic poisons, all of which act unfavorably upon the secretory and excretory organs when present.—Stewart.

Inebriety.—Inebriety is curable in one-third the cases. The basis of treatment is complete compulsory prolonged abstinence; without this method there is no chance of recovery. This abstinence should be supplemented by treatment of the condition of the nervous system, of which inebriety is the symptom. The patient should be placed under discipline and subjected to an efficacious surveillance. The duration of the treatment should be at least one year.—Montyel.

Sedative Cough Mixture in Phthisis.—

℞ Codeinæ sulph. ..... gr. ij.
Liq. atrop. sulph. ..... ♏ xij.
Liq. strychniæ ..... ♏ j.
Syr. tolutani ..... ʒss.
Infus. rosæ acidi ..... ad. ʒvj.

S.—Tablespoonful in a wineglass of water every four or six hours.

Psoriasis.—Remove the scales by alkaline washes, and then apply glycerole of starch, oil of cade, of each 3½ ounces; soft soap, 75 grains; salicylic acid, 45 grains. The parts are washed with warm water and tar soap every three or four days. In obstinate cases the scales are removed and the following ointment employed: Ichthyol, pyrogallol, and salicylic acid, of each 30 grains; vaselin, lard, and lanolin, of each 1 ounce.—Coffin.

Pernicious Anæmia.—That pernicious anæmia is not a special disease, but secondary to numerous exhausting conditions. That these induce an initial anæmia which is followed in certain cases by degenerative changes in the blood-vessels. That capillary hemorrhages result and induce an excessive degree of anæmia. That some cases are due chiefly to external bleedings, which account for all the characteristic symptoms and post-mortem appearances. That the treatment should be based on etiological considerations.—Stockman.

Napoleon's Favorite Prescriptions.—The following are given by Charles B. Williams as prescriptions frequently used by Napoleon I.:

(1) ℞ Pulv. ipecac. ..... gr. xxx.
Pulv. scillæ,
Pulv. ammoniæ ..... āā gr. xl.
Div. in pil. No. xxxiv.
S.—Two pills night and morning.

The above was used for difficulty of breathing, bronchitis, etc.

(2) ℞ Liq. ammoniæ fortioris ..... ♏x.
Syrupi erysemi ..... ʒjss.
Infusionis tiliæ florum ..... ʒijss.
S.—To be taken at one dose.

This was used for immediate relief of hoarseness.

The syrup of erysemum and the infusion of linden flowers would be difficult to obtain at the present day, and these may be replaced as in the following:

℞ Liq. ammoniæ fortioris ..... ♏x.
Syrup acaciæ ..... ʒjss.
Aq. aurantii flor. ..... ʒijss.
S.—To be taken at a dose.

—*Medical and Surgical Reporter.*

Fever in Nephritis.—Fever may occur in the course of Bright's disease under three conditions: 1, At the onset of acute nephritis as a result of the infection or intoxication causing the disease, or of the inflammatory or degenerative lesions in the kidneys themselves; 2, in the course of acute or chronic Bright's disease as a result of various complications; and, 3, in uræmia. The fever associated with uræmia may be sudden and pronounced, and associated with coma, delirium, or convulsions—eclamptic fever; or it may be more general, more lasting, less marked, and associated with typhoidal symptoms—slow uræmic fever.—Stengel.

In Urine.—There are at least seven toxic substances in the normal urine. These are: 1, A diuretic substance (urea); 2, a narcotic poison; 3, a sialogogue; 4, a temperature-reducing substance; 5 and 6, convulsants (one, doubtless, potassium); and 7, a poison which causes contraction of the pupil.—Bouchard.

Guaiacol.—1. Guaiacol is an efficient local sedative, as shown by its analgesic power when employed in painful affections. 2. It is more potent when administered hypodermically than when it is applied to the skin surface. 3. It has not, in practically afebrile conditions, produced any noticeable lowering of temperature or other unpleasant effects in my experience. 4. When employed in febrile affections, it may cause objectionable effects, such as rigors, followed by high temperature. 5. Guaiacol seems to be powerless to control inflammatory processes, particularly when acute in character.—Anders.

Predisposition of Persons to Consumption.—Many people think that consumption is inherited, but the closest investigation has shown that it is not inherited, and that only the susceptibility or liability to the disease is inherited. Thus the children of a tubercular family do not necessarily inherit the disease itself, but they inherit the constitution, which, when exposed to the germ, furnishes a soil which propagates the disease with great rapidity, and one after the other succumbs.

Cough.—The obstinate cough due to a dilated heart, or one affected at the orifices with organic changes, is very frequent and should be constantly kept in mind

Not seldom, when I have not known what else to do, I have freely stimulated a somewhat weak cardiac action and thus stopped a bad cough in a few days.—Robinson.

Taches Bleuatres.—Revilliod believes the spots to be due to the excrement of the pediculus, which he states is an insect of very cleanly habits, and that during the night he leaves his usual seat at the root of the hair and deposits his fæces in the adjacent parts of the body! Bowditch is inclined to believe that Moursou's original statement of the relation between the pediculus and the taches bleuâtres is undoubtedly correct.

Typhoid Fever.—The author concludes that, 1, the antiseptic treatment is the rational one; 2, guaiacol is a safe remedy and prevents the toxin-poisoning of the later stages; 3, it will lower the temperature when applied externally; 4, the typhoid patients do better by keeping the bowels acting up to a certain point, rather than checking them, and will derive comfort and benefit from daily douching of the large intestine with warm or cold water.—Hull.

Acute Intestinal Invagination.—1. Operation should be resorted to as early as possible after non-operative methods have been thoroughly tried without success. 2. After a laparotomy disinvagination is of value when it can be accomplished without any great difficulty. If the intestinal wall is suspicious looking at the point of invagination, the peritoneal cavity should be walled off with iodoform gauze, or the particular portion of the intestine should be drawn outside of the abdominal wall. 3. When disinvagination is impossible the resection of the invagination is the least dangerous procedure. 4. The resection of the entire invagination should be performed when the invaginating sheath is so markedly altered that there is danger of perforation. 5. The formation of an anus præternaturalis or an entero-anastomosis have usually no place in these cases; only in the presence of collapse is the formation of an artificial anus permissible.—Rudygier.

Chronic Intestinal Invagination.—In chronic invagination internal medication and non-operative methods must be employed, but should be abandoned after a week's trial. Disinvagination is of little avail, although four successful cases have been reported—one at nine months, two at six months, and one at ten weeks. Resection of the invagination is here also the operative method of choice. Entero-anastomosis should only be undertaken in the presence of adhesions. An artificial anus should not be thought of in the treatment of chronic invagination.—Rudygier.

Tuberculin.—Three instances are cited in which Koch's tuberculin was used in tubercular affections which were not pulmonary—tubercular cystitis and tubercular hip-joint diseases (two cases). From the improvement which has been noted in these cases we may conclude that there is ample justification for its use in the positive, although sometimes necessarily more or less transitory, immunizing influence.—Denison.

Schleich's Method of Local Anæsthesia.—Dr. Theophilus Parvin, at the last meeting of the County Medical Society, read a paper on "Schleich's Method of Local Anæsthesia" by subcutaneous and parenchymatous injections of weak cocaine-morphine solutions, and demonstrated the effect in his own person, by allowing an incision of an inch in length to be made in his forearm and to be stitched up, under its influence, in the presence of the society. He declared it to be an absolutely painless procedure and predicted great future usefulness for this method in surgery, and that at least fifty per cent. of the operations now done under general anæsthetics will ultimately be done by this method, which he declared suitable even for major operations.—*Boston Medical and Surgical Journal.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 21, 1895.

	Cases.	Deaths.
Tuberculosis	99	112
Typhoid fever	33	13
Scarlet fever	91	6
Cerebro-spinal meningitis	0	2
Measles	234	22
Diphtheria	248	37
Small-pox	1	0

Naso-pharyngeal Catarrh and One of Its Causes.—Post-nasal catarrh is so frequent in this country that when European authors speak of American catarrh they mean this affection. Dr. W. Freudenthal, of New York, in a paper read in the section on Laryngology and Otology at the forty-sixth annual meeting of the American Medical Association (Some Points Regarding the Etiology and Treatment of Post-nasal Catarrh, with Remarks on Hygiene of the Respiratory Organs.—*The Journal of the American Medical Association*, November 9, 1895) shows that the causes of the catarrh—as it is generally called—depend on conditions which heretofore have not received the attention they deserve. The naso-pharynx has the function of impregnating the inspired air with humidity, and the importance of this moistening process has been demonstrated by Aschenbrandt's experiments. Dr. Freudenthal repeated these experiments with Aschenbrandt's apparatus, not only in healthy, but also in pathological cases. He found that in cases in which the nose had been galvano-cauterized, in which the patient had been suffering from hay-fever, or those in which there were adenoid vegetations, there was a diminution of moisture for the inhaled air. In the latter cases the air became normally moistened again when passing through the naso-pharynx after the lymphoid tissue had been removed. Of the several conditions which prevent the retro-pharynx from performing its function, there is one which is most important, namely: the faulty manner in which our houses are heated in winter. The atmosphere of a room in winter should be kept moderately humid, it should contain between 50° and 60° F. relative humidity; the lowest point should never go below 40° F. Dr. Freudenthal tested many New York houses during the last two winters, and never found a relative humidity of even 50° F.; when the outside temperature was about 30° F. he never saw even 40° F. The highest point reached was 30° F.; but 25°, 20°, even 18° F. relative humidity, was nothing unusual when the weather was very cold. Even in one of our best-arranged hospitals the relative humidity seldom reached 40° F. It is impossible to say how very detrimental this state of things is. The mucous membranes of the air-passages require a certain humidity of the air in order to keep up their functions. If this humidity is wanting they will in time themselves become dry, even in summer. It would appear to be of much more importance to suspend on the wall of our room a hygrometer than a thermometer, and to regulate the humidity of the atmosphere of our houses in winter by some means or another.

The Signs of Death.—The following are the signs on which a medical man should rely as furnishing the best evidence of the reality of death, prior to the commencement of putrefactive changes, namely: the absence of circulation and respiration; the gradual cooling of the body, the extremities cooling first and the trunk last; gradual supervention of rigor mortis; the production of post-mortem stains or ecchymoses.

In 1848 Bouchut found that in all cases of apparent death, although the contractions of the heart were reduced in force and frequency, by auscultation, he was able to detect the pulsations of the heart, and so distinguish apparent from real death. The careful use of the stethoscope by a medical man will enable him to distinguish a living from a dead body. Certain forms of rigidity that may occur during life may be mistaken for rigor mortis. Rigidity during life may occur from tetanus, apoplexy, catalepsy, syncope, asphyxia, and hysterical spasm; but the three striking differences from cadaveric rigidity are presented as follows: 1, The warmth of the body is preserved; 2, the whole of the body becomes equally rigid at the same moment, due to the occurrence of a general muscular spasm (with rigor mortis the rigidity usually commences in the muscles of the neck and lower jaw, and then gradually affects the other parts of the body): 3, if a joint be forcibly bent, such as the arm at the elbow, the limb will, if in a state of spasm from disease, return to its original position when the force is removed, whereas if it be in a state of rigor mortis it will not return.—*British Medical Journal.*

In Honor of Stephen Girard.—A tablet "in commemoration of the courage and humanity displayed by Stephen Girard during the epidemic of yellow fever prevailing in Philadelphia in the year 1793" was unveiled in Girard College in Philadelphia a few days ago. The incident discloses a phase of character in the philanthropist not generally understood. During the fever epidemic he abandoned his business and his luxurious home, and assumed the superintendency of a yellow-fever hospital. He took up the work others recoiled from, hired nurses, brought order out of chaos, and did the work because it was his duty.

Abuse of Medical Charity in Brighton.—The people of Brighton are being attacked regarding the abuse of medical charities there. Brighton is one of the richest towns in England, yet the statistics show that out of the 150,000 of its inhabitants 38,113 patients were last year admitted to the various hospitals and dispensaries.

An Antiseptic Dressing.—During the recent war the Japanese army surgeons made use of a dressing consisting of the ash of rice-straw. After the wound was cleansed this ash was freely applied, and over it sublimate gauze or linen was placed and retained by a bandage. The antiseptic properties of the ash are attributed largely to the presence of potassium carbonate. The ash is also a good dehydrater, and tends to dry the wound.

Antiseptic Ointments.—Professor Breslau has recently published a paper in which he gives the results of a long series of experiments, very carefully conducted, into the relative efficiency of antiseptic ointments. He tried menstrua, oil, vaseline, fat, lanoline, anhydrous lanoline, and cold cream. He came to the conclusion that, of all these, carbolized lanoline and carbolized cold cream were much the best. As antiseptic agents, he tried corrosive sublimate, resorcin, silver nitrate, boric acid and salicylic acid, and noted the same fact, *i.e.*, that all of them were more efficient with lanoline or cold cream as a menstruum than in any other way. The professor also tested many of the ointments used in practice, such as ungt. zinci, ungt. hyd., and unguentum hydrargyri ammoniati, and found the mercurial preparations alone effectual.—*Medical Press.*

The Royal College of Physicians and the Ladies.—Many physicians of England recently presented a petition to the Royal College of Physicians, praying that women be admitted to the licentiateship, and the discussion on the request was the occasion for a number of ungallant remarks from some of the fellows. Dr. Charles West moved that the petition be denied, and said that the motives which influenced women in wishing to enter the medical profession appeared to him to be quite unworthy. Up to one hundred and fifty years ago, midwifery had been entirely in the hands of women, but they had done absolutely nothing to advance its practice, and it had been left to a man—Ambroise Paré—to introduce turning, while the invention of the forceps had been due also to a man—Chamberlen. In America women had practised medicine for fifty years, but he was not aware that they had made any contribution to our knowledge, and in the subject of children, which was supposed to be one for the study of which they were particularly adapted, he had failed to find any contribution to practical medicine made by a woman. Dr. Douglas Powell said that there was nothing in the practice of medicine that men could not do as well as, or better than, women. The profession was overstocked already, and to dilute it or further overstock it with women would only tend to cheapen and degrade it. The College was looked upon as a referee in questions of public health and many social questions, and he thought it would be a very grave thing for them to decide that it was advisable that women should enter the medical profession; the question had never been debated in a medical body possessed of such authority as the College. The duties of a woman lay in the household, and in bearing, rearing, and educating children. Sir James Russell Reynolds said that women were physically, mentally, and morally unfitted for the practice of medicine. Sir Richard Quain said that it seemed to him that men were becoming effeminate, and women masculine, and we do not wonder that he thought so when looking around on the old women who were opposing the petition and trying to stem the tide. The petition was rejected by a vote of 59 to 50. A similar petition was rejected eighteen years ago, by 68 votes to 18. The next time it will undoubtedly be granted.

A Handsome Legacy.—Sir Henry Thompson has recently received by legacy, from a relative and patient, property to the value of $500,000. It is not often that similar windfalls, or anything approaching them, accrue to medical men, who as a rule are more accustomed to abuse than gratitude, and when they do occur they are generally, as happened in the present instance, contested by some disappointed relative. Sir Henry was, however, successful in his contest to sustain the will, and has now come into possession of the property.

Congenital Syphilis.—The Paris correspondent of the *Medical Press* reports a clinical lecture on this affection, delivered in a hospital for syphilis in that city. The lecturer, whose name the correspondent does not give, said that the manifestations of congenital syphilis have for fundamental characters: 1, The infection is not the result of penetration through the lymphatic system; 2, there are no primary sores; 3, it affects the whole organism, externally and internally.

The influence of the father on the syphilis of the child has been notably exaggerated, but it is nevertheless certain.

The influence of the mother on the syphilis of the infant is absolutely certain, independently of all paternal disease. According to Kassowitz, a diseased mother could infect her children for ten years But Barensprung affirms that tertiary syphilis of the mother has no influence on the fœtus, while Diday pretends that the offspring is not guaranteed by the absence of secondary or tertiary symptoms of the mother. When both parents are syphilitic, infection of the fœtus is regarded as certain by the majority of authors. The cutaneous manifestations of infantile syphilis consist in lesions of the skin, the mucous membrane, and the viscera. The eruptions on the skin are varied.

Pemphigus.—One of the first and most characteristic of the phenomena of syphilis in the infant. Its seat is generally the palm of the hands and the soles of the feet. The gravity of the pemphigus is consider-

able, it takes long to get well, and frequently the child succumbs from cachexia.

Roseola.—Found on the abdomen, the chest, and the inside of the limbs; the spots, at first bright red, assume a salmon color and do not disappear by pressure.

Mucous Patches.—Found around the natural orifices, these lesions produce fissures and vegetations when the treatment is neglected.

Vesicles-Pustules.—Resembling impetigo both in appearance and in situation. They are met with on the face, around the nose, eyelids, forehead; these vesicles secrete a purulent liquid from an ulcerated base.

Coryza.—One of the most frequent lesions of congenital syphilis. At first a kind of cold in the head, hindering the respiration and suction, subsequently a serous discharge is perceived, obliging the infant to breathe by the mouth on account of the congested mucous membrane of the narines.

The visceral lesions have been described by many writers. The organs usually attacked are the lungs, the liver, and the testicle. The two former are filled with nodes producing subacute inflammation, while the latter is attacked by chronic inflammation, marked by peri-tubular and peri-vascular sclerosis; the organ is of stony hardness and hypertrophied; later atrophy sets in, leaving but a trace of the gland.

The osseous lesions affect principally the cranium, and more especially the parietal bones, where tuberosities are formed, giving a singular aspect to the head.

The treatment of infantile syphilis is simple enough. It suffices to rub in daily a small quantity (about the size of a nut) of mercurial ointment on the abdomen, the calves of the legs, and the chest. If cutaneous syphilides exist, a bath of corrosive sublimate is ordered, and for the mucous patches, calomel ointment.

Alcoholism and Longevity.—When we look abroad over the world and take a bird's-eye view of the evil effects of intemperance in its various aspects, its production of disease and death, the destruction of happiness and home, pauperism and crimes innumerable, with general demoralization, we are astonished that any thinking man, much less a physician, should come to the conclusion that drinking men and drunkards enjoy greater longevity than total abstainers.—Dr. T. B. Greeley in *Medical Progress.*

Princess and Physician.—There is in Vienna at present an Armenian princess named Beglarion, only twenty-six years old, who is a doctor of medicine. Her father is wealthy, and to be able better to practise the science she has acquired in Tiflis, Switzerland, and Salzburg, she is going to build a hospital on his estate—small to begin with, but with hopes of making it a big concern in time. In Vienna she has been received with open arms by the circle which is still in excitement after the attack by Professor Albrecht upon woman's right to study, and she will deliver a lecture on the question of woman's rights in Armenia. When a little girl she was often present when the peasant women on her father's estate brought their sick children to her mother, asking her to advise and help. She often said to herself, "If mother had learned what the doctor knows, she could help them instead of sending them home crying." Then on a box someone gave her was the picture of a wounded soldier, whose grateful eyes rested on the nurse bandaging his wound. This picture moved the child's fancy to such a degree, that she promised herself solemnly over and over again that she would be a nurse when she grew up, and she hoped a war would break out about that time. It was not difficult to obtain permission to attend the girls' grammar school at Tiflis, and afterward her mother rewarded her for studying hard by going to Berne with her.

When Mlle. Beglarion returned home from Berne for her holidays in 1892, as a young medical student, the Russian doctors allowed her to work in the cholera hospitals, where she did excellent service with a number of other women doctors, who have been praised by the Russian Home Department. When she came home with her doctor's diploma in her pocket, the sick from far and near flocked to her father's house to consult her. On Sundays, she always had some seventy patients, and thirty on week days. Three months ago, she went to Salzburg to act as assistant in Madame Rosa Kerschbaumer's eye hospital.

Decrease of Leprosy in Norway.—Leprosy is, to all appearance, very much on the decrease in Norway. There were about 3,000 lepers in that country in 1856; in the latter end of 1892 there were only 900 cases. Dr. Kaurin's statistics recently published on this question, show that a strict segregation of lepers is important for the eradication of the disease.

Necessity of Frequent Visits.—The Supreme Court of California (Todd *vs.* Myers, 40 Cal., 355), in an action brought by a physician for professional services—the defence being that the visits were too frequent and not necessary—rules that "The defendant having admitted the employment of the plaintiff as a physician to treat his wife and children, the plaintiff was the proper judge of the necessity of frequent visits, and, in the absence of proof to the contrary, the Court will presume that all the professional visits made were deemed necessary and were properly made. It would be a dangerous doctrine for the sick to require a physician to be able to prove the necessity of each visit before he can recover for his services. This is necessarily a matter of judgment, and one concerning which no one save the attending physician can decide. It depends not only upon the condition of the patient, but in some degree upon the course of treatment adopted."

First Aid in Accidents by Electricity.—The following hints may prove useful in giving first aid to a person injured by an electrical current: 1. The current should be shut off at once if the means are at hand, and the person called upon understands how to do it. 2. If this cannot be done, be careful not to touch the injured person's body with the hand. If no india-rubber gloves are at hand, the body should be dragged away from the wires by the coat tails, or the coat should be taken off and folded (a dry cloth may be used for the purpose), when the injured person may be grasped through it and dragged away. 3. When it is not possible to remove the injured person from the wires, raise that part of the body that is in contact with the earth or the wire from it, using the covered hand. This will break the current, and it will generally be possible then to get the body away. 4. If this cannot be done, take a dry cloth and place it between the body and the ground, and then disentangle the body from the wires. 5. If the body is freed from the wires, remove all the clothing from the neck and treat the injured person as one drowned. Open the mouth and grasp the tongue, which should be covered with a cloth; then pull the tongue forward and gradually allow it to fall back; this movement should be repeated sixteen times a minute. Take care that the root of the tongue is thoroughly moved. 6. The bystanders should not be allowed to give the injured person spirits or wine.—*Medical Press.*

Widespread Tuberculosis in the Animal Kingdom.—Professor Delépine, writing on this subject, has shown that—taking very large numbers as the basis of his estimate—at least sixteen per cent. of cattle are afflicted with this disease; and that, whereas in some districts it may be comparatively rare, there are parts in which a non-tuberculous cow is the exception. Pigs also are affected in the same manner, although not to the same extent, about one in every thirty-six being attacked by the disease. Cats and dogs are also subject to tuber-

culosis, and it is to be feared, from their exceeding friendliness, may be a source of danger to children with whom they play. Although the form of tuberculosis with which poultry are affected differs in some particulars from that of man, it is a very common disease, and commits great ravages in poultry-yards. But any animal which conforms with man's habit of dwelling under artificial shelter, is apt to contract tuberculosis; and so it is that whether they be monkeys, camels, giraffes, antelopes, llamas, lions, tigers, foxes, tapirs, zebras, etc., they all, according to Professor Delèpine, are liable to tuberculosis when they are kept in menageries.—*The Hospital.*

Negro Suicides are Rare.—A remarkable characteristic of the colored population of the city is the fact that the proportion of them who commit suicide, who solicit alms or free lodging, and who are arrested, is much smaller than among any other class of people. A colored suicide is a rarity, and, while the officials of the Coroners' office admit that there are some, they cannot remember when they had the last case of the kind. There are on an average about one hundred and twenty-five cases of suicide reported to the coroner annually, and of these less than five would be colored. Deputy Coroner Dugan, who has been in the office for many years, can remember but a few cases of colored suicides. The natural light-heartedness and sunny temperament of the colored people may be given as their great safeguard against suicide. Reverses and disappointments, which in a more sensitive class of people would result in despondency and eventual self-destruction, are laughed aside by the negro, who habitually looks on the bright side of life, and manages to get enjoyment out of whatever comes his way. While the mere fact of being out of work does not affect the colored people enough to drive them to suicide, the evidence of their natural industry cannot be better illustrated than by making note of the small proportion of them who ask alms or seek lodgings in the city station-houses. A colored tramp is more of a novelty than a colored suicide. They are nearly always willing to work at anything that turns up, and all are, as a rule, self-sustaining.—*Philadelphia Record.*

A Cry for a Clean Sweep.—Is it not time that we had a radical reformation of the Department of Charities and Correction—head, root, and branch? Will the Mayor, instead of yielding to the importunities of social and political friends, listen to the facts presented by men who have served for years in the city hospitals, and who know upon whom the responsibility rests for the condition of these institutions, and to those who have been interested in practical charity in the city, and who have come in contact with the mismanagement of this department? You cannot hope, Mr. Mayor, to have any reform in this department, even when you have appointed a third commissioner. A clean sweep must be made, and should be made, in order to give the medical profession the proper representation. The "reorganization," so far, appears merely as an attempt of the one man who has been the head and front of the mismanagement of the hospitals under the old *régime*, to make a semblance of reform. In order to do this he can now point to his record—the dismissal of a hundred doctors or so. But, while the doctors have been dismissed, the old "heelers," incompetent superintendents, and other worthless employees of the department still fatten at the public crib. No one except the medical men who have had occasion to come in contact with the Commissioners of Charities and Correction, can appreciate the treatment that has been accorded the members of the past medical boards by these persons. Whenever a reform was suggested, the report has been pigeonholed; and the men who have urged it have been told, in anything but a Chesterfieldian vein, that if they did not like the way things were managed in the department, they had better resign; that there were a dozen ready to fill the vacancy; and as their friends had been satisfied, the Commissioners would like the opportunity of satisfying someone else's friends. It is time that medical men were allowed the privilege of living up to the rules of the department they serve. At present an adverse report is still simply pigeonholed; and if an attempt is made to prove the facts, the man or men who take that step are disciplined and dismissed. The cry that went up from the Commissioners, whenever they were approached with these statements of imperfect management, has been that they have "done no wrong." But they must have known that their appointees were incompetent. "Reform in the medical boards" in this way is absurd because it tries to begin at the wrong end. The reform should have begun at the head of the administrative force, and should have been made to extend down to the meanest employee who goes to make up the ring that has so far controlled this department. If the Mayor is really in earnest in carrying out reform, he should sweep this department quite clean, and give us a set of Commissioners, none of whom is bound by the methods of the old régime or by the ties of promises made to political leaders. Give us two more men of the same stamp as Commissioner Faure, and let one of them be a medical man, and not a politician, medical or otherwise, and then we may at last see the hospitals run pro bono publico, instead of for the good and advantage of those who are in supreme control. The medical profession as a body should insist upon this; it could easily control sufficient influence to compel a clean sweep in the Charity Board, and a remodelling of the plan of reorganization on a plane of just apportionment. The protests of the County Societies should be followed by public protests from medical men, as well as by protests from their friends and patients, against unjust discrimination, unequal representation, and mismanagement in the executive offices.—*American Medico-Surgical Bulletin.* (Alas! all appeals have been useless and the cry has not been heeded.—ED.)

Comparative Vitality of the Sexes.—It is the common impression that men are not only less subject to illness, but are longer lived, than women. The life tables of insurances companies, however, show that the term of life of women is slightly longer than that of men. The difference in the mortality-rates during the first few years of life is striking. During the first year, the mortality among males is decidedly greater than among females. Although more boys are born than girls, the proportions are reduced to almost even terms at the end of the first year by the excessive male mortality. Even during the first four years the mortality among males exceeds that among females, notwithstanding the fact that there are practically no distinctions made in the management of the two sexes. Both are subject to the same conditions, are dressed virtually the same, and receive the same food. At about five years the comparative death-rate among girls begins to increase. This has been attributed to the fact that boys of this age are more in the open air. The mortality in both sexes diminishes from this time until the twelfth year, when it attains its lowest point. It then steadily rises, being larger in each successive year. Between the twelfth and sixteenth years the death-rate among girls increases more rapidly than among boys; but after the sixteenth year, for several years, the rate of increase is more rapid on the male side. The explanations that have been offered for these peculiarities are not wholly satisfactory; but one fact is clear, that during early years females possess a greater tenacity of life than do males.—*Maryland Medical Journal.*

The Action of Vaccinia Serum.—Hlava and Houl have been investigating the immunizing and curative properties of vaccinia serum, with a view to substituting its subcutaneous injection for inoculation with ani-

mal lymph, which has the disadvantages of uncertainty in action, rapid loss of protective power, and occasional serious complications (*Wiener klinische Rundschau*, October 6 and 13, 1895). They employed three different methods of preparing the serum from calves: (A) The animals were inoculated with vaccinia; in four days the resulting pustules were pricked and the lymph collected; subsequently a second and third injection of stronger lymph were made, without causing any pustulation or rise of temperature; the serum was collected about a fortnight after the last injection. (B) Inoculation as in A; no lymph collected; first reinoculation caused a rise of temperature, second none; serum collected fifteen days after the latter. (C) Serum, plasma, and blood—the latter two mixed with two per cent. sodium citrate—taken from the calf four days after inoculation. Experiments were made with all these upon calves, and then, no ill effects having been observed, upon children. The serum was injected, and at the same time or subsequently the children were inoculated with vaccinia. Serum B was found too weak to produce much effect, though the vaccine vesicles were not so well developed as if it had not been used; 3 to 10 c.c. of serum A prevented the development of vaccine vesicles in 6 children out of 13 on whom it was tried; the injection of serum C to the extent of 0.6 to 1.0 c.c. per kilo of body weight entirely prevented the action of vaccine lymph inoculated four days later. (The experiments with blood and plasma are not yet published.) Experiments have not yet been tried in variola; if they succeed, Hlava and Houl claim to have prepared a serum which will replace inoculation with vaccine lymph. It is immaterial whether the serum contains an antitoxin or the "vaccinia germ;" if the latter is the case, the method approaches that of vaccination with an impoverished pure cultivation.—*British Medical Journal.*

The Differential Diagnosis of Inflammatory and Non-inflammatory Effusions.—M. Rivalta, of Rome, has employed a simple test on which he places great reliance, in determining whether an exudate is of inflammatory or non-inflammatory origin. With this object, he removes, with an ordinary hypodermic syringe, some of the suspected fluid. Two hundred grammes of distilled water is poured into a large glass, to the latter two drops of anhydrous acetic acid is added, and a drop of the fluid to be examined is dropped into the mixture. It can be noted, in case the fluid is of inflammatory origin, that the suspected drop in descending to the bottom of the glass, assumes a white-bluish coloration and a spiral form like the smoke from a cigar. This phenomenon may be repeated each time a drop of the suspected fluid is introduced into the glass. If a little more acetic acid be added to the glass the precipitate formed at once disappears, thus permitting the conclusion that the precipitate was not mucine, insomuch as the latter is insoluble in an excess of acetic acid. M. Rivalta concluded that the substance present in the inflammatory exudate is a nucleo-albumin produced from the protoplasm of the leucocytes and pus-corpuscles. The foregoing method of examination, when applied to transudates of non-inflammatory origin, constantly yields negative results.—*Semaine Médicale*, May 15, 1895.

Broadbent on Diagnosis.—In his recent address upon Medicine before the British Medical Association, Sir William Broadbent, in discussing the important subject of diagnosis, made use of the following words: The basis of therapeutics is diagnosis, the grasp of the actual condition underlying the symptoms or phenomena, and the greater our command of powerful remedies, and the more precise our knowledge of their effects and of the mode in which these effects are produced, the more important does accuracy in diagnosis become. A diagnosis, to be real, implies not only the recognition of the disease which may be present and an accurate appreciation of the morbid changes which have taken place in various organs, it embraces a knowledge of the nature and intensity of the pathological processes which have been and are in operation, and of the causes that set them going, and also of the results to which they tend. A further element, moreover, enters into the consideration: an estimate, by the aspect of the patient, by the pulse and temperature, and by other subjective and objective indications, of the impression made on the system, and of the resistance which it is capable of to the lethal tendencies of the disease. Year by year we see improvement in this respect; not only that hospital physicians and teachers endeavor to carry diagnosis to a greater pitch of accuracy and a higher point of refinement than ever before, but that the entire body of medical men are trained, by improved education and systematic clinical teaching, to appreciate and to practise careful diagnosis in their daily work. Diagnosis, we may say, has reached an extraordinary degree of advancement. There are, no doubt, still new fields to conquer, but in the recognition of diseases, local and general, there is not much which concerns the human race which remains to be done. The same degree of knowledge, however, does not extend to morbid processes. Our comprehension of the significance and essential character of inflammation is by no means complete and satisfactory. The part which fever plays and the place which it holds among the phenomena of disease is far from being fully understood. It cannot have been intended by nature for the destruction of the subject, and we can see distinctly that in some cases it forms a part of the defensive operations; possibly, indeed, its general tendency is defensive, by promoting the production of phygocytes, or possibly a certain elevation of temperature may be fatal to maleficent organisms which have taken possession of the blood or tissues. We are not certain, indeed, whether the heat producing oxidation in the structures receives its stimulus from, or takes place at the bidding of, the nervous centres: or, on the other hand, is due to the enfeeblement of the restraint which they normally exercise over it; or whether it defies control by the thermotaxic nervous centres.

NEW BOOKS RECEIVED.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

INJURIES AND DISEASES OF THE GENITAL AND URINARY ORGANS. By Henry Morris, M.A., M.B., F.R.C.S. 8vo, 478 pages. Illustrated. Price, $4. Published by William Wood & Company, New York.

PRINCIPLES OF SURGERY. By Dr. N. Senn. Royal octavo, 656 pages. Illustrated. Prices, cloth, $4.50 net; sheep, or half-Russia, $5.50 net. Published by the F. A. Davis Co., Philadelphia, Pa.

AN AMERICAN TEXT-BOOK OF SURGERY. Various Authors. Edited by Dr. William W. Keen and Dr. J. William White. Second Edition. Illustrated. Royal octavo, 1248 pages. Prices, cloth, $7.00; sheep, $8. Published by W. B. Saunders, Philadelphia, Pa.

A MANUAL OF THE PRACTICE OF MEDICINE. By Dr. George Roe Lockwood, M.D. 8vo, 935 pages. Illustrated. Price, $2.50. Published by W. B. Saunders, Philadelphia, Pa.

HISTORY OF THE CLASS OF 1844, WASHINGTON COLLEGE. Edited by Rev. W. F. Hamilton, D.D. 8vo, 69 pages. Illustrated. Printed by Jas. B. Rodgers Printing Co., Philadelphia, Pa.

SPECTACLES AND EYEGLASSES: Their Forms, Mounting, and Proper Adjustment. By Dr. R. J. Phillips, M.D. Second Edition, Revised. With 49 Illustrations. 12mo, 99 pages. Price, $1. Published by P. Blakiston, Son & Co., Philadelphia.

DELICATE, BACKWARD, PUNY AND STUNTED CHILDREN: Their Developmental Defects, and Physical, Mental, and Moral Peculiarities Considered as Ailments Amenable to Treatment by Medicines. By Dr. J. Compton Burnett, M.D. 16mo, 164 pages. Price by mail, $1.05. Published by Boericke & Tafel, Philadelphia, Pa.

INDEX.

A

Abdomen, gunshot wound of the, 67, 491, 741; surgery of contusions of the, 647.
Abdominal incision, 678.
Abdominal section, some conditions requiring special care after, 440.
Aberdeen University, quarter-centenary of, 824.
Abortion, after-treatment of, 336; conduct of the physician in a case of, 26, 178; diagnosis and chronology of, 444; indications for the induction of, 310; treatment of threatened, 913; tubal, 318.
Abrahams, R., syphilis *vs.* tuberculosis, 910.
Abscess, iliac, treatment of, 26.
Accidents, police attention to alleged trivial, 486.
Acetanilid, antiseptic properties of, 716.
Achylia gastrica, 5, 192, 205.
Acidity of the organic and other fluids, method of expressing the, 483.
Acne rosacea, treatment of, 392, 395, 785.
Aconite, pathognomonic symptoms of poisoning by, 357.
Acromegaly and gigantism, 89.
Addison's disease, supra-renal extract in, 380, 823.
Adenoid forceps, 175.
Adenoid growths in the naso-pharynx, 296, 675.
Adulterated boots and ulcerated throats, 847.
Adulteration of drugs, 521.
Advertising, genius in, 418.
Age, inherited, 464.
Air-passages, upper, tuberculosis of the, 99.
Albu, Albert, notice of book by, 598.
Albumin in the urine, domestic test for, 599.
Alcohol, benefits of abstention from, 681; consumption of, in France, 140, 884; influence of, on sexual perversions, epilepsy, and other psychic anomalies, 232; injurious effects of, 717; properties of, in wines and liquors, 533.
Alcoholism and longevity, 930; ipecac for insomnia of, 91.
Alkalinity of the organic and other fluids, method of expressing the, 483.
Allen, Charles W., erysipelas in its etiological relation to preceding skin lesion, and its local treatment, 723.
Allport, Frank, new celia forceps, 70.
Alopecia after acute diseases, treatment of, 311, 785; diagnosis and treatment of, 386.
Amblyopia and amaurosis, hysterical, 56, 256; caused by chocolate, 843.
Ambulance organization in Berlin, 143.
American Dermatological Association, 525.
American Humane Association, 34.
American Laryngological Society, 95.
American medicine, Austrian view of, 539.
American Neurological Association, 57.
Ames, Frederick H. S., maternal impressions, 719.
Amputation, bloodless, at the shoulder-joint, 885; two successful cases of, at the hip-joint, 887.
Anæmia, formula for, 357; pernicious, 425, 927.
Anæsthesia, chloroform, deaths from, 522; ether, blood alteration of, 922; from oxygen and chloroform or ether, 505, 642, 863; hysterical, in a man, 57; infiltration, an improved syringe for, 827; local, Schleich's method of, 928; posture during, 824.
Anæsthetic, a new, 487.
Anal fissure, treatment of, 913; fistula, treatment of, 678.
Analgesia, general, with symptoms of sclerosis of the pyramidal tract and of the columns of Goll, 906.
Anasarca, formula for, 780.
Anastomosis, intestinal, Maunsell's method of, 605; intestinal, with the Murphy button, 778, 859; intestinal, with the Murphy button, dangers of, 920.
Anderson, Dr. R. B., judicial persecution of, 466, 753.
Andrews, Alfred J., holders to use with the dynamometer, 248.
Andronesco, C. I., notice of book by, 130.
Anencephalous monsters, 309, 893.
Aneurism, abdominal, 713; of the aorta, 165, 167, 168, 912; of the aorta, dissecting, rupturing into the pericardium, 713; of the subclavian, 886; of the superior pancreatico-duodenalis, 170.
Angina, Ludwig's, 99.
Angioma cavernosum of the spleen, 418.
Angiokeratoma of the scrotum, 525.
Animals and plants, fundamental difference between, 377.
Ankle-joint, diseases of the, 606.
Ankylosis true, 352.
Ano, fistula in, treatment of, 26.
Anthracosis, pulmonary, 477.
Anticancrin, 826.
Anti-noise league, 811.
Antiphthisin, 78, 871.
Antipyretics, the analgesic, 860; use and abuse of, 72.
Antipyrin, mandelate of, 344.
Antiquities, medical, 393.
Antiseptic dressings, 929; fluid, a new, 817.
Antitoxin of diphtheria, action of, upon the kidneys, 374; curative value of, 194; phenol as a preservative of, 571; present status of, in London, 107.
Antitoxin of tetanus, 273.
Antivenene, 162.
Antivivisection and polo, 551.
Antrum, empyema of the, 600; empyema of the, of tuberculous origin, 592.
Aorta, aneurism of the, 165, 167, 168, 912; dissecting aneurism of the, rupturing into the pericardium, 713; the isthmus of the, 788.
Appendicitis, 304, 912; a curious case of, 289; during pregnancy and labor, 609; experimental, 627; indication for operation, 716; in pregnant women, diagnosis and treatment of, 407; new theory of, 757; perforative, with general perforative peritonitis, 375; recovery from, without removal of the appendix, 781; rheumatism as a cause of, 373, 749; surgical treatment of, 26; treatment of, 678.
Appendix, a piece of bone in the, 639; anatomy of the, 757; foreign body in the, 172; hernia of the, 388; intestine constricted by the, 555; inversion of the, 304; length and position of the, 862.
Aphrodisiac, tonic, 786.
Apoplexy, 27, 429.
Argyll-Robertson pupil, 677.
Aristocratic doctors, 576.
Army, medical service of the, 811; of the, in France, 864.
Army ration, the, 773.
Army, vacancies in the medical corps of the, 582.
Aronson, Dr. Alexander I., resolutions on the death of, 56.
Arteries, torsion instead of ligatures of the, 285.
Arteritis, obliterative, in a boy, 340.
Arthritis, chronic rheumatic, formula for, 358.
Ascites, formula for, 533.
Asepsis, moist or dry, 924.
Ashhurst, John, Jr., notice of book edited by, 849
Ashmead, Albert S., another cholera ship, 496.
Asiari, Dr. Giacomo, hundredth birthday of, 415.
Asphyxia of the new-born, 211, 763.
Asthenopia, gold spectacles as a cause of, 571; neurological aspect of, 806.
Asthma, formula for, 392, 677, 786.
Asylum abuses in Germany, 234, 537, 580; practice, routine medication in, 516.
Ataxia, Friedreich's, 85; hereditary cerebellar, 709, 865; hereditary spinal, 865.
Athetosis, operative treatment of, 277.
Athletes, medical, 19; stimulants for, 775.
Athletics, danger of excess in, 756.
Autoscope, the, 675.
Axis-adjustment, a new method of delivering the placenta, 225.
Ayers, Edward A., diagnosis and chronology of abortions, 444.

B

Babcock, Robert H., some considerations with regard to the senile heart, 649.
Babes, Victor, notice of book edited by, 813.
Bacteriological diagnosis, 754; researches, practice of medicine in the light of, 577, 600.
Bacteriology, caution in regard to undue reliance upon, 878; progress in, 70.
Bailey, Dr., account-book of, 598.
Bailey, Pearce, a case of general analgesia, with symptoms of sclerosis of the pyramidal tracts and of the columns of Goll, 906.
Baillon, Dr., death of, 236.
Baldness and dyspepsia, 684.
Baldwin, E. K., a chemical and experimental research on antiphthisin, 871.
Ballantyne, J. W., notice of book by, 129.
Balls-Headley, W., notice of book by, 93.
Bambas, Joannes Ch., death of, 380.
Bannan, Theresa, bicycling for women, 142.
Bardeleben, Professor Henry Adolf, death of, 452, 487.
Barkan, Louis, potassium permanganate in pulmonary phthisis, 66.
Barney, Joseph N., acute traumatic tetanus, Chopart's operation, death, 382.
Barrington, Dr. Frank E., death of, 631.
Barry, James, a woman army surgeon, 344, 754.
Baruch, Simon, clinical aspect of dyspepsia, 469.
Bashore, Harvey B., geology, 339.
Bassini operation for hernia, post-mortem examination of parts involved in, six weeks after its performance, 887.
Bates, W. H., gold spectacles as a cause of asthenopia, 571.
Bath, death in a, 899.
Bathing and disease of the ear, 90.
Baths, public, in New York City, 344.
Bavaria, quackery in, 715.
Baylies, E. B., acute œdema of the larynx, 714.
Beatty, W. Kirker, trephining for fractured skull, 492; case of acute atrophy of the liver, 273.
Beglarion, Mlle., an Armenian princess and physician, 930.
Behring's law of immunity, 389.
Belgium, professional dignity in, 416.
Bell, J. N., poisoning by oysters, 803.
Bennett, C. I., religion, disturbed industry, and suicide, 394.
Bequests to Massachusetts institutions, 416.
Beriberi, 808; another ship with, 496.
Berlin, ambulance organization in, 143.
Berry, William B., where shall our consumptive patients be sent? 49
Bicycle and medical practice, 127; face, a new explanation of the, 308; from a medical standpoint, 464; specialist, 702.
Bicycling for invalids and doctors, 415; for women, 142; in hay-fever, 142.
Bicyclists, rules for, 573.
Bile, influence of, on the proteolytic action of the pancreatic juice, 878.
Bile-duct, congenital obliteration of the, 565; surgery of the, 780.
Biliousness, formula for, 786.
Billings, John S., notice of book by, 204; retirement of, 487.

Bissell, J. Dougal, a contribution to the study of the nature, cause, and treatment of suspended animation in the new born, 763.
Black, D. Campbell, notice of book by, 633.
Black eye, treatment of, 820.
Blackford, Charles Minor, Jr., alkaline injections in gonorrhœa, 535.
Bladder, absorption of drugs by the, 576; comparative frequency of stone in the, in the white and negro races, 781; cystotomy for stone in the, 782; drainage of the, 357; hernia of the, 564; rupture of, associated with myelitis, 173; stone in the, a hiding-place for, 352; tuberculosis of the, supra-pubic cystotomy for, 562.
Blech, Gustavus, successful treatment of enuresis nocturna by the test operation, 418.
Bleyer, J. Mount, nuclein is nature's antitoxin, 437.
Blindness, prevention of, through legislative enactment, 103.
Blood, absorption of, from the peritoneal cavity, 221; alkalinity of the, and infection, 662; alterations of, in ether anæsthesia, 922; examination of the, 685; improved hæmatocrit method of examination of, 222; in Bright's disease, 562; in chronic cyanosis, 196; nucleated red corpuscles of the, 196.
Blood-changes in neurasthenia, 321.
Blood-platelets in functional nervous diseases, 126.
Boas, I., notice of book by, 201.
Bone, deformities resulting from acute infections in, 613.
Bone-grafting, 716.
Bone marrow, a case of splenic myelogenous leukæmia not cured by, 858; therapeutic use of the extract of, 576.
Bone-setters and natural doctors, 413.
Book-borrowers, medical, 360.
